The Dobzhansky–Muller model is quite simple. First, assume that a single ancestral population is subdivided into two separate populations by some barrier to gene flow (by the formation of a new mountain range, for instance), and that these two populations then evolve as independent lineages. In one of the two populations, a new allele (*A*) arises and becomes fixed. In the other population, another new allele (*B*) becomes fixed at a different gene locus. Neither new allele at either locus results in any loss of reproductive compatibility. However, the two new forms of these two different genes have never occurred together in the same individual or population. Recall that the products of many genes must work together in an organism. It is possible that the new protein forms encoded by the two new alleles will not be compatible with each other. If individuals from the two populations come back together after these genetic changes, they may still be able to interbreed. However, the hybrid offspring may have a new combination of genes that is functionally inferior to that of either parent, or even lethal. This will not happen with all new combinations of genes, but over time, isolated populations will accumulate many allele differences at many gene loci. Some combinations of these differentiated genes will not function well together in hybrids. Thus genetic

incompatibility between the two isolated populations will develop over time.

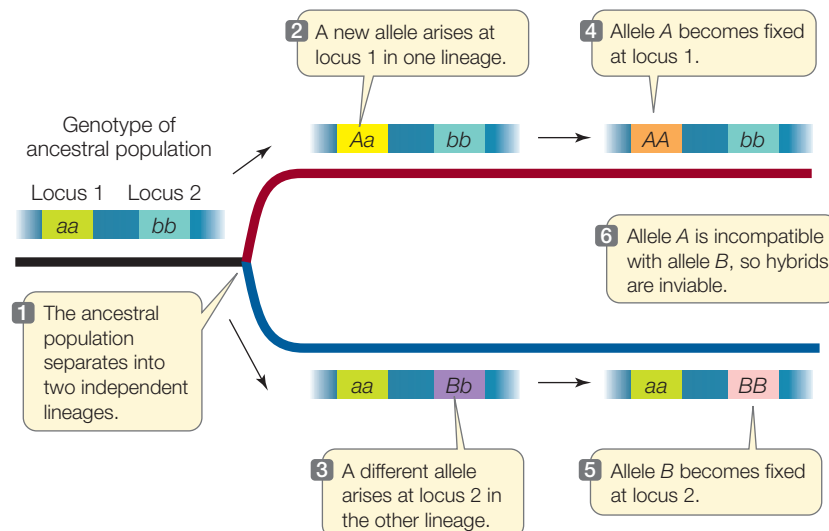

Many empirical examples support the Dobzhansky–Muller model. This model works not only for pairs of individual genes, but also for some kinds of chromosomal rearrangements. Bats of the genus *Rhogeessa*, for example, exhibit considerable variation in centric fusions of their chromosomes. The chromosomes of the various species contain the same basic chromosomal arms, but in some species two acrocentric (one-armed) chromosomes have fused at the centromere to form larger, metacentric (two-armed) chromosomes. A polymorphism in centric fusion causes few, if any, problems in meiosis because the respective chromosomes can still align and assort normally. Therefore, a given centric fusion can become fixed in a lineage. However, if a different centric fusion becomes fixed in a second lineage, then hybrids between individuals of each lineage will not be able to produce normal gametes in meiosis (Figure 23.4). Most of the closely related species of *Rhogeessa* display different combinations of these centric fusions and are thereby reproductively isolated from one another.

Reproductive isolation develops with increasing genetic divergence

As pairs of species diverge genetically, they become increasingly reproductively isolated (Figure 23.5). Both the rate at which reproductive isolation develops and the mechanisms that produce it vary from group to group, as we'll see in the next two sections of this chapter. Reproductive incompatibility has been shown to develop gradually in many groups of plants, animals, and fungi, reflecting the slow pace at which incompatible genes accumulate in each lineage. In some cases, complete reproductive isolation may take millions of years. In other cases (as with the chromosomal fusions of *Rhogeessa* described above), reproductive isolation can develop over just a few generations.

Partial reproductive isolation has evolved in strains of *Phlox drummondii* artificially isolated by humans. In 1835, Thomas Drummond, after whom this species of garden plant is named, collected seeds in Texas and distributed them to nurseries in

23.3 The Dobzhansky–Muller Model In this simple two-locus version of the model, two lineages from the same ancestral population become physically separated from each other and evolve independently. A new allele becomes fixed in each descendant population, but at a different locus. Neither of the new alleles is incompatible with the ancestral alleles, but the two new alleles in the two different genes are incompatible with each other. Thus the two descendant lineages are reproductively incompatible.

*Rhogeessa tumida*

23.4 Speciation by Centric Fusion In this chromosomal version of the Dobzhansky–Muller model, two independent centric fusions of one-armed chromosomes occur in two sister lineages. Neither centric fusion by itself results in difficulties at meiosis, whether the fusion is found in just one or in both pairs of chromosomes. After fixation of the different fusions in each lineage, however, F_1 hybrids between the two lineages are sterile, because the three different chromosomes involved in these centric fusions cannot pair normally at meiosis in hybrids. Most of the species in the bat genus *Rhogeessa* differ from one another by such centric fusions.

Europe. The European nurseries established more than 200 true-breeding strains of *P. drummondii* that differed in flower size, flower color, and plant growth form. The breeders did not select directly for reproductive incompatibility between

strains, but in subsequent experiments in which strains were crossed, biologists found that reproductive compatibility between strains (as measured by seed production) had been reduced by 14 to 50 percent, depending on the cross—even though the strains had been isolated from one another for less than two centuries.

23.5 Reproductive Isolation Increases with Genetic Divergence

Among pairs of *Drosophila* species, the more the species differ genetically, the greater their reproductive isolation from each other. Each dot represents a comparison of one species pair. Such positive relationships between genetic distance and reproductive isolation have been observed in many groups of plants, animals, and fungi.

RECAP 23.2

When two parts of a population become isolated from each other by some barrier to gene flow, they begin to diverge genetically. The Dobzhansky-Muller model describes how new alleles or chromosomal arrangements that arise in the two descendant lineages can lead to genetic incompatibility, and hence reproductive isolation, of the two lineages.

- How can centric fusions occur in one *Rhogeessa* lineage without causing any reproductive difficulties, when different centric fusions in two different lineages of *Rhogeessa* lead to disruption of meiosis in hybrid individuals? [See p. 470 and Figure 23.4](#)
- What empirical evidence can you cite in support of the idea that genetic divergence of populations leads to loss of reproductive compatibility? [See pp. 470–471 and Figure 23.5](#)

We have now seen how the splitting of an ancestral population leads to genetic divergence and reproductive incompatibility in the two descendant lineages. How do populations become separated in the first place?

23.3

What Barriers to Gene Flow Result in Speciation?

Many biologists who study speciation have concentrated on geographic processes that can result in the division of an ancestral species. Splitting of the geographic range of a species is one obvious way of achieving such a division, but it is not the only way.

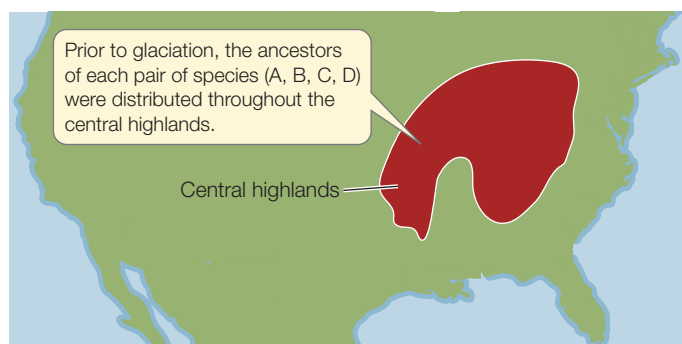

Physical barriers give rise to allopatric speciation

Speciation that results when a population is divided by a physical barrier is known as **allopatric speciation** (Greek *allos*, “other”; *patria*, “homeland”). Allopatric speciation is thought to be the dominant mode of speciation in most groups of organisms. The physical barrier that divides the range of a species may be a body of water or a mountain range for terrestrial organisms or dry land for aquatic organisms—in other words, any type of habitat that is inhospitable to the species. Such barriers can form when continents drift, sea levels rise and fall, glaciers advance and retreat, or climates change. The populations separated by such barriers are often, but not always, initially large. The lineages that descend from these founding populations evolve differences for a variety of reasons, including mutation, genetic drift, and adaptation to different environments in the two areas. As a result, many pairs of closely related **sister species**—species that are each other’s closest relatives—may exist on either side of the geographic barrier. An example of a physical geographical barrier that produced many pairs of sister species was the Pleistocene glaciation that isolated freshwater streams in the eastern highlands of the Appalachian Mountains from streams in the Ozark and Ouachita Mountains (Figure 23.6). This splitting event resulted in many parallel speciation events among isolated lineages of stream-dwelling organisms.

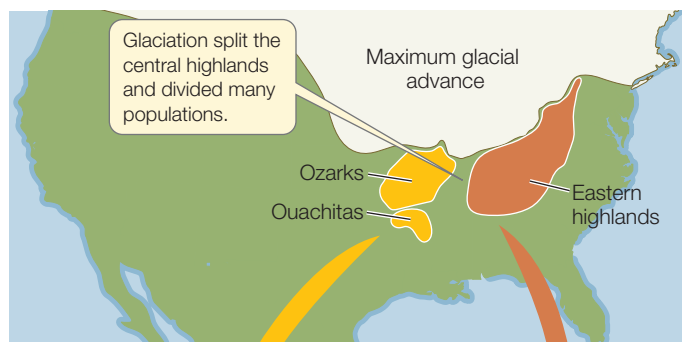

Allopatric speciation may also result when some members of a population cross an existing barrier and establish a new, isolated population. Many of the more than 800 species of *Drosophila* found in the Hawaiian Islands are restricted to a single island. We know that these species are the descendants of new populations founded by individuals dispersing among the islands when we find that the closest relative of a species on one island is a species on a neighboring island rather than a species on the same island. Biologists who have studied the chromosomes of these fruit flies estimate that speciation in this group of *Drosophila* has resulted from at least 45 such founder events (Figure 23.7).

23.6 Allopatric Speciation Allopatric speciation may result when an ancestral population is divided into two separate populations by a physical barrier and those populations then diverge. (A) Many species of freshwater stream fishes were distributed throughout the central highlands of North America in the Pliocene epoch (about 3–5 million years ago). (B) During the Pleistocene, glaciers advanced and isolated fish populations in the Ozark and Ouachita Mountains to the west from fish populations in the highlands of the Appalachian Mountains to the east. Numerous species diverged as a result of this separation, including the ancestors of the four pairs of sister species shown here.

23.7 Founder Events Lead to Allopatric Speciation The large number of species of picture-winged *Drosophila* in the Hawaiian Islands is the result of founder events: the founding of new populations by individuals dispersing among the islands. The islands, which were formed in sequence as Earth's crust moved over a volcanic "hot spot," vary in age.

 Founder Events and Allopatric Speciation
Life10e.com/at23.3

The 13 species of finches found in the islands of the Galápagos archipelago, some 1,000 km off the coast of Ecuador, are one of the most famous examples of allopatric speciation. Darwin's finches (as they are usually called, because Darwin was the first scientist to study them) arose in the Galápagos from a single South American finch species that colonized the islands. Today the Galápagos species differ strikingly not only from their closest mainland relative, but also from one another (Figure 23.8). The islands are sufficiently far apart that the birds move among them only infrequently. In addition, environmental conditions differ widely from island to island. Some islands are relatively flat and arid; others have forested mountain slopes. Over millions of years, finch lineages on the different islands have differentiated to the point that when occasional immigrants do arrive from other islands, they either do not breed with the residents or, if they do, the resulting offspring do not survive as well as the offspring of established residents. The genetic distinctness of each finch species from the others and the genetic cohesiveness of the individual species are thus maintained.

Sympatric speciation occurs without physical barriers

Although geographic isolation is usually required for speciation, speciation can also occur in the absence of a physical barrier. Speciation without physical isolation is called **sympatric speciation** (Greek *sym*, "together with"). But how can such speciation happen? Given that speciation is usually a gradual

process, how can reproductive isolation develop when individuals have frequent opportunities to mate with one another?

DISRUPTIVE SELECTION Sympatric speciation may occur with some forms of disruptive selection (see Section 21.3) if individuals with different genotypes have a preference for distinct microhabitats where mating takes place. For example, sympatric speciation via disruptive selection appears to be taking place in the apple maggot fly (*Rhagoletis pomonella*) of eastern North America. Until the mid-1800s, *Rhagoletis* flies courted, mated, and deposited their eggs only on hawthorn fruits. About 150 years ago, European immigrants introduced apple trees into the region, and some flies began to lay their eggs on apples. Apple trees are closely related to hawthorns, but the smell of the fruits differs, and the apple fruits appear earlier in the season than those of hawthorns. Some early-emerging female *Rhagoletis* laid their eggs on apples, and over time, a genetic preference for the smell of apples evolved among early-emerging insects. When the offspring of these flies sought out apple trees for mating and egg deposition, they mated with other flies reared on apples, which shared the same genetic preferences.

Today the two groups of *Rhagoletis pomonella* in eastern North America appear to be on the way to becoming distinct species. One group mates and lays eggs primarily on hawthorn fruits, the other on apples. The incipient species are partially reproductively isolated because they mate primarily with individuals raised on the same fruit and which emerge at the same of year. In addition, the larvae of the apple-feeding flies now grow more rapidly on apples than they originally did. Sympatric speciation that arises from such host-plant specificity may be widespread among insects, many of which feed on only one plant species.

POLYPLOIDY The most common means of sympatric speciation is **polyploidy**, which results from the duplication of sets of chromosomes within individuals. Polyploidy can arise either from chromosome duplication in a single species (**autopolyploidy**) or from the combining of the chromosomes of two different species (**allopolyploidy**).

An autopolyploid individual originates when (for example) two accidentally unreduced diploid gametes (each with two sets of chromosomes) combine to form a tetraploid individual (with four sets of chromosomes). Tetraploid and diploid individuals of the same species are reproductively isolated because their hybrid offspring are triploid and thus are usually sterile; those offspring rarely produce viable gametes because their chromosomes do not segregate evenly during meiosis (Figure 23.9). So a tetraploid individual usually cannot produce viable offspring by mating with a diploid individual—but it *can* do so if it self-fertilizes or mates with another tetraploid. Thus polyploidy can result in complete reproductive isolation in two generations—an important exception to the general rule that speciation is a gradual process.

Allopolyploids may be produced when individuals of two different (but closely related) species interbreed. Such hybridization often disrupts normal meiosis, which can result in chromosomal doubling. Allopolyploids are often fertile because

Bud eater
The bud eater's heavy bill is adapted for grasping and wrenching buds from branches.

Seed eaters
Bills of seed eaters are adapted for harvesting and crushing seeds.

Insect eaters
The bills of insect eaters vary because they eat different types and sizes of insects and they capture them in different ways.

23.8 Allopatric Speciation among Darwin's Finches The descendants of the ancestral finch that colonized the Galápagos archipelago several million years ago evolved into at least 13 different species whose beaks are variously adapted to feed on buds, seeds, and insects.

ANCESTOR FINCH

Warbler finch
(*Certhidea olivacea*)

Large-billed finches can crush large, hard seeds.

Small-billed finches cannot crush large seeds well, but are adept at handling small seeds.

Cactus finches are adapted to opening cactus fruits and extracting the seeds.

The large tree finch uses its heavy bill to twist apart wood to reach larvae inside.

The small and medium tree finches pick insects from leaves and branches and explore crevices for hidden prey.

The woodpecker finch uses its long bill to probe dead wood, crevices, and bark for insects.

The warbler finch uses quick motions to capture insects on plant surfaces.

23.9 Tetraploids Are Reproductively Isolated from Their Diploid Ancestors

Even if the triploid offspring of a diploid and a tetraploid parent survives and reaches sexual maturity, most of the gametes it produces have aneuploid (unbalanced) numbers of chromosomes. Such triploid individuals are effectively sterile. (For simplicity, the diagram shows only three homologous chromosomes. Most species have many more chromosomes, so viable gametes are extremely rare.)

each of the chromosomes has a nearly identical partner with which to pair during meiosis.

Speciation by polyploidy has been particularly important in the evolution of plants, although it has contributed to speciation in animals as well (such as the treefrogs in Figure 23.2). New species arise by polyploidy more easily among plants than among animals because many species of plants can reproduce by self-fertilization. In addition, if polyploidy arises in several offspring of a single parent, the siblings can fertilize one another. Botanists estimate that about 70 percent of flowering plant species and 95 percent of fern species are the result of recent polyploidization. Some of these species arose from hybridization between two species followed by chromosomal duplication and self-fertilization. Other species diverged from polyploid ancestors, so that the new species share their ancestors' duplicated sets of chromosomes.

RECAP 23.3

Allopatric speciation results from the separation of populations by geographic barriers; it is the dominant mode of speciation among most groups of organisms. Sympatric speciation may result from disruptive selection that results in ecological isolation, but polyploidy is the most common cause of sympatric speciation among plants.

- Explain why an effective barrier to gene flow for one species may not effectively isolate another species. **See p. 472**
- What are some obstacles to sympatric speciation? **See p. 473**
- What is the difference between allopolyploidy and autopolyploidy? **See pp. 473–474**

Most populations separated by a physical barrier become reproductively isolated only slowly and gradually. If two incipient species once again come into contact with each other, what keeps them from merging back into a single species?

23.4 What Happens When Newly Formed Species Come into Contact?

As we saw in Section 23.2, once a barrier to gene flow is established, reproductive isolation will begin to develop through genetic divergence. Over many generations, differences accumulate in the isolated lineages, reducing the probability that individuals from each lineage will mate successfully with individuals in the other when they come back into contact. In this way, reproductive isolation can evolve as a by-product of the genetic changes in the two diverging lineages.

Reproductive isolation may be incomplete when incipient species come back into contact, however, in which case some hybridization will occur. If hybrid individuals are less fit than non-hybrids, selection will favor parents that do not produce hybrid offspring. Under these conditions, selection will result in the strengthening, or **reinforcement**, of mechanisms that prevent hybridization.

Mechanisms that prevent hybridization from occurring are called **prezygotic isolating mechanisms**. Mechanisms that reduce the fitness of hybrid offspring are called **postzygotic isolating mechanisms**. Postzygotic isolating mechanisms result in selection against hybridization, which in turn leads to the reinforcement of prezygotic isolating mechanisms.

Prezygotic isolating mechanisms prevent hybridization

Prezygotic isolating mechanisms, which come into play before fertilization, can prevent hybridization in several ways.

MECHANICAL ISOLATION Differences in the sizes and shapes of reproductive organs may prevent the union of gametes from different species. With animals, there may be a match between the shapes of the reproductive organs of males and females of the same species, so that reproduction between individuals with mismatched reproductive structures is not physically possible. In plants, mechanical isolation may involve a pollinator. For example, some orchid species produce flowers that look and smell like the females of particular species of bee or wasp (Figure 23.10). When a male insect visits and attempts to mate with a flower (thinking it is a female of his species), his mating behavior results in the transfer of pollen to and from his body by appropriately configured anthers and stigmas on the orchid. Other insects, which may visit the flower but do not attempt to mate with it, do not trigger this transfer of pollen.

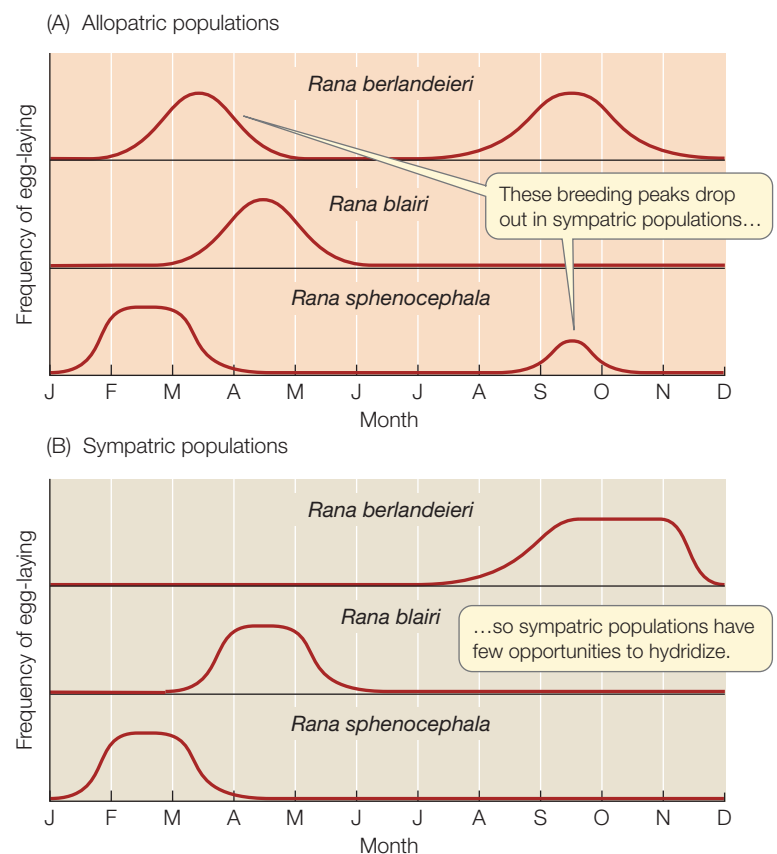

TEMPORAL ISOLATION Many organisms have distinct mating seasons. If two closely related species breed at different times of the year (or different times of day), they may never have an opportunity to hybridize. For example, in sympatric populations of three closely related leopard frog species, each species breeds at a different time of year (Figure 23.11). Although there is some overlap in the breeding seasons, the opportunities for hybridization are minimized.

23.10 Mechanical Isolation through Mimicry Many orchid species maintain reproductive isolation by means of flowers that look and smell like females of one—and only one—bee or wasp species. A male insect of the correct species must land on the flower and attempt to mate with it; only males of this particular species are physically configured to collect and transfer the orchid's pollen. The constraints of this method of pollen transfer reproductively isolate the plant from related orchid species that attract different insect pollinators. The species shown here are the two players in one such interspecific relationship; see Figure 56.11 for another example.

BEHAVIORAL ISOLATION Individuals may reject, or fail to recognize, individuals of other species as potential mating partners. For example, the mating calls of male frogs of related species diverge quickly (Figure 23.12). Female frogs respond to mating calls from males of their own species but ignore the calls of other species, even closely related ones. The evolution of female preferences for certain male coloration patterns among the cichlids of Lake Malawi, described at the opening of this chapter, is another example of behavioral isolation.

Sometimes the mate choice of one species is mediated by the behavior of individuals of other species. For example, whether or not two plant species hybridize may depend on the food preferences of their pollinators. The floral traits of plants, including their color and shape, can enhance reproductive isolation either by influencing which pollinators are attracted to their flowers or by influencing where pollen is deposited on the bodies of their pollinators. A plant whose flowers are pendant (hanging downward; Figure 23.13A) will be pollinated by an animal with different physical characteristics than will a plant whose flowers grow upright (Figure 23.13B). Because each pollinator prefers (and is adapted to) a different type of flower, pollinators will rarely transfer pollen from one plant species to the other.

23.11 Temporal Isolation of Breeding Seasons (A) The peak breeding seasons of three species of leopard frogs (*Rana*) overlap when the species are physically separated (allopatry). (B) Where two or more species of *Rana* live together (sympatry), overlap between their peak breeding seasons is greatly reduced or eliminated. Selection against hybridization in areas of sympatry helps reinforce this prezygotic isolating mechanism.

Gastrophryne olivacea*Gastrophryne carolinensis*

23.12 Behavioral Isolation in Mating Calls The males of most frog species produce species-specific calls. The calls of the two closely related frog species shown here differ in their dominant frequency (a high-frequency sound wave results in a high-pitched sound; a low frequency results in a low-pitched sound). Female frogs are attracted to the calls of males of their own species.

Go to Media Clip 23.1
Narrowmouth Toads Calling for Mates
Life10e.com/mc23.1

Such isolation by pollinator behavior is seen in the mountains of California in two sympatric species of columbines (*Aquilegia*) that have diverged in flower color, structure, and orientation. *Aquilegia formosa* (Figure 23.13C) has pendant flowers with short spurs (spikelike, nectar-containing structures) and is pollinated by hummingbirds. *A. pubescens* (Figure 23.13D) has upright, lighter-colored flowers with long spurs and is pollinated by hawkmoths. The difference in pollinators means that these two species are effectively reproductively isolated even though they populate the same geographic range.

HABITAT ISOLATION When two closely related species evolve preferences for living or mating in different habitats, they may never come into contact during their respective mating periods.

(A)

(C) *Aquilegia formosa*

(B)

(D) *A. pubescens*

23.13 Reproductive Isolating Mechanisms May Be Mediated by Species Interactions

(A) This hummingbird's morphology and behavior are adapted for feeding on nectar from pendant flowers. (B) The nectar-extracting proboscis of this hawkmoth is adapted to flowers that grow upright. (C) *Aquilegia formosa* flowers are normally pendant and are pollinated by hummingbirds. (D) Flowers of *A. pubescens* are normally upright and are pollinated by hawkmoths. In addition, their long floral spurs appear to restrict access by some other potential pollinators.

The *Rhagoletis* flies discussed in Section 23.3 experienced such habitat isolation, as did the cichlid fishes that first adapted to rocky or sandy habitats upon entering Lake Malawi, as described at the opening of this chapter.

GAMETIC ISOLATION The sperm of one species may not attach to the eggs of another species because the eggs do not release the appropriate attractive chemicals, or the sperm may be unable to penetrate the egg because the two gametes are chemically incompatible. Thus, even though the gametes of two species may come into contact, the gametes never fuse into a zygote.

Gametic isolation is extremely important for many aquatic species that spawn (release their gametes directly into the environment). It has been extensively studied in sea urchins. A protein known as bindin is found in sea urchin sperm and functions in attaching ("binding") the sperm to eggs. All sea urchin species studied produce this egg-recognition protein, but the bindin gene sequence diverges so rapidly that it has become species-specific—that is, sperm can attach only to eggs of the same species, so no interspecific hybridization occurs.

Postzygotic isolating mechanisms result in selection against hybridization

Genetic differences that accumulate between two diverging lineages may reduce the survival and reproductive rates of hybrid offspring in any of several ways:

- **Low hybrid zygote viability.** Hybrid zygotes may fail to mature normally, either dying during development or developing phenotypic abnormalities that prevent them from becoming reproductively capable adults.
- **Low hybrid adult viability.** Hybrid offspring may have lower survivorship than non-hybrid offspring.
- **Hybrid infertility.** Hybrids may mature into infertile adults. For example, the offspring of matings between horses and donkeys—mules—are sterile. Although otherwise healthy, mules produce no descendants.

Natural selection does not directly favor the evolution of postzygotic isolating mechanisms. But if hybrids have low fitness, then individuals that breed only within their own species will leave more surviving offspring than will individuals that interbreed with another species. Therefore, individuals that avoid interbreeding with members of other species will have a selective advantage, and any trait that contributes to such avoidance will be favored.

Donald Levin of the University of Texas has studied reinforcement of prezygotic isolating mechanisms in flowers of the genus *Phlox*. Levin noticed that most individuals of *P. drummondii* in most of the range of the species in Texas have pink flowers. However, where *P. drummondii* is sympatric with its close relative, the pink-flowered *P. cuspidata*, most *P. drummondii* have red flowers. No other *Phlox* species has red flowers. Levin performed an experiment whose results showed that reinforcement may explain why red flowers are favored where the two species are sympatric (**Figure 23.14**).

Likely cases of reinforcement are often detected by comparing sympatric and allopatric populations of potentially hybridizing species, as in the case of *Phlox*. If reinforcement is occurring, then sympatric populations of closely related species are expected to evolve more effective prezygotic reproductive barriers than do allopatric populations of the same species. As Figure 23.11 shows, the breeding seasons of sympatric populations of different leopard frog species overlap much less than do those of allopatric populations. Similarly, the frequencies of the frog mating calls illustrated in Figure 23.12 are more divergent in sympatric populations than in allopatric populations. In both cases, there appears to have been natural selection against hybridization in areas of sympatry.

INVESTIGATINGLIFE

23.14 Flower Color Reinforces a Reproductive Barrier in *Phlox* Most *Phlox drummondii* flowers are pink, but in regions where they are sympatric with *P. cuspidata*—which is always pink—most *P. drummondii* individuals are red. Most pollinators preferentially visit flowers of one color or the other. In this experiment, Donald Levin explored whether flower color reinforces a prezygotic reproductive barrier, lessening the chances of interspecific hybridization.^a

HYPOTHESIS Red-flowered *P. drummondii* are less likely to hybridize with *P. cuspidata* than are pink-flowered *P. drummondii*.

Method 1. Introduce equal numbers of red- and pink-flowered *P. drummondii* individuals into an area with many pink-flowered *P. cuspidata*.

2. After the flowering season ends, measure hybridization by assessing the genetic composition of the seeds produced by *P. drummondii* plants of both colors.

Results Of the seeds produced by pink-flowered *P. drummondii*, 38% were hybrids with *P. cuspidata*. Only 13% of the seeds produced by red-flowered individuals were genetic hybrids.

CONCLUSION *P. drummondii* and *P. cuspidata* are less likely to hybridize if the flowers of the two species differ in color.

Hybrid zones may form if reproductive isolation is incomplete

Unless reproductive isolation is complete, closely related species may hybridize in areas where their ranges overlap, resulting in the formation of a hybrid zone. When a hybrid zone first forms, most hybrids are offspring of crosses

WORKING WITH DATA:

Does Flower Color Act as a Prezygotic Isolating Mechanism?

Original Paper

Levin, D. A. 1985. Reproductive character displacement in *Phlox*. *Evolution* 39: 1275–1281.

Analyze the Data

Donald Levin proposed that *Phlox drummondii* has red flowers only in locations where it is sympatric with pink-flowered *Phlox cuspidata* because having red flowers decreases interspecific hybridization. To test this hypothesis, Levin introduced equal numbers of red- and pink-flowered *P. drummondii* individuals into an area with many pink-flowered *P. cuspidata*. At the end of the flowering season, he assessed the genetic composition of the seeds produced by *P. drummondii*. The results are shown in the table (below, right).

QUESTION 1

Check the 95% confidence intervals for the proportion of hybrid seeds in red- and pink-flowered *P. drummondii* (shown graphically in Figure 23.14). There are many websites available for calculating confidence intervals; a good one is the Vassar College statistical computation site, VassarStats.net. You can go to this site and select “Proportions” from the left-hand menu, then select “The Confidence Interval of a Proportion.” What are the numerical values of the 95% confidence intervals?

QUESTION 2

You can see that the proportions of hybrids among the seeds of red- versus pink-flowered samples are significantly different because the 95% confidence intervals do not overlap. To quantify the significance of this difference, use the website suggested in Question 1, but select “Significance of the Difference between Two Independent Proportions” from the “Proportions” menu. What null hypothesis are you testing in this case? (See Appendix B if you need help.) What is the *P*-value of getting results at least as different as these two samples if your null hypothesis is true?

QUESTION 3

How would you extend or improve the experimental design of this study? What kinds of additional test sites or conditions would you want to examine? How might replicate or control sites make the study more convincing?

Morph (flower color)	Number of seeds (progeny)		
	<i>P. drummondii</i>	Hybrid	Total
Red	181 (87%)	27 (13%)	208
Pink	86 (62%)	53 (38%)	139

Go to **BioPortal** for all **WORKING WITH DATA** exercises

between purebred individuals of the two hybridizing species. However, subsequent generations include a variety of individuals with varying proportions of their genes derived from the original two species, so hybrid zones often contain recombinant individuals resulting from many generations of hybridization.

Detailed genetic studies can tell us much about why narrow hybrid zones may persist for long periods between the ranges of two species. In Europe, the hybrid zone between two toad species of the genus *Bombina* has been studied intensively. The fire-bellied toad (*B. bombina*) lives in eastern Europe; the closely related yellow-bellied toad (*B. variegata*) lives in western and southern Europe. The ranges of the two species overlap in a long but very narrow zone stretching 4,800 kilometers from eastern Germany to the Black Sea (Figure 23.15). Hybrids between the two species suffer from a range of defects, many of which are lethal. Those hybrids that survive often have skeletal abnormalities, such as misshapen mouths, ribs that are fused to vertebrae, and a reduced number of vertebrae. By following the fates of thousands of toads from the hybrid zone, investigators found that a hybrid toad, on average, is only half as fit as a purebred individual of either species. The hybrid zone remains narrow because there is strong selection against hybrids and because adult toads do not move over long distances. The zone has persisted for hundreds of years, however, because individuals of both species continue to move short distances into it, continually replenishing the hybrid population.

23.15 A Hybrid Zone The narrow zone (shown in orange) in which fire-bellied toads meet and hybridize with yellow-bellied toads has been stable for hundreds of years.

RECAP 23.4

Reproductive isolation may result from prezygotic or postzygotic isolating mechanisms. Lower fitness of hybrids can lead to the reinforcement of prezygotic isolating mechanisms.

- Distinguish among five types of prezygotic isolating mechanisms. **See pp. 476–477**
- Why are postzygotic isolating mechanisms said to *reinforce* prezygotic isolating mechanisms? **See pp. 478–479**
- Why don't most narrow hybrid zones, such as the one between *Bombina bombina* and *B. variegata*, get wider over time? **See p. 479 and Figure 23.15**

Some groups of organisms have many species, others only a few. Hundreds of species of *Drosophila* evolved in the small area of the Hawaiian Islands over about 20 million years. In contrast, there are only a few species of horseshoe crabs in the world, and only one species of ginkgo tree, even though these latter groups have persisted for hundreds of millions of years. Why do different groups of organisms have such different rates of speciation?

23.5 Why Do Rates of Speciation Vary?

Many factors influence the likelihood that a lineage will split to form two or more species. Therefore, rates of speciation (the proportion of existing species that split to form new species over a given period) vary greatly among groups of organisms. What are some of the factors that influence the probability of a given lineage splitting into two?

Several ecological and behavioral factors influence speciation rates

DIET SPECIALIZATION Populations of species that have specialized diets may be more likely to diverge than are those with more generalized diets. To investigate the effects of diet specialization on rates of speciation, Charles Mitter and colleagues compared species richness in some closely related groups of true bugs (hemipterans). The common ancestor of these groups was a predator that fed on other insects, but a dietary shift to herbivory (eating plants) evolved at least twice in the groups under study. Herbivorous bugs typically specialize on one or a few closely related species of plants, whereas predatory bugs tend to feed on many different species of insects. High diversity of host plant species can thus lead to a correspondingly high species diversity among herbivorous specialists. The Mitter et al. study showed that among these insects, the herbivorous groups do indeed have many more species than the related predatory groups (**Figure 23.16**).

POLLINATION Speciation rates are faster in animal-pollinated than in wind-pollinated plants. Animal-pollinated groups have, on average, 2.4 times as many species as related groups pollinated by wind. Among animal-pollinated plants, speciation rates are correlated with pollinator specialization. In columbines (*Aquilegia*), the rate of evolution of new species has been about three times faster in lineages that have long nectar spurs than in

23.16 Dietary Shifts Can Promote Speciation Herbivorous groups of hemipteran insects have speciated several times faster than closely related predatory groups.

lineages that lack spurs. Why do nectar spurs increase the speciation rate? Apparently it is because spurs restrict the number of pollinator species that visit the flowers, thus increasing opportunities for reproductive isolation (see Figure 23.13).

SEXUAL SELECTION It appears that the mechanisms of sexual selection (see Section 21.2) result in high rates of speciation, as we saw in the case of the cichlids of Lake Malawi. Some of the most striking examples of sexual selection are found in birds with polygynous mating systems. Bird-watchers travel thousands of miles to Papua New Guinea to witness the mating displays of male birds of paradise, which have long, brightly colored tail feathers (**Figure 23.17A**) and look distinctly different

(A) *Paradisaea minor*

(B) *Manucodia comrii*

23.17 Sexual Selection Can Lead to Higher Speciation Rates (A) Birds of paradise and (B) manucodes are closely related bird groups of the South Pacific. Speciation rates are much higher among the sexually dimorphic, polygynous birds of paradise (33 species) than among the sexually monomorphic, monogamous manucodes (5 species).

from females of their species—a phenomenon called sexual dimorphism. Males assemble at display grounds called leks, and females come there to choose a mate. After mating, the females leave the display grounds, build their nests, lay their eggs, and feed their offspring with no help from the males. The males remain at the lek to court more females.

The closest relatives of the birds of paradise are the manucodes (Figure 23.17B). Male and female manucodes differ only slightly in size and plumage (they are sexually monomorphic). They form monogamous pair bonds, and both sexes contribute to raising the young. There are only 5 species of manucodes, compared with 33 species of birds of paradise. By itself, this one comparison would not be convincing evidence that sexually dimorphic clades have higher rates of speciation than do monomorphic clades. However, when biologists examined all the examples of birds in which one clade is sexually dimorphic and the most closely related clade is sexually monomorphic, the sexually dimorphic clades were significantly more likely to contain more species. But why would sexual dimorphism be associated with a higher rate of speciation?

Animals with complex sexually selected behaviors are likely to form new species at a high rate because they make sophisticated discriminations among potential mating partners. They distinguish members of their own species from members of other species, and they make subtle discriminations among members of their own species on the basis of size, shape, appearance, and behavior. Such discriminations can greatly influence which individuals are most successful in mating and producing offspring, so they may lead to rapid evolution of behavioral isolating mechanisms among populations.

DISPERSAL ABILITY Speciation rates are usually higher in groups with poor dispersal abilities than in groups with good dispersal abilities because even narrow barriers can be effective in dividing a species whose members are highly sedentary. Until recently, the Hawaiian Islands had about 1,000 species of land snails, many of which were restricted to a single valley. Because snails move only short distances, the high ridges that separate the valleys were

effective barriers to their dispersal. Unfortunately, introductions of other species and changes in habitat have resulted in the recent extinction of most of these unique Hawaiian land snails.

Rapid speciation can lead to adaptive radiation

The rapid proliferation of a large number of descendant species from a single ancestor species is called an **evolutionary radiation**. Evolutionary radiations often occur when a species colonizes a new area, such as an island archipelago that contains no other closely related species, because of the large number of open ecological niches. If such a rapid proliferation of species results in an array of species that live in a variety of environments and differ in the characteristics they use to exploit those environments, it is referred to as an **adaptive radiation**.

Several remarkable adaptive radiations have occurred in the Hawaiian Islands. In addition to its 1,000 species of land snails, the native Hawaiian biota includes 1,000 species of flowering plants, 10,000 species of insects, and more than 100 bird species. However, there were no amphibians, no terrestrial reptiles, and only one native terrestrial mammal (a bat) on the islands until humans introduced additional species. The 10,000 known native species of insects on Hawaii are believed to have evolved from about 400 immigrant species; only 7 immigrant species are believed to account for all the native Hawaiian land birds. Similarly, as we saw earlier in this chapter, an adaptive radiation in the Galápagos archipelago resulted in the 13 species of Darwin's finches, which differ strikingly in the size and shape of their bills and, accordingly, in the food resources they use (see Figure 23.8).

The 28 species of Hawaiian sunflowers called silverswords are an impressive example of an adaptive radiation in plants (Figure 23.18). DNA sequences show that these species share a relatively recent common ancestor with a species of tarweed from the Pacific coast of North America. Whereas all mainland

Madia sativa (tarweed)

Argyroxiphium sandwicense

Wilkesia gymnoxiphium

Dubautia menziesii

23.18 Rapid Evolution among Hawaiian Silverswords The Hawaiian silverswords, three closely related genera of the sunflower family, are believed to have descended from a single common ancestor (a plant similar to the tarweed *Madia sativa*) that colonized Hawaii from the Pacific coast of North America. The four plants shown here are more closely related than they appear to be based on their morphology.

tarweeds are small, upright herbs (non-woody plants such as *Madia sativa*; see Figure 23.18), the silverswords include shrubs, trees, and vines as well as both upright and ground-hugging herbs. Silversword species occupy nearly all the habitats of the Hawaiian Islands, from sea level to above the timberline in the mountains. Despite their extraordinary morphological diversification, all silverswords are genetically very similar.

The Hawaiian silverswords are more diverse in size and shape than the mainland tarweeds because their tarweed ancestors first arrived on islands that harbored very few plant species. In particular, there were few trees and shrubs because such large-seeded plants rarely disperse to oceanic islands. Trees and shrubs have evolved from non-woody ancestors on many oceanic islands. On the mainland, however, tarweeds live in ecological communities that contain many tree and shrub species in lineages with long evolutionary histories. In those environments, opportunities to exploit the “tree” way of life have already been preempted.

RECAP 23.5

Dietary specialization, pollinator specialization, sexual selection, and poor dispersal abilities are correlated with high rates of speciation. Open ecological niches present opportunities for adaptive radiations.

- How can pollinator specialization in plants and sexual selection in animals increase rates of speciation? **See pp. 480–481**
- Why do adaptive radiations often occur when a founder species invades an isolated geographic area? **See p. 481**

23.19 Evolution in the Laboratory For their experiments on the evolution of prezygotic isolating mechanisms in *Drosophila melanogaster*, Rice and Salt built an elaborate system of varying habitats contained within vials inside a large fly enclosure. Some groups of flies developed preferences for widely divergent habitats and became reproductively isolated within 35 generations.

The processes described in this chapter, operating over billions of years, have produced a world in which life is organized into millions of species, each adapted to live in a particular environment and to use environmental resources in a particular way. In the next chapter we consider how species evolve at the level of their genes and genomes.

Can biologists study the process of speciation in the laboratory?

ANSWER

Although speciation usually takes thousands or millions of years, and although it is typically studied in natural settings such as Lake Malawi, some aspects of speciation can be studied and observed in controlled laboratory experiments. Most such experiments use organisms with short generation times, in which evolution is expected to be relatively rapid.

William Rice and George Salt conducted an experiment in which fruit flies (*Drosophila melanogaster*) were allowed to choose food sources in different habitats. The habitats—where mating also took place—were vials in different parts of an experimental cage (**Figure 23.19**). The vials differed in three environmental factors: (1) light; (2) the direction (up or down) in which the fruit flies had to move to reach food; and (3) the concentrations of two aromatic chemicals, ethanol and acetaldehyde. In just 35 generations, the two groups of flies that chose the most divergent habitats had become reproductively isolated from each other, having evolved distinct preferences for the different habitats.

The experiment by Rice and Salt (see *American Naturalist* 131: 911–917, 1988) demonstrated an example of habitat isolation as a prezygotic isolating mechanism. Even though the different habitats were in the same cage, and individual fruit flies were capable of flying from one habitat to the other, habitat preferences were inherited by offspring from their parents, and populations from the two divergent habitats did not interbreed. Similar habitat isolation is thought to have resulted in the early split between cichlids that preferred the rocky versus the sandy shores of Lake Malawi. In controlled experiments like this one, biologists can observe many aspects of the process of speciation directly.

CHAPTERSUMMARY 23

23.1 What Are Species?

- **Speciation** is the divergence of biological lineages and the emergence of reproductive isolation between those lineages.
- The **morphological species concept** distinguishes species on the basis of physical similarities and differences.
- The **biological species concept** distinguishes species on the basis of **reproductive isolation**.
- The **lineage species concept** recognizes evolutionarily independent lineages as species, allowing biologists to consider species over evolutionary time.

23.2 What Is the Genetic Basis of Speciation?

- Speciation usually results from the interruption of gene flow within a population.
- The Dobzhansky–Muller model describes how reproductive isolation between two physically isolated populations can develop through the accumulation of incompatible genes or chromosomal arrangements. **Review Figures 23.3, 23.4, ANIMATED TUTORIAL 23.1**
- Reproductive isolation increases with increasing genetic divergence between populations. **Review Figure 23.5**

23.3 What Barriers to Gene Flow Result in Speciation?
See ANIMATED TUTORIAL 23.2

- **Allopatric speciation**, which results when populations are separated by a physical barrier, is the dominant mode of speciation in most groups of organisms. This type of speciation may follow founder events, in which some members of a population cross a barrier and found a new, isolated population. **Review Figures 23.6–23.8, ANIMATED TUTORIALS 23.2 and 23.3**

- **Sympatric speciation** results when the genomes of two groups diverge in the absence of physical isolation. Such divergence can result from disruptive selection if individuals with different genotypes prefer distinct microhabitats.
- Sympatric speciation can occur within two generations via **polyploidy**. Polyploidy may arise from chromosome duplications within a species (**autopolyploidy**) or from hybridization that results in combining the chromosomes of two species (**allopolyploidy**). **Review Figure 23.9**

23.4 What Happens When Newly Formed Species Come into Contact?

- **Prezygotic isolating mechanisms** prevent hybridization; **postzygotic isolating mechanisms** reduce the fitness of hybrids.
- Postzygotic isolating mechanisms lead to **reinforcement** of prezygotic isolating mechanisms by natural selection. **Review Figures 23.11, 23.12, 23.14**
- Hybrid zones may form and persist if reproductive isolation between species is incomplete. **Review Figure 23.15**

23.5 Why Do Rates of Speciation Vary?

- Dietary specialization, pollinator specialization, sexual selection, and dispersal ability all influence speciation rates. **Review Figure 23.16**
- **Evolutionary radiation** refers to the rapid proliferation of descendant species from a single ancestor species. This often occurs following colonization, when new species may rapidly move into unoccupied ecological niches in a process known as **adaptive radiation**.

CHAPTERREVIEW

REMEMBERING

- Which of the following is *not* a condition expected to favor allopatric speciation?
 - Continents drift apart and separate previously connected lineages.
 - A mountain range separates formerly connected populations.
 - Different environments on two sides of a barrier cause populations to diverge.
 - The range of a species is separated by loss of intermediate habitat.
 - Tetraploid individuals arise in one part of the range of a species.
- Which of the following is *not* a potential prezygotic reproductive barrier?
 - Temporal segregation of breeding seasons
 - Differences in chemicals that attract mates
 - Hybrid infertility
 - Spatial segregation of mating sites
 - Sperm that cannot penetrate an egg
- A common means of sympatric speciation is
 - polyploidy.
 - hybrid infertility.
 - temporal segregation of breeding seasons.
 - spatial segregation of mating sites.
 - imposition of a geographic barrier.
- Which of the following is often associated with higher rates of speciation?
 - Sexual dimorphism in birds
 - Diet specialization in insects
 - Poor dispersal ability
 - Animal pollination in plants
 - All of the above

UNDERSTANDING & APPLYING

- 5. The Dobzhansky–Muller model of speciation suggests that divergence among alleles at *different* gene loci leads to genetic incompatibility between species. Why is genetic incompatibility between two alleles at the *same* locus considered less likely?
- 6. Why do some combinations of chromosomal centric fusions cause problems in meiosis? Can you diagram what would happen at meiosis in a hybrid of the divergent lineages shown in Figure 23.4?
- 7. Assume that the reproductive isolation seen in the *Phlox* strains discussed in Section 23.2 results from lethal combinations of incompatible alleles at several loci among the various strains. Given this assumption, why might the reproductive isolation seen among these strains be partial rather than complete?
- 8. If allopatric speciation is the most prevalent mode of speciation, what do you predict about the geographic distributions of many closely related species?

ANALYZING & EVALUATING

- 9. In each of the species of columbine shown in Figure 23.13, the orientation of the flowers and the length of flower spurs are associated with a particular type of pollinator (hummingbirds or hawkmoths). Columbine flowers vary in other ways as well; for example, they differ in color, and probably in odor. What experiments could you design to determine the traits that various pollinators use to distinguish among the flowers of different columbine species?

- 10. The different finch species in the phylogeny shown in Figure 23.8 have all evolved on islands of the Galápagos archipelago within the past 3 million years. Molecular clock analysis (see Chapter 24) has been used to determine the dates of the various speciation events in that phylogeny. Geological techniques for dating rock samples (see Chapter 25) have been used to determine the ages of the various Galápagos islands. The table below shows the number of species of Darwin’s finches and the number of islands that have existed in the archipelago at several times during the past 4 million years.

Time (mya)	Number of islands	Number of finch species
0.25	18	14
0.50	18	9
0.75	9	7
1.00	6	5
2.00	4	3
3.00	4	1
4.00	3	0

- a. Plot the number of species of Darwin’s finches and the number of islands in the Galápagos archipelago (dependent variables) against time (independent variable).
- b. Are the data consistent with the hypothesis that isolation of populations on newly formed islands is related to speciation in this group of birds? Why or why not?
- c. If no more islands form in the Galápagos archipelago, do you think that speciation by geographic isolation will continue to occur among Darwin’s finches? Why or why not? What additional data could you collect to test your hypothesis (without waiting to see if speciation occurs)?

Evolution of Genes and Genomes

CHAPTER OUTLINE

- 24.1** How Are Genomes Used to Study Evolution?
- 24.2** What Do Genomes Reveal about Evolutionary Processes?
- 24.3** How Do Genomes Gain and Maintain Functions?
- 24.4** What Are Some Applications of Molecular Evolution?

Adapting to a Murky Environment The elephant-nose fish (*Gnathonemus petersi*), a river-dwelling species from West Africa, is one of many fishes in which weakly discharging electric organs have evolved via duplications and modifications in sodium channel proteins.

SOME FISHES GENERATE HIGH-VOLTAGE electric discharges (up to 650 volts) that they use to stun their prey; perhaps the best known examples are the electric eels of Central and South America. Several other fish species produce weaker electric discharges. Most of these weakly electric fishes live in murky water, where visual cues are limited. They use electric signals to locate (but not to stun) their prey. Electric signals also allow them to communicate with other individuals of their own species.

Electric organs have evolved independently in several fish lineages. How did these organs evolve? Consider first the physical basis of the electric discharges. Voltage-gated sodium channels are large protein complexes that underlie the generation and propagation of rapid electric signals in nerve, muscle, and heart tissues. Electric signals are transmitted along nerves to muscles as the sodium channels embedded in cell membranes are stimulated to open. These channels control the concentration of positively charged sodium ions (Na^+) on the inside relative to the outside of cells, resulting in an electric charge that is transmitted across the surface of the muscle, leading to muscular contraction.

Most vertebrates have multiple copies of the genes encoding the several proteins that make up the sodium channel. These copies arose in the distant past through a series of gene duplications. Such duplications allowed the differentiation and specialization of protein function, making it possible for different sodium channels to exist in different types of tissue. In the case of electric fishes, one of the sodium channel genes expressed in muscle diverged, and a new functional protein evolved. Changes in a relatively small number of nucleotide positions in the gene resulted in modified sodium channels, allowing the development of a new organ with a unique function—the generation of externally transmitted electric energy.

The repeated evolution of electric organs from muscle tissue has been facilitated by the relative simplicity of the molecular changes required. Gene duplication has expedited the process, since redundant genes allow for such specialization in protein function. Finally, interspecific differences in sodium channel function have arisen from additional changes in the nucleotide sequences of the genes. These small differences allow different species to use different communication signals, which improves intraspecific communication while reducing interspecific interference.

How do evolutionary studies of sodium channel genes help us understand some human genetic disorders?

See answer on p. 502.

24.1 How Are Genomes Used to Study Evolution?

An organism's **genome** is the full set of genes it contains, as well as any noncoding regions of the DNA (or, in the case of some viruses, RNA). Most of the genes of eukaryotic organisms are found on chromosomes in the nucleus, but genes are also present in chloroplasts and mitochondria. In organisms that reproduce sexually, both males and females contribute nuclear genes, but mitochondrial and chloroplast genes are usually transmitted only via the cytoplasm of one of the two gametes (usually from the female parent).

Genomes must be replicated to be transmitted from parents to offspring. DNA replication does not occur without error, however. Mistakes in DNA replication—mutations—provide much of the raw material for evolutionary change. Mutations are essential for the long-term survival of life because they are the initial source of the genetic variation that permits species to evolve in response to changes in their environment.

A particular allele of a gene will not be passed on to successive generations unless an individual carrying that allele survives and reproduces. The allele must function in combination with many other genes in the genome or it will quickly be selected against. Moreover, the degree and timing of a gene's expression are affected by its location in the genome. For these reasons, the genes of an individual organism can be viewed as interacting members of a group, among which there are divisions of labor but also strong interdependencies.

A genome, then, is not simply a random collection of genes in a random order along chromosomes. Rather, it is a complex set of integrated genes, regulatory sequences, and structural elements, interspersed with vast stretches of noncoding DNA that may have little direct function. Both the positions of genes and their sequences are subject to evolutionary change, as are the extent and location of noncoding DNA. All of these changes can affect the phenotype of an organism.

Biologists have now sequenced the complete genomes of a large number of organisms, including humans. The information in these sequences is helping us understand how and why organisms differ, how they function, and how they have evolved.

Evolution of genomes results in biological diversity

The field of **molecular evolution** investigates the mechanisms and consequences of the evolution of macromolecules—particularly nucleic acids (DNA and RNA) and proteins. Molecular evolutionists study relationships between the structures of genes and proteins and the functions of organisms. They also examine molecular variation to reconstruct evolutionary history and to study the mechanisms and consequences of evolution. Students of this field ask questions such as: What does molecular variation tell us about a gene's function? Why do the genomes of different organisms vary in size? What evolutionary forces shape patterns of variation among genomes? And a crucial question from an evolutionary perspective: How do genomes acquire new functions? Investigations into the evolution of particular nucleic acids and proteins are instrumental in reconstructing the evolutionary histories of genes. Ultimately,

molecular evolutionary biologists hope to explain the molecular basis of biological diversity.

The evolution of nucleic acids and proteins depends on genetic variation introduced by mutations. One of several ways in which genes evolve is by means of nucleotide substitutions (the incorporation of point mutations in populations). In genes that encode proteins, nucleotide substitutions sometimes result in amino acid replacements that can change the charge, the structure, and other chemical and physical properties of the encoded protein. Phenotypic changes in a protein molecule often affect the way that protein functions in the organism.

Evolutionary changes in genes and proteins can be identified by comparing nucleotide or amino acid sequences from different organisms. The longer two sequences have been evolving separately, the more differences they accumulate (bearing in mind that different genes in the same species evolve at different rates). Determining how long ago changes in nucleotide or amino acid sequences occurred is a useful step toward inferring their causes. Knowledge of the pattern and rate of evolutionary change in a given macromolecule is useful in reconstructing the evolutionary history of groups of organisms.

To compare genes or proteins from different organisms, biologists need a way to identify homologous parts of macromolecules. (Recall from Section 22.1 that homologous features are those shared by two or more species that have been inherited from a common ancestor.) Homologous parts of a protein can be identified by their homologous amino acid sequences. And, since nucleotide sequences encode amino acid sequences, the concept of homology extends down to the level of individual nucleotide positions. Therefore one of the first steps in studying the evolution of genes or proteins is to align homologous positions in the amino acid or nucleotide sequence of interest.

Genes and proteins are compared through sequence alignment

Once the nucleotide or amino acid sequences of molecules from different organisms have been determined, they can be compared. Homologous positions can be identified only if we first pinpoint the locations of deletions and insertions that have occurred in the molecules of interest in the time since the organisms diverged from a common ancestor. A simple hypothetical example illustrates this **sequence alignment** technique. In **Figure 24.1** we compare two amino acid sequences from homologous proteins in different organisms. The two sequences at first appear to differ in both the number and identity of their amino acids. If we insert a gap after the first amino acid in sequence 2 (after leucine), however, the similarities in the two sequences become obvious. This gap represents the occurrence of one of two evolutionary events: an insertion of an amino acid in the longer protein or a deletion of an amino acid in the shorter protein. Having adjusted for this insertion or deletion event, we can see that the two sequences differ by only one amino acid at position 6 (serine or phenylalanine).

Go to Activity 24.1 Amino Acid Sequence Alignment
Life10e.com/ac24.1

RESEARCH TOOLS

24.1 Amino Acid Sequence Alignment Amino acid sequence alignment is a way of arranging protein sequences to identify regions of homology between the sequences. Gaps are inserted between the amino acid residues to align similar residues in columns. Differences and similarities between each pair of aligned sequences are then summarized in a similarity matrix. Homologous DNA sequences can be aligned in a similar manner.

1 Two amino acid sequences seem quite different...

Sequence 1 leu arg phe cys cys ser arg
Sequence 2 leu phe cys cys phe arg

2 ...but if we insert a gap in Sequence 2, there is nearly complete alignment.

Sequence 1 leu arg phe cys cys ser arg
Sequence 2 leu — phe cys cys phe arg

3 With this alignment established, we can compare additional sequences.

Sequence 1 leu arg phe cys cys ser arg
Sequence 2 leu — phe cys cys phe arg
Sequence 3 leu — phe cys cys phe arg
Sequence 4 leu arg ile cys cys ser arg
Sequence 5 leu arg ile cys ala ser arg
Sequence 6 leu arg phe cys ile ser arg

Similarity matrix

Sequence number

	1	2	3	4	5	6
1	1	2	2	1	2	1
2	5	1	0	3	4	3
3	5	7	1	3	4	3
4	6	4	4	1	1	2
5	5	3	3	6	1	2
6	6	4	4	5	5	1

Sequence number

Numbers above the diagonal line are the number of differences.

Numbers below the diagonal line are similarities.

Adding a single gap—that is, identifying a deletion or an insertion—aligns the two sequences in Figure 24.1. Additional sequences can now be added to the alignment in a similar manner. Longer amino acid sequences, and those that have diverged more extensively, require more elaborate adjustments. Explicit models (incorporated into computer algorithms) have been developed to account for the relative probabilities of deletions, insertions, and particular amino acid replacements.

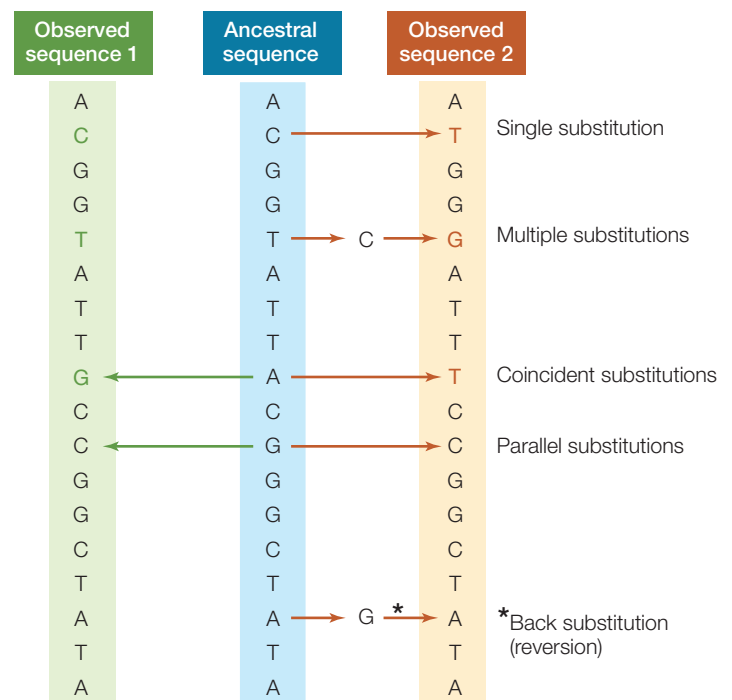

Having aligned the sequences, we can compare them by counting the number of nucleotides or amino acids that differ between them. Summing the numbers of the same and different amino acids in each pair of sequences allows us to construct a **similarity matrix**, which gives us a measure of the minimum number of changes that have occurred since the divergence of each pair of organisms (see Figure 24.1).

Go to Activity 24.2 Similarity Matrix Construction
Life10e.com/ac24.2

Models of sequence evolution are used to calculate evolutionary divergence

The sequence comparison procedure illustrated in Figure 24.1 gives a simple count of the number of similarities and differences between the proteins of two species. In the context of two aligned DNA sequences, we can count the number of differences at homologous nucleotide positions, and this count indicates the minimum number of nucleotide changes that must have occurred since the two sequences diverged from a common ancestral sequence.

Although it is useful in determining a *minimum* number of changes between two DNA sequences, the count provided by sequence alignment almost certainly underestimates the *actual* number of changes that have occurred since the sequences diverged. Any given change counted in a similarity matrix of DNA sequences may result from multiple substitution events that occurred at a given nucleotide position over time. As illustrated in **Figure 24.2**, any of the following events may have

24.2 Multiple Substitutions Are Not Reflected in Pairwise Sequence Comparisons Two observed sequences descended from a common ancestral sequence (center) have undergone a series of substitutions. Although the two observed sequences differ by only three nucleotides (colored letters), these three differences result from a total of nine substitutions (arrows).

24.3 Amino Acid Sequences of Cytochrome c The amino acid sequences shown in the table were obtained from analyses of the enzyme cytochrome c from 33 species of plants, fungi, and animals. Note the lack of variation across the sequences at positions 70–80, suggesting that this region is under strong stabilizing selection and that changing its amino acid sequence would impair the protein's function. The molecular models at the upper left are created from these sequences and show the three-dimensional structures of tuna and rice cytochrome c. Alpha helices are in red, and the molecule's heme group is shown in yellow.

Life10e.com/mc24.1

occurred at a given nucleotide position that would not be revealed by a simple count of similarities and differences between two DNA sequences:

- **Multiple substitutions.** More than one change has occurred at a given position between the ancestral sequence and at least one of the observed sequences.
- **Coincident substitutions.** At a given position, different substitutions have occurred between the ancestral sequence and each observed sequence.
- **Parallel substitutions.** The same substitution has occurred independently between the ancestral sequence and each observed sequence.
- **Back substitutions** (also called reversions). In a variation on multiple substitutions, after a change at a given position, a subsequent substitution has changed the position back to the ancestral state.

To correct for undercounting of substitutions, molecular evolutionists have developed mathematical models that describe how DNA (and protein) sequences evolve. These models take into account the relative rates of change from one nucleotide to another; for example, transitions (changes between the two purines, $A \leftrightarrow G$, or between the pyrimidines, $C \leftrightarrow T$) are more frequent than transversions (a purine is replaced by a pyrimidine, or vice versa). These models also include parameters such as the different rates of substitution across different parts of a gene and the proportions of each nucleotide present in a given sequence. Once such parameters have been estimated, the model is used to correct for multiple substitutions, coincident substitutions, parallel substitutions, and back substitutions. The revised estimate accounts for the *total* number of substitutions likely to have occurred between two sequences, which is almost always greater than the observed number of differences.

As sequence information becomes available for more and more genes in an ever-expanding database, sequence alignments can be extended across multiple homologous sequences, and the minimum number of insertions, deletions, and substitutions can be summed across homologous genes of an entire group of organisms. Similar databases have been constructed for homologous proteins. **Figure 24.3** shows aligned data for cytochrome *c* protein sequences in 33 species of animals, plants, and fungi. Such information is used extensively in determining evolutionary relationships among species.

Experimental studies examine molecular evolution directly

Although molecular evolutionists are often interested in naturally evolved genes and proteins, molecular evolution can also be observed directly in the laboratory. Increasingly, evolutionary biologists are studying evolution experimentally. Because substitution rates are related to generation time rather than to absolute time, most of these experiments use unicellular organisms or viruses with short generations. Viruses, bacteria, and unicellular eukaryotes (such as the yeasts) can be cultured in large populations in the laboratory, and many of these organisms can evolve rapidly. In the case of some RNA viruses, the

natural substitution rate may be as high as 1 substitution per 1,000 nucleotides per generation. Therefore in a virus of a few thousand nucleotides, one or more substitutions are expected (on average) every generation, and these changes can easily be determined by sequencing the entire viral genome (because of its small size). Generation time may be only tens of minutes (rather than years or decades, as in many animals), so biologists can directly observe substantial molecular evolution in a controlled population over the course of days, weeks, or months.

An example of an experimental evolutionary study is shown in **Figure 24.4**. Paul Rainey and Michael Travisano wanted to examine a potential cause of adaptive radiations, which are a major source of biological diversity (see Section 23.5). While Rainey and Travisano clearly couldn't experimentally manipulate animals over many millions of years, they could test the idea that heterogeneous environments with unoccupied niches lead to adaptive radiation by experimentally manipulating a bacterial lineage.

Rainey and Travisano inoculated several flasks containing culture medium with the same strain of the bacterium *Pseudomonas fluorescens*. They then shook some of the cultures to maintain a constantly uniform environment. They left others alone (static cultures), allowing them to develop spatially

INVESTIGATINGLIFE

24.4 Evolution in a Heterogeneous Environment Paul Rainey and Michael Travisano cultured the rapidly evolving bacterium *Pseudomonas fluorescens* in homogeneous and heterogeneous environments to examine the relationship among phenotypic diversity, molecular divergence, and environmental variability.^a

HYPOTHESIS Heterogeneous environments are more conducive to the evolution of phenotypic diversity than are homogeneous environments.

Method One colony of *Pseudomonas fluorescens* (all of a single genotype) was used to inoculate many replicate cultures.

Results In the shaken flasks, the ancestral morph persisted; the uniform environment did not result in morphological diversification. In the static flasks, two new morphs regularly arose, each adapted to a different local environment. Molecular analysis revealed that the mutations that produce these phenotypes arose in both shaken and static cultures, but the mutations did not persist in the uniform (shaken) environment because the phenotypes they produced were selectively disadvantageous under homogeneous conditions.

Ancestral morph (smooth)

“Wrinkly spreader” morph

“Fuzzy spreader” morph

CONCLUSION Phenotypic change and diversification are enhanced in a heterogeneous environment.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

^aRainey, P. B. and M. Travisano. 1998. *Nature* 394: 69–72.

distinct environments. In the static cultures, the environment on the surface of the medium differed from that on the walls of the flasks and from parts of the culture not touching any surfaces.

When the cultures were started, the ancestral phenotype of the bacterium produced a smooth colony phenotype, which the investigators called a “smooth morph.” In just a few days, however, the static cultures consistently and independently developed two other morphs: a “wrinkly spreader” and a “fuzzy spreader.” The researchers determined that the two new morphs had a genetic basis and were adaptively superior in certain environments found within the static cultures. For example, the “wrinkly spreader” cells adhered firmly to one another as well as to surfaces and thus were able to form a mat

across the surface of the medium, where they could compete successfully for oxygen.

DNA sequencing of the genomes of these morphs showed that the same phenotypes had evolved repeatedly in different static cultures and that many different substitutions could produce the same phenotypes. The homogeneous shaken cultures, in contrast, showed no changes in phenotype. The same mutations occurred in the shaken cultures, but they did not persist because the novel phenotypes they produced were selectively disadvantageous (i.e., less fit) under the “shaken” environmental conditions.

Experimental molecular evolutionary studies are used for a wide variety of purposes and have greatly expanded the ability of evolutionary biologists to test evolutionary concepts

and principles. Biologists now routinely study evolution in the laboratory and, as we will see later in this chapter, they can use in vitro evolutionary techniques to produce novel molecules that perform new functions with industrial and pharmaceutical uses.

RECAP 24.1

The genomes of all organisms evolve over time. Evolutionary changes can be detected by comparing the nucleic acid and protein sequences of different species. Experimental studies of molecular evolution allow biologists to study many processes of evolution directly under controlled conditions.

- How do biologists align nucleotide and amino acid sequences they wish to compare, and how do they determine the minimum number of changes that have occurred between pairs of aligned sequences? **See pp. 486–487 and Figure 24.1**
- Explain why a simple count of nucleotide differences between two sequences underestimates the actual number of nucleotide substitutions since the sequences diverged. **See Figure 24.2**

We have seen that molecular evolutionists can directly observe the evolution of genomes over time, compare the genomes of different organisms, and reconstruct the changes that have occurred during their evolution. Let's turn now to the question of how genomes change and examine some of the consequences of those changes.

24.2 What Do Genomes Reveal about Evolutionary Processes?

A mutation, as we saw in Section 15.1, is any change in the genetic material. A nucleotide substitution is the product of one type of mutation, incorporated into a population. Many nucleotide substitutions have no effect on phenotype, even if the change occurs in a gene that encodes a protein, because most amino acids are specified by more than one codon (see Figure 14.6). A substitution that does not change the encoded amino acid is known as a **synonymous substitution** or **silent substitution** (Figure 24.5A). Synonymous substitutions do not affect the functioning of a protein (although they may have other effects, as described in Section 15.1) and are therefore less likely than other types of substitutions to be subject to natural selection.

A nucleotide substitution that *does* change the amino acid sequence encoded by a gene is known as a **nonsynonymous substitution** or **missense substitution** (Figure 24.5B). In general, nonsynonymous substitutions are likely to be deleterious to the organism. But not every amino acid replacement alters a protein's shape and charge (and hence its functional properties), so some nonsynonymous substitutions may also be selectively neutral (or nearly so). Conversely, an amino acid replacement that confers an advantage to the organism would result in positive selection for the corresponding nonsynonymous substitution.

24.5 When One Nucleotide Does or Doesn't Make a Difference

(A) Synonymous (silent) substitutions do not change the amino acid specified and do not affect protein function; such substitutions are unlikely to be subject to natural selection. (B) Nonsynonymous (missense) substitutions do change the amino acid sequence and are likely to have an effect (often deleterious) on protein function; such substitutions are targets for natural selection.

Investigators have measured the average rate of nonsynonymous nucleotide substitutions in several mammalian protein-coding genes at about 0.9 substitutions per position per billion years. Synonymous substitutions in these genes have occurred about five times more frequently than nonsynonymous substitutions. In other words, *substitution rates are highest at nucleotide positions that do not change the amino acid being expressed* (Figure 24.6). Substitution rates are even higher in **pseudogenes**, which are duplicate, nonfunctional copies of genes.

24.6 Rates of Substitution Differ Rates of nonsynonymous substitution typically are much lower than rates of synonymous substitution and the substitution rate in pseudogenes. This pattern reflects differing levels of functional constraints.

Most natural populations harbor far more genetic variation than we would expect to find if genetic variation were influenced by natural selection alone. This discovery, combined with the knowledge that many mutations do not change molecular function, stimulated the development of the neutral theory of molecular evolution.

Much of evolution is neutral

In 1968, Motoo Kimura proposed the **neutral theory** of molecular evolution. Kimura suggested that, at the molecular level, the majority of the variants we observe in most populations are selectively neutral; that is, they confer neither an advantage nor a disadvantage on their bearers. These neutral variants accumulate through genetic drift rather than through positive selection.

The rate of fixation of neutral mutations by genetic drift is independent of population size. To see why this is so, consider a diploid population of size N and a neutral mutation rate μ (mu) per gamete per generation at a locus. The number of new mutations would be, on average, $\mu \times 2N$, because $2N$ gene copies are available to mutate. The probability that a given mutation will be fixed by drift alone is its frequency, which equals $1/(2N)$ for a newly arisen mutation. We can multiply these two terms to get the rate of fixation of neutral mutations (m) in a given population of N individuals:

$$m = 2N\mu \frac{1}{2N}$$

Therefore the rate of fixation m of neutral mutations depends only on the neutral mutation rate μ and is independent of population size. A given mutation is more likely to appear in a large population than in a small one, but any mutation that does appear is more likely to become fixed in a small population. These two influences of population size cancel each other out, so the rate of fixation of neutral mutations is equal to the mutation rate (i.e., $m = \mu$).

As long as the underlying mutation rate is constant, macromolecules evolving in separate populations should diverge from one another in neutral changes at a constant rate. Investigators have confirmed that the rate of evolution of particular genes and proteins is often relatively constant over time and can therefore be used as a “molecular clock.” As we described in Section 22.3, molecular clocks can be used to calculate evolutionary divergence times between species.

Although much of the genetic variation we observe in populations is the result of neutral evolution, the neutral theory does not imply that most mutations have no effect on the organism. Many mutations are never observed in populations because they are lethal or strongly detrimental to the organism and are thus quickly removed from the population through natural selection. Similarly, mutations that confer a selective advantage tend to be quickly fixed in populations, so they do not result in variation at the population level either. Nonetheless, in any population, some amino acid positions will remain constant under purifying selection, others will vary through neutral genetic drift, and still others will differ between species as a result of positive selection for change. How can these evolutionary processes be distinguished?

Positive and purifying selection can be detected in the genome

As we have just seen, substitutions in a protein-coding gene can be either synonymous or nonsynonymous, depending on whether they change the resulting amino acid sequence of the protein. The relative rates of synonymous and nonsynonymous substitutions are expected to differ in regions of genes that are evolving neutrally, under positive selection for change, or staying unchanged under purifying selection.

- If a given amino acid in a protein can be one of many alternatives (without changing the protein’s function), then an amino acid replacement is *neutral* with respect to the fitness of an organism. In this case, the rates of synonymous and nonsynonymous substitutions in the corresponding DNA sequences are expected to be very similar, so the ratio of the two rates should be close to 1.
- If a given amino acid position is under *positive* selection for change, the observed rate of nonsynonymous substitutions is expected to exceed the rate of synonymous substitutions in the corresponding DNA sequences.
- If a given amino acid position is under *purifying* selection, then the observed rate of synonymous substitutions is expected to be much higher than the rate of nonsynonymous substitutions in the corresponding DNA sequences.

By comparing the gene sequences that encode homologous proteins from many species, scientists can determine the history and timing of synonymous and nonsynonymous substitutions. This information can be mapped on a phylogenetic tree, as we saw in Chapter 22. Regions of genes that are evolving under neutral, purifying, or positive selection can be identified by comparing the nature and rates of substitutions across the phylogenetic tree.

A study of the evolution of lysozyme illustrates how and why particular amino acid positions might be under different modes of selection (**Figure 24.7**). The enzyme lysozyme (see Figure 3.9) is found in almost all animals. It is produced in the tears, saliva, and milk of mammals and in the albumen (whites) of bird eggs. Lysozyme digests the cell walls of bacteria, rupturing and killing them. As a result, it plays an important role as a first line of defense against invading bacteria. Most animals defend themselves against bacteria by digesting them, which is probably why most animals have lysozyme. Some animals also use lysozyme in the digestion of food.

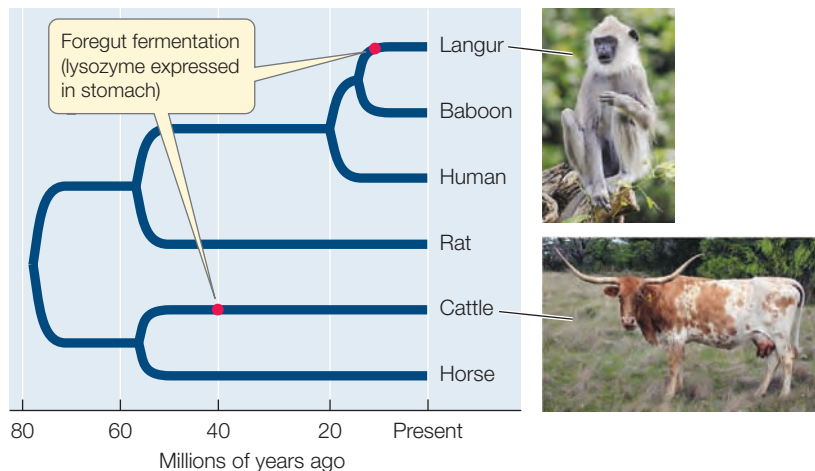

Among mammals, a mode of digestion called foregut fermentation has evolved twice. In mammals with this mode of digestion, the foregut—the posterior esophagus or the stomach—has been converted into a chamber in which bacteria break down ingested plant matter by fermentation. Foregut fermenters can extract nutrients from the otherwise indigestible cellulose that makes up a large proportion of plant tissue. Foregut fermentation evolved independently in ruminants (a group of hooved mammals that includes cattle) and in certain leaf-eating monkeys, such as langurs. Caro-Beth Stewart knew that these evolutionary events were independent because both langurs and ruminants have close relatives that are not foregut fermenters.

INVESTIGATINGLIFE

24.7 Convergent Molecular Evolution Langurs (a group of monkeys) and cattle are only distantly related but both have evolved foregut fermentation. They uniquely express the enzyme lysozyme in their stomachs (foreguts) to aid in breaking down bacteria that are involved in fermentation. Stewart and colleagues compared the gene sequences of lysozyme in mammals with and without foregut fermentation to see if there is convergence in the independently evolved amino acid sequences of lysozyme in langurs and cattle.^a

HYPOTHESIS Similar selective conditions in distantly related mammals have resulted in convergence of adaptations for foregut fermentation in the amino acid sequences of lysozyme.

Method 1. Isolate and sequence lysozyme from two distantly related mammal species with foregut fermentation (langur and cattle) as well as other mammals that are more closely related to either langurs or to cattle but lack foregut fermentation.

2. Tabulate the pairwise differences in the amino acid sequences. Plot the amino acid changes on the phylogenetic tree and count the number of convergent similarities between each pair of species. The results can then be plotted as a matrix.

Results The matrix shows the number of *all* pairwise amino acid differences above the diagonal and the number of *convergent* similarities below the diagonal.

	Langur	Baboon	Human	Rat	Cattle	Horse
Langur		14	18	38	32	65
Baboon	0		14	33	39	65
Human	0	1		37	41	64
Rat	0	1	0		55	64
Cattle	5	0	0	0		71
Horse	0	0	0	0	1	

The lysozymes of langurs and cattle are convergent for 5 amino acids.

CONCLUSION The lysozyme sequences of the two species with foregut fermentation account for the majority of the convergent amino acid replacements observed among these species, demonstrating molecular convergence associated with the independent evolution of foregut fermentation.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

^aStewart, C.-B. et al. 1987. *Nature* 330: 401–404.

In both foregut-fermenting lineages, lysozyme has been modified to play a new, nondefensive role. This lysozyme ruptures some of the bacteria that live in the foregut, releasing nutrients

metabolized by the bacteria, which the mammal then absorbs. How many changes in the lysozyme molecule were needed to allow it to perform this function amid the digestive enzymes and acidic conditions of the mammalian foregut? To answer this question, Stewart and her colleagues compared the lysozyme-coding sequences in foregut fermenters with those in several of their nonfermenting relatives. They determined which amino acids differed and which were shared among the species, as well as the rates of synonymous and nonsynonymous substitutions in lysozyme genes across the evolutionary history of the sampled species.

For many of the amino acid positions of lysozyme, the rate of synonymous substitutions in the corresponding gene sequence was much higher than the rate of nonsynonymous substitutions. This observation indicates that many of the amino acids that make up lysozyme are evolving under purifying selection. In other words, there is selection against change in the protein at these positions, and the observed amino acids must therefore be critical for lysozyme function. At other positions, several different amino acids function equally well, and the corresponding gene sequences had similar rates of synonymous and nonsynonymous substitutions. The most striking finding was that amino acid replacements in lysozyme happened at a much higher rate in the lineage leading to langurs than in any other primate lineage. The high rate of nonsynonymous substitutions in the langur lysozyme gene shows that lysozyme went through a period of rapid change in adapting to the foregut of langurs. Moreover, the lysozymes of langurs and cattle share five unique amino acid replacements, all of which lie on the surface of the lysozyme molecule, well away from the enzyme's active site. Two of these shared replacements involve changes from arginine to lysine, which makes the proteins more resistant to attack by the stomach enzyme pepsin. By understanding the functional significance of amino acid replacements, molecular evolutionists can explain the observed changes in amino acid sequences in terms of changes in the functioning of the protein.

A large body of fossil, morphological, and molecular evidence shows that langurs and ruminants do not share a recent common ancestor. However, langur and ruminant lysozymes share several amino acids that neither mammal shares with the lysozymes of its own closer relatives. The lysozymes of these two mammals

WORKING WITH DATA:

Detecting Convergence in Lysozyme Sequences

Original Paper

Stewart, C.-B., J. W. Schilling, and A. C. Wilson. 1987. Adaptive evolution in the stomach lysozymes of foregut fermenters. *Nature* 330: 401–404.

Analyze the Data

Caro-Beth Stewart and her colleagues collected lysozyme sequences from six species of mammals. A small sample of their data is shown in the table. The phylogeny of these six species is well supported from analysis of many genes and much morphological data. Using the phylogenetic tree (see Figure 24.7), plot the amino acid changes across the phylogeny of the six mammals. Assume that the ancestral state is the amino acid present at the base of the tree.

Species	Amino acid position										
	2	14	17	21	50	63	75	87	117	118	130
Langur	I	K	L	K	E	Y	D	N	Q	N	V
Baboon	I	R	L	R	Q	Y	N	D	Q	N	V
Human	V	R	M	R	R	Y	N	D	Q	N	V
Rat	T	R	M	Y	Q	Y	N	D	K	N	V
Cattle	V	K	L	K	E	W	D	N	R	D	L
Horse	V	A	M	G	G	W	N	E	K	D	L
Ancestral state	V	R	M	R	Q	W	N	D	K	N	V

QUESTION 1

Which amino acid positions show unique convergence between the langur and cattle lineages (i.e., the derived state is found only in cattle and langurs)?

QUESTION 2

Which additional position is convergent between cattle and the ancestor of langurs and baboons?

QUESTION 3

Did you detect any other convergent amino acid changes between any other pair of lineages? What does this suggest about the convergent changes you observed between cattle and langurs?

Go to BioPortal for all WORKING WITH DATA exercises

have undergone convergent evolution at some amino acid positions despite their very different ancestry. The amino acids they share give these lysozymes the ability to lyse the bacteria that ferment plant material in the foregut.

The hoatzin, an unusual leaf-eating South American bird and the only known avian foregut fermenter, offers another remarkable example of the convergent evolution of lysozyme. Many birds have an enlarged esophageal chamber called a crop. The crop of the hoatzin contains lysozyme and bacteria and acts as a fermenting chamber. Many of the amino acid replacements that occurred in the adaptation of hoatzin crop lysozyme are identical to those that evolved in ruminants and langurs. Thus even though the hoatzin and foregut-fermenting mammals have not shared a common ancestor in hundreds of millions of years, they have all evolved similar adaptations in their lysozymes that enable them to recover nutrients from their fermenting bacteria.

Genome size also evolves

We know that genome size varies tremendously among organisms. Across broad taxonomic categories, there is some correlation between genome size and organismal complexity. The genome of the tiny bacterium *Mycoplasma genitalium* has only 470 genes. *Rickettsia prowazekii*, the bacterium that causes typhus, has 634 genes. *Homo sapiens*, by contrast, has about 21,000 protein-coding genes. Figure 24.8 shows the numbers of genes in a sample of organisms whose genomes have been fully sequenced, arranged by their evolutionary relationships.

As this figure reveals, a larger genome does not always indicate greater complexity (compare rice with the other plants, for example). It is not surprising that more complex genetic instructions are needed for building and maintaining a large multicellular organism than a small single-celled bacterium. What is surprising is that some multicellular organisms, such as lungfishes, some salamanders, and lilies, have about 40 times as much DNA as humans do. Structurally, a lungfish or a lily is not 40 times more complex than a human. So why does genome size vary so much?

Differences in genome size are not so great if we take into account only the portion of the DNA that actually encodes RNAs or proteins. Although the organisms with the largest total amounts of nuclear DNA (some ferns and flowering plants) have 80,000 times as much DNA as do the bacteria with the smallest genomes, no species has more than about 100 times as many protein-coding genes as a bacterium. Therefore much of the variation in genome size lies not in the number of functional genes but in the amount of noncoding DNA (Figure 24.9).

Why do the cells of most eukaryotic organisms have so much noncoding DNA? Does this noncoding DNA have a function, or is it “junk”? Although some of this DNA does not appear to have a direct function, it can alter the expression of the surrounding genes. The degree or timing of a gene’s expression can be changed dramatically depending on the gene’s position relative to noncoding sequences. Other regions of noncoding DNA consist of pseudogenes that are carried in the genome simply because the cost of doing so is very small. These

24.8 Genome Size Varies Widely This tree shows the numbers of genes from a sample of organisms whose genomes have been fully sequenced, arranged by their evolutionary relationships. Bacteria and archaea typically have fewer genes than most eukaryotes. Among eukaryotes, multicellular organisms with tissue organization (plants and animals; blue branches) have more genes than single-celled organisms (red branches) or multicellular organisms that lack pronounced tissue organization (green branches).

pseudogenes may become the raw material for the evolution of new genes with novel functions. Some noncoding DNA functions solely in maintaining chromosomal structure. Still other sequences consist of “selfish” transposable elements that proliferate because they reproduce faster than the host genome.

DNA does not just accumulate in genomes over time; noncritical nucleotide sequences are also lost from genomes. Some species differ so much in genome size because they lose noncritical sequences at very different rates. Investigators can use retrotransposons to estimate the rates at which species lose DNA. Retrotransposons are transposable elements (see Figure 17.5) that copy themselves through an RNA intermediate. The most common type of retrotransposon carries duplicated sequences at each end, called long terminal repeats, or LTRs. Occasionally, LTRs recombine in the host genome in

such a way that the DNA between them is excised. When this happens, one recombined LTR is left behind. The number of such “orphaned” LTRs in a genome is a measure of how many retrotransposons have been lost. By comparing the number of LTRs in the genomes of Hawaiian crickets (*Laupala*) and fruit flies (*Drosophila*), investigators found that *Laupala* loses DNA more than 40 times more slowly than does *Drosophila*. Therefore it is not surprising that the genome of *Laupala* is much larger than that of *Drosophila*.

24.9 A Large Proportion of DNA Is Noncoding Most of the DNA of bacteria and yeasts encodes RNAs or proteins, but a large percentage of the DNA of multicellular species is noncoding.

Why do species differ so greatly in the rate at which they gain or lose apparently functionless DNA? One hypothesis is that genome size is related to the rate at which the organism develops, which may be under selection pressure. Large genomes can slow down the rate of development and thus alter the relative timing of expression of particular genes. As discussed in Section 20.2, changes in the timing of gene expression—heterochrony—can produce major changes in phenotype. Thus although some noncoding DNA sequences may have no direct function, they may still affect the development of the organism.

Another hypothesis is that the proportion of noncoding DNA is related primarily to population size. Noncoding sequences that are only slightly deleterious to the organism are likely to be purged by selection most efficiently in species with large population sizes. In species with small populations, the effects of genetic drift can overwhelm selection against noncoding sequences that have small deleterious consequences. Therefore selection against the accumulation of noncoding sequences is most effective in species with large populations, and such species (such as bacteria and yeasts) have relatively little noncoding DNA compared with species with small populations (see Figure 24.9).

RECAP 24.2

The neutral theory of molecular evolution provides an explanation for the relatively constant rate of molecular change seen in many species. By examining the relative rates of synonymous and nonsynonymous substitutions in genes over time, biologists can distinguish the evolutionary mechanisms acting on individual genes.

- Describe how the ratio of synonymous to nonsynonymous substitutions can be used to determine whether a particular gene region is evolving neutrally, under positive selection, or under purifying selection. **See pp. 492–493**
- Contrast two hypotheses proposed to explain the differences in genome size among different organisms. **See pp. 494–495**

We have examined some of the ways in which organisms can lose DNA without losing gene functions. But how do organisms gain new functions through time?

24.3

How Do Genomes Gain and Maintain Functions?

As we noted in the previous section, most multicellular organisms have many more genes than do most unicellular species. But multicellular organisms evolved from unicellular ancestors. How did the numbers of genes within the genomes of multicellular organisms increase over evolutionary time? There are two primary mechanisms that can result in such increases: genes can be transferred from other species, or genes can be duplicated within species.

Lateral gene transfer can result in the gain of new functions

Chapter 23 described how, through the process of speciation, ancestral lineages divide into descendant lineages, and it is those speciation events that are captured by the branches in the tree of life. However, there are also processes of **lateral gene transfer**, which allow individual genes, organelles, or fragments of genomes to move horizontally from one lineage to another. Some species may pick up fragments of DNA directly from the environment. Other genes may be picked up in a viral genome and transferred to a new host when the virus becomes integrated into the new host's genome. Hybridization between species also results in the transfer of large numbers of genes.

Lateral gene transfer can be highly advantageous to a species that incorporates novel genes from a distant relative. Genes that confer antibiotic resistance, for example, are commonly transferred among different species of bacteria. Lateral gene transfer is another way, in addition to mutation and recombination, in which species can increase their genetic variation. That genetic variation then provides the raw material on which selection acts, resulting in evolution.

A phylogenetic tree constructed from a single laterally transferred genome fragment is likely to reflect only the evolutionary history of that fragment, rather than the overall organismal phylogeny (see Section 26.3). Most biologists prefer to build trees from large samples of genes or their products, so that the underlying species tree (as well as any lateral gene transfer events) can be reconstructed. Depictions of lateral gene transfer events on the underlying species tree are known as **reticulations**.

The degree to which lateral gene transfer events occur in various parts of the tree of life is a matter of considerable current investigation and debate. Lateral gene transfer appears to be relatively uncommon among most eukaryote lineages, although the two major endosymbioses that gave rise to mitochondria and chloroplasts can be viewed as lateral transfers of entire bacterial genomes to the eukaryote lineage. Some groups of eukaryotes, most notably some plants, are subject to relatively high levels of hybridization among closely related species. Hybridization leads to the exchange of many genes among recently separated lineages of plants. The greatest degree of lateral transfer, however, appears to occur among bacteria. Many bacterial genes have been transferred repeatedly among lineages of bacteria, to the point that relationships among bacterial species are often hard to decipher. Nonetheless, the broad relationships of the major groups of bacteria can still be determined (as we will discuss in Part Seven of this book). Lateral transfer of genes also makes it difficult to identify the boundaries of bacterial species, which is one reason why fewer bacterial species have been named than are known to exist.

Most new functions arise following gene duplication

Gene duplication is yet another way in which genomes can acquire new functions. When a gene is duplicated, one copy of that gene is potentially freed from having to perform its

original function. The initially identical copies of a duplicated gene can have any one of four subsequent fates:

- Both copies of the gene may retain their original function (which can result in a change in the amount of gene product that is produced by the organism).
- Both copies of the gene may retain the ability to produce the original gene product, but the expression of the genes may diverge in different tissues or at different times in development.
- One copy of the gene may be incapacitated by the accumulation of deleterious substitutions and become a nonfunctional pseudogene, or may be eliminated from the genome altogether.
- One copy of the gene may retain its original function while the second copy accumulates enough substitutions that it can perform a different function.

How often do gene duplications arise, and which of these four outcomes is most likely? Investigators have found that rates of gene duplication are fast enough for a yeast or *Drosophila* population to acquire several hundred duplicate genes over the course of a million years. They have also found that most of the duplicated genes in these organisms are very young. Many extra genes are lost from a genome within 10 million years (which is rapid on an evolutionary time scale).

Some genes may be duplicated many times, resulting in large numbers of related pseudogenes scattered throughout the genome. In the human genome, the functional copy of the ribosomal protein gene *RPL21* is located on chromosome pair 13, but pseudogenes derived from it are found on most of the other chromosome pairs (Figure 24.10). Although not all genes are represented by pseudogenes, there are nearly as many known pseudogenes in the human genome as there are functional protein-coding genes.

Although many extra genes disappear rapidly, some duplication events lead to the evolution of genes with new functions. Several successive rounds of duplication and mutation may result in a **gene family**: a group of homologous genes with related functions, often arrayed in tandem along a chromosome. An example of this process is provided by the globin

gene family (see Figure 17.10). The globins were among the first proteins to be sequenced and compared. Comparisons of their amino acid sequences strongly suggest that the different globins arose via gene duplications. These comparisons also allow us to estimate how long the globins have been evolving separately because differences among these proteins have accumulated with time.

Hemoglobin, a tetramer (four-subunit molecule) consisting of two α -globin and two β -globin polypeptide chains, carries oxygen in blood. Myoglobin, a monomer, is the primary O_2 storage protein in muscle. Myoglobin's affinity for O_2 is much higher than that of hemoglobin, but hemoglobin has evolved to be more diversified in its roles. Hemoglobin binds O_2 in the lungs or gills, where the O_2 concentration is relatively high, transports it to deep body tissues, where the O_2 concentration is low, and releases it in those tissues. With its more complex tetrameric structure, hemoglobin is able to carry four molecules of O_2 , as well as hydrogen ions and carbon dioxide, in the blood.

To estimate the time of the globin gene duplication that gave rise to the α - and β -globin gene clusters, we can create a **gene tree**—a phylogenetic tree that describes the evolutionary history of particular genes or gene families, in this case the gene sequences that encode the various globins (Figure 24.11). The rate of molecular evolution of globin genes has been estimated from other studies, using the divergence times of groups of vertebrates that are well documented in the fossil record. These studies indicate an average rate of divergence for globin genes of about 1 nucleotide substitution every 2 million years. By applying this rate to the globin gene tree, we can estimate the divergence time of the two globin gene clusters at about 450 million years ago.

Many gene duplications affect only one or a few genes at a time, but entire genomes are duplicated in polyploid organisms (which include many plants). When all the genes are duplicated, there are massive opportunities for new functions to evolve. That is exactly what appears to have happened in the evolution of vertebrates. The genomes of the jawed vertebrates appear to have four diploid sets of many major genes, which has led biologists to conclude that two genome-wide duplication events occurred in the ancestor of these species.

(A) Human chromosomes

(B)

24.10 Some Functional Genes are Duplicated Many Times as Nonfunctional Pseudogenes (A) The functional gene that encodes ribosomal protein *RPL21* is located on human chromosome 13 (indicated in red). In addition, there are many nonfunctional pseudogenes of *RPL21* in the human genome, produced through repeated duplication events (indicated in blue). (B) Although *RPL21* represents a relatively extreme example of pseudogene duplication, there are almost as many known pseudogenes in the human genome as there are functional genes.

24.11 A Globin Family Gene Tree A molecular clock analysis suggests that the α -globin (blue) and β -globin (green) gene clusters diverged about 450 million years ago, soon after the origin of the vertebrates.

These duplications have allowed considerable specialization of individual vertebrate genes, many of which are now highly tissue-specific in their expression. A good example is the duplication of sodium channel genes, which allowed the evolution of the electric organs of electric fishes described at the opening of this chapter.

Some gene families evolve through concerted evolution

Although the members of the globin gene family have diversified in form and function, the members of many other gene families do not evolve independently of one another. For instance, almost all organisms have many copies (up to thousands) of the ribosomal RNA genes. Ribosomal RNA (rRNA) is the principal structural element of ribosomes and, as such, has a primary role in protein synthesis. Every living species needs to synthesize proteins, often in large amounts (especially during early development). Having many copies of the rRNA genes ensures that organisms can rapidly produce many ribosomes and thereby maintain a high rate of protein synthesis.

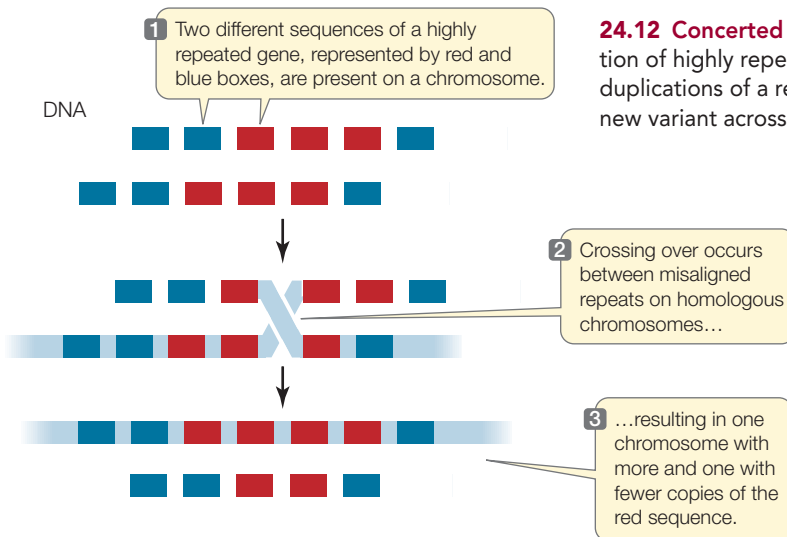

Like all portions of the genome, ribosomal RNA genes evolve, and differences accumulate in the rRNA genes of different species. But within any one species, the multiple copies of the rRNA genes are very similar, both structurally and functionally. This similarity makes sense because, ideally, every ribosome in a species should synthesize proteins in the same way. In other words, within a given species, the multiple copies of these rRNA genes are evolving in concert with one another, a phenomenon called **concerted evolution**.

How does concerted evolution occur? Two different mechanisms appear to be responsible. The first of these is **unequal crossing over**. When DNA is replicated during meiosis in a diploid species, the homologous chromosome pairs align and recombine by crossing over (see Section 11.4). In the case of highly repeated genes, however, it is easy for genes to become displaced in alignment, since so many copies of the same genes are present on the chromosomes (**Figure 24.12A**). The end result is that one chromosome may gain extra copies of the repeat and the other chromosome may have fewer copies of the repeat. If a new substitution arises in one copy of the repeat, it can spread to new copies (or be eliminated) through unequal crossing over. Thus, over time, a novel substitution will either become fixed or it will be lost entirely. In either case, all copies of the repeat will remain very similar to one another.

The second mechanism that produces concerted evolution is **biased gene conversion**. This mechanism can be much faster than unequal crossing over and has been shown to be the primary mechanism for concerted evolution of rRNA genes. DNA strands are frequently broken and repaired (see Section 13.4). At many times during the cell cycle, the genes for ribosomal RNA are clustered close together. If damage occurs to one of the genes, a copy of the rRNA gene on another chromosome may be used to repair the damaged copy, and the sequence that is used as a template can thereby replace the original sequence (**Figure 24.12B**). In many cases, this repair system appears to be biased in favor of using particular sequences as templates for repair, and thus the favored sequence rapidly spreads across all copies of the gene. In this way, changes may appear in a single copy and then rapidly spread to all the other copies.

Regardless of the mechanism responsible, the net result of concerted evolution is that the copies of a highly repeated gene do not evolve independently of one another. Mutations still occur, but once they arise in one copy, they either spread rapidly

(A) Unequal crossing over

24.12 Concerted Evolution Two mechanisms can produce concerted evolution of highly repeated genes. (A) Unequal crossing over results in deletions and duplications of a repeated gene. (B) Biased gene conversion can rapidly spread a new variant across multiple copies of a repeated gene.

(B) Biased gene conversion

across all the copies or are lost from the genome completely. This process allows the products of each copy to remain similar over time in both sequence and function.

RECAP 24.3

Lateral gene transfer can result in the transfer of genetic functions between even distantly related species. Gene duplication can lead to the evolution of new functions. Some highly repeated genes undergo concerted evolution, which maintains uniform functionality.

- Explain the potential advantages of lateral gene transfer. [See p. 496](#)
- What are four possible outcomes of gene duplication? [See p. 497](#)
- Describe the pattern of concerted evolution among highly repeated genes and the mechanisms that lead to concerted evolution. [See p. 498 and Figure 24.12](#)

We have seen how the principles and methods of molecular evolution have opened new vistas in evolutionary biology. Next we will consider some of the practical applications of this field.

24.4 What Are Some Applications of Molecular Evolution?

Studies of molecular evolution have practical applications throughout biology, from understanding basic aspects of biological function to studies of human health.

Molecular sequence data are used to determine the evolutionary history of genes

A gene tree can show the evolutionary relationships of a single gene in different species, or it can trace the evolution of members of a gene family (as in Figure 24.11). The methods for constructing a gene tree are the same as those we described in Section 22.2 for building phylogenetic trees of species. The process involves identifying differences between genes and using those differences to reconstruct the evolutionary history of the genes. Gene trees are often used to construct phylogenetic trees of species, but the two types of trees are not necessarily equivalent. Processes such as gene duplication can give rise to differences between the phylogenetic trees of genes and species. From a gene tree, biologists can reconstruct the history and timing of gene duplication events and learn how gene diversification has resulted in the evolution of new protein functions.

All the genes of a particular gene family have similar sequences because they have a common ancestry. As we discussed in Section 22.1, features that are similar as a result of common ancestry are said to be homologous. When discussing gene trees, however, we usually need to distinguish between two forms of homology. Homologous genes that are found in different species and whose divergence we can trace to the speciation events that gave rise to those species are called **orthologs**. Homologous genes in the same or different species that are related through gene duplication events are called **paralogs**. When we examine a gene tree, the questions we wish to address determine whether we should compare orthologs or paralogous genes. If we wish to reconstruct the evolutionary history of the species that contain the genes, then our comparison should be restricted to orthologs (because they will reflect the history of speciation events). If we are interested in the changes in function that have resulted from gene duplication events, however, then the appropriate comparison is among paralogs (because they will reflect the history of gene duplication events). If our focus is on the diversification of a gene family through both processes, then we will want to include both paralogs and orthologs in our analysis.

Figure 24.13 depicts a gene tree for the members of a gene family called *engrailed* (its members encode transcription

24.13 Phylogeny of the *engrailed* Genes

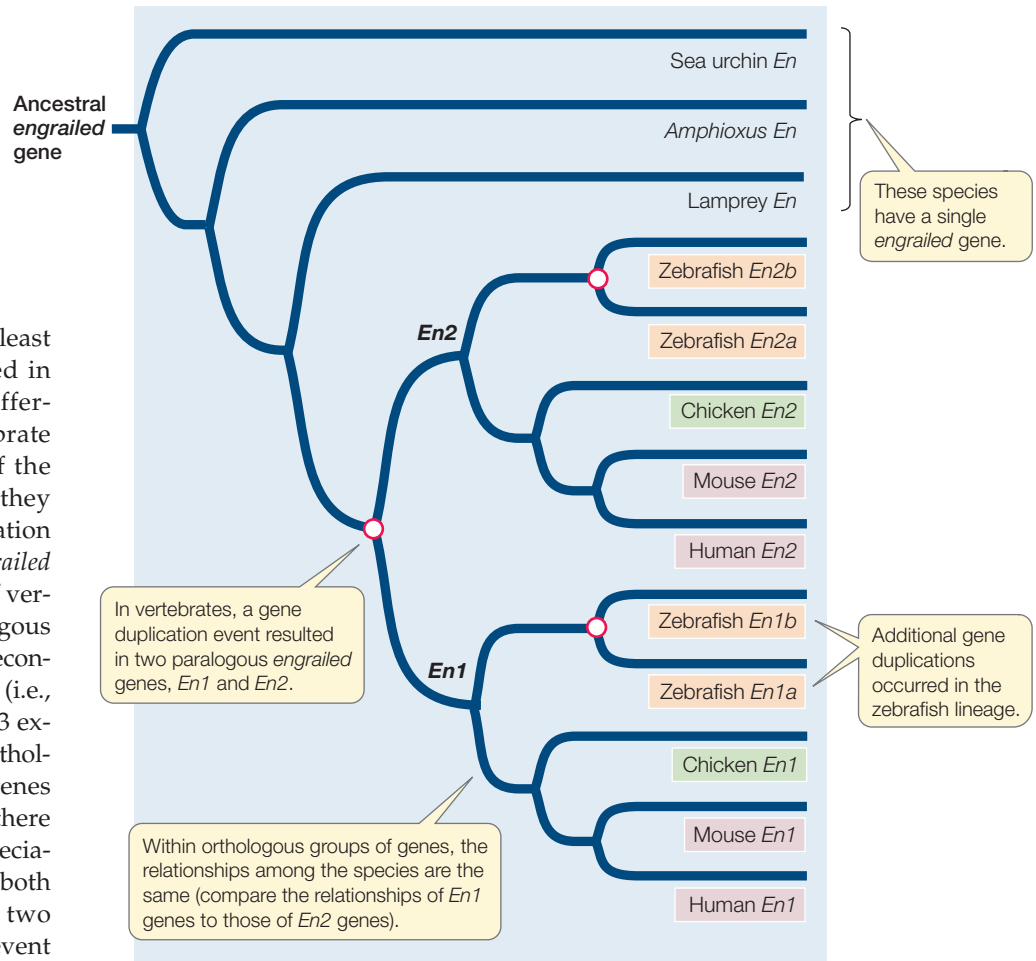

The *engrailed* genes are homologous because they share a common ancestor. Speciation events have generated orthologous *engrailed* genes, and gene duplication events (open circles) have generated paralogous *engrailed* genes among bony vertebrates.

factors that regulate development). At least three gene duplications have occurred in this family, resulting in up to four different *engrailed* genes (*En*) in some vertebrate species (such as the zebrafish). All of the *engrailed* genes are homologs because they have a common ancestor. Gene duplication events have generated paralogous *engrailed* genes (*En1* and *En2*) in some lineages of vertebrates. We could compare the orthologous sequences of the *En1* group of genes to reconstruct the history of the bony vertebrates (i.e., all the vertebrate species in Figure 24.13 except the lamprey), or we could use the orthologous sequences of the *En2* group of genes and expect the same answer (because there is only one history of the underlying speciation events). All bony vertebrates have both groups of *engrailed* genes because the two groups arose from a gene duplication event in the common ancestor of bony vertebrates. If we wanted to focus on the diversification that occurred as a result of this duplication, then the appropriate comparison would be between the paralogous genes of the *En1* versus *En2* groups.

Gene evolution is used to study protein function

Earlier in this chapter we discussed the ways in which biologists can detect regions of genes that are under positive selection for change. What are the practical uses of this information? Consider the evolution of the family of genes encoding voltage-gated sodium channels, which we introduced at the opening of this chapter. Sodium channels have many functions, including the control of nerve impulses in the nervous system. Sodium channels can be blocked by various toxins, such as tetrodotoxin (TTX), a neurotoxin present in the tissues of some puffer fishes and several other animals. A human who eats those tissues of a puffer fish that contain TTX can become paralyzed and die because the toxin blocks sodium channels and prevents nerves and muscles from functioning.

But puffer fishes have sodium channels too, so why doesn't the TTX cause paralysis in the puffer fish itself? The sodium channels of puffer fishes (and other animals that sequester TTX, such as the rough-skinned newt shown in Figure 21.20) have evolved to become resistant to the toxin. Nucleotide substitutions in the puffer fish genome have resulted in changes in the proteins that make up the sodium channels, and those changes prevent TTX from binding to the sodium channel pore.

Several different substitutions that result in TTX resistance have evolved in the various duplicated sodium channel genes of the many species of puffer fish. Many other changes that have nothing to do with the evolution of TTX resistance have occurred in these genes as well. Biologists who study the function of sodium channels can learn a great deal about how the channels work (and about neurological diseases that are caused by mutations in the sodium channel genes) by understanding which changes have been selected for TTX resistance. They do this by comparing the rates of synonymous and nonsynonymous substitutions across the genes in various lineages that have evolved TTX resistance. In a similar manner, molecular evolutionary principles are used to understand function and diversification of function in many other proteins.

In vitro evolution is used to produce new molecules

As biologists studied the relationships among selection, evolution, and function in macromolecules, they realized that molecular evolution could be used in a controlled laboratory environment to produce new molecules with novel and useful functions. Thus were born the applications of **in vitro evolution**.

Living organisms produce thousands of compounds that humans have found useful. The search for such naturally occurring compounds, which can be used for pharmaceutical, agricultural, or industrial purposes, has been termed

“bioprospecting.” These compounds are the result of millions of years of molecular evolution across millions of species of living organisms. Yet biologists can also imagine molecules that *could* have evolved but, lacking the right combination of selection pressures and opportunities, have not. For instance, we might want to have a molecule that binds a particular environmental contaminant so that the contaminant can be isolated and extracted from the environment. But if the contaminant is synthetic (i.e., not produced naturally), it is unlikely that any living organism will have evolved a molecule with the function we desire. This problem was the inspiration for the field of in vitro evolution.

The principles of in vitro evolution are based on the principles of molecular evolution that we have learned from the natural world. Consider the evolution of a new RNA molecule that was produced in the laboratory using the principles of mutation and selection. This molecule’s intended function was to join two other RNA molecules (acting as a ribozyme with a function similar to that of the naturally occurring DNA ligase described in Section 13.3, but for RNA molecules). The process started with a large pool of random RNA sequences (10^{15} different sequences, each about 300 nucleotides long), which were then selected for any ligase activity (Figure 24.14). None were very effective ligases, but some were slightly better than others. The best of the ribozymes were selected and reverse-transcribed into cDNA (using the enzyme reverse transcriptase). The cDNA molecules were then amplified using the polymerase chain reaction (PCR; see Figure 13.21).

PCR amplification is not perfect, and it introduced many new mutations into the pool of sequences. These sequences were then transcribed back into RNA molecules using RNA polymerase, and the process was repeated. The ligase activity of the RNAs evolved quickly; after 10 rounds of in vitro evolution, it had increased by about 7 million times. Similar techniques have since been used to create a wide variety of molecules with novel enzymatic and binding functions.

Molecular evolution is used to study and combat diseases

Many of the most problematic human diseases are caused by living, evolving organisms that present a moving target for modern medicine. Recall the example of influenza described at the opening of Chapter 21 and that of HIV in Chapter 22. The control of these and many other human diseases depends on techniques that can track the evolution of pathogenic organisms over time.

The transportation advances of the past century have allowed humans to move around the world with unprecedented speed and frequency. Unfortunately, this mobility has allowed pathogens to be transmitted among human populations at increasing rates, which has led to the global emergence of many “new” diseases. Most of these emerging diseases are caused by viruses. Virtually all new viral diseases have been identified by evolutionary comparison of their genomes with those

24.14 In Vitro Evolution Starting with a large pool of random RNA sequences, investigators produced a new ribozyme through rounds of mutation and selection for the ability to ligate RNA sequences.

of known viruses. In recent years, for example, rodent-borne hantaviruses have been identified as the source of widespread respiratory illnesses, and the virus (and its host) that causes Sudden Acute Respiratory Syndrome (SARS) was identified using evolutionary comparisons of genes. Studies of the origins, the timing of emergence, and the global diversity of many human pathogens depend on the principles of molecular evolution, as do the efforts to develop and use effective vaccines against these pathogens. For example, the techniques used to develop modern polio vaccines, as well as the methods used to track their effectiveness in human populations, rely on molecular evolutionary approaches.

In the future, molecular evolution will become even more critical to the identification of human (and other) diseases. Once biologists have collected data on the genomes of enough organisms,

it will be possible to identify an infection by sequencing a portion of the infecting organism's genome and comparing this sequence with other sequences on an evolutionary tree. At present it is difficult to identify many common viral infections (those that cause "colds," for instance). As genomic databases and evolutionary trees increase, however, automated methods of sequencing and rapid phylogenetic comparison of the sequences will allow us to identify and treat a much wider array of human illnesses.

RECAP 24.4

Molecular evolution has provided biologists with new tools to understand the functions of macromolecules and how those functions can change over time. These tools can be used to develop synthetic molecules and to identify and combat human diseases.

- Why might a biologist limit a particular investigation to orthologous (as opposed to paralogous) genes? **See pp. 499–500**
- Explain how gene evolution can be used to study protein function. **See p. 500**
- Describe the process of in vitro evolution. **See pp. 500–501 and Figure 24.14**

Now that we have discussed how organisms and biological molecules evolve, we are ready to consider the broader evolutionary history of life on Earth. Chapter 25 will describe the long-term evolutionary changes that have given rise to all of life's diversity.

How do evolutionary studies of sodium channel genes help us understand some human genetic disorders?

ANSWER

Our understanding of how genes and proteins function is largely based on comparative evolutionary analyses of homologous genes across many species. These analyses reveal the parts of the genes that are conserved across species and evolutionary time, as well as the parts of the genes that covary with certain functions (such as the generation of electric signals, as in the case of the sodium channel genes discussed in the chapter opening story). These evolutionary patterns allow biologists to correlate sequence variation with function. These correlations, in turn, allow biologists to predict the causes (and in many cases, suggest treatments) for genetic disorders found in humans. For example, certain mutations in sodium channel genes can cause the inability to feel pain. Other mutations may result in extreme sensitivity to pain, heart disease, or sudden infant death. Understanding the relationship between sequence variation and function is the first step in understanding these disorders, as well as a necessary step in finding treatments for people who suffer from these disorders.

CHAPTER SUMMARY 24

24.1 How Are Genomes Used to Study Evolution?

- A **genome** is an organism's full set of genes, regulatory sequences, and structural elements as well as noncoding DNA.
- The field of **molecular evolution** concerns relationships between the structures of genes and proteins and the functions of organisms.
- **Sequence alignments** of proteins or nucleic acids from different organisms allow us to compare the sequences and identify homologous positions. **Review Figure 24.1, ACTIVITY 24.1**
- The minimum number of changes between sequences can be calculated from a **similarity matrix**. Models of sequence evolution can be used to account for changes that cannot be observed directly. **Review Figure 24.2, ACTIVITY 24.2**

24.2 What Do Genomes Reveal about Evolutionary Processes?

- **Nonsynonymous substitutions** of nucleotides result in amino acid replacements in proteins, but **synonymous substitutions** do not. **Review Figure 24.5**
- The **neutral theory** of molecular evolution states that much of the molecular change in nucleotide sequences does not change genome function. The rate of fixation of neutral mutations is independent of population size and is equal to the mutation rate.

- Positive selection for change in a protein-coding gene may be detected by a higher rate of nonsynonymous than synonymous substitutions. The reverse is true of purifying selection.
- Common selective constraints can lead to convergent evolution of amino acid sequences in distantly related species. **Review Figure 24.7**
- The total size of genomes varies much more widely across multicellular species than does the number of functional genes. **Review Figures 24.8, 24.9**

24.3 How Do Genomes Gain and Maintain Functions?

- **Lateral gene transfer** can result in the rapid acquisition of new functions from distantly related species.
- **Gene duplications** can result in increased production of the gene's product, in nonfunctional **pseudogenes**, or in new gene functions. Several rounds of gene duplication can give rise to multiple genes with related functions, collectively known as a **gene family**. **Review Figures 24.10, 24.11.**
- **Gene trees** describe the evolutionary history of particular genes or gene families. **See ACTIVITY 24.3**
- Some highly repeated genes undergo **concerted evolution**, in which the multiple copies within the genome maintain their similarity, even as the genes diverge among species. **Review Figure 24.12, ANIMATED TUTORIAL 24.1**

continued

24.4 What Are Some Applications of Molecular Evolution?

- **Orthologs** are genes that are related through speciation events, whereas **paralogs** are genes that are related through gene duplication events. **Review Figure 24.13**
- Protein function can be studied by examining gene evolution. Detection of positive selection can be used to identify molecular changes that have resulted in functional changes.

- **In vitro evolution** is used to produce synthetic molecules with particular desired functions. **Review Figure 24.14**
- Many diseases are identified, studied, and combated through molecular evolutionary investigations.

CHAPTERREVIEW

REMEMBERING

1. A higher rate of synonymous than nonsynonymous substitutions in a protein-coding gene is expected under
 - a. purifying selection.
 - b. positive selection.
 - c. neutral evolution.
 - d. concerted evolution.
 - e. none of the above
2. Before nucleotide and amino acid sequences can be compared in an evolutionary framework, they must be aligned to account for
 - a. deletions and insertions.
 - b. selection and neutrality.
 - c. parallelisms and convergences.
 - d. gene families.
 - e. all of the above
3. The rate of fixation of neutral mutations, $m = 2N\mu \frac{1}{2N}$, is
 - a. independent of population size.
 - b. higher in small populations than in large populations.
 - c. higher in large populations than in small populations.
 - d. slower than the rate of fixation of deleterious mutations.
 - e. none of the above
4. When a gene is duplicated, which of the following may occur?
 - a. Production of the gene's product may increase.
 - b. The two copies may become expressed in different tissues.
 - c. One copy of the gene may accumulate deleterious substitutions and become functionless.
 - d. The two copies may diverge and acquire different functions.
 - e. All of the above
5. Genome size varies widely among different multicellular organisms (see graph below). What is the greatest contributing cause of this variation?
 - a. The number of protein-coding genes
 - b. The amount of noncoding DNA
 - c. The number of duplicated genes
 - d. The degree of concerted evolution
 - e. The amount of positive selection for change in protein-coding genes

- a. speciation event.
- b. substitution event.
- c. insertion event.
- d. deletion event.
- e. duplication event.

UNDERSTANDING & APPLYING

- 7. Rates of evolutionary change differ among different molecules, and different species differ widely in generation times and population sizes. How does this variation limit how and in what ways we can use the concept of a molecular clock to help us answer questions about the evolution of both molecules and organisms?
- 8. Based on what you have learned about evolutionary processes, what modifications could you introduce into in vitro evolution experiments (such as the one shown in Figure 24.14) to increase the diversity or rate of evolution of new molecules?

ANALYZING & EVALUATING

- 9. Over evolutionary history, many groups of organisms that inhabit caves have lost the organs of sight. For instance, although surface-dwelling crayfishes have functional eyes, several crayfish species that are restricted to underground habitats lack eyes. Opsins are a group of light-sensitive proteins known to have an important function in vision (see Chapter 46), and opsin genes are expressed in eye tissues. Opsin genes are present in the genomes of eyeless, cave-dwelling crayfishes. Two alternative hypotheses that might explain the presence of opsin genes in an eyeless organism are (1) the genes are no longer experiencing purifying selection because there is no longer selection for function in vision; or (2) the genes are experiencing selection for a function other than vision. How would you investigate these two hypotheses using the sequences of the opsin genes in various species of crayfishes?

- 10. Analysis of synonymous and nonsynonymous substitutions in protein-coding genes can be used to distinguish neutral evolution, positive selection, and purifying selection. An investigator compared many gene sequences encoding surface proteins from influenza viruses sampled over time and collected the data shown in the table. Use the table to answer the following questions.

Amino acid position	Synonymous substitutions	Nonsynonymous substitutions
12	0	7
15	1	9
61	0	12
80	7	0
137	12	1
156	24	2
165	3	4
226	38	3

- a. Which positions encode amino acids that have probably changed as a result of positive selection? Why?
 - b. Which positions encode amino acids that have probably changed as a result of purifying selection? Why?
- (Hint: To calculate rates of each substitution type, you will need to consider the number of synonymous and nonsynonymous substitutions present *relative to the number of possible substitutions of each type*. There are approximately 3 times as many possible nonsynonymous substitutions as there are synonymous substitutions.)

The History of Life on Earth

CHAPTER OUTLINE

- 25.1** How Do Scientists Date Ancient Events?
- 25.2** How Have Earth's Continents and Climates Changed over Time?
- 25.3** What Are the Major Events in Life's History?

ALMOST ANYONE who has spent time around freshwater ponds is familiar with dragonflies. Their bright colors and transparent wings stimulate our visual senses on bright summer afternoons as they fly about their business of devouring mosquitoes, mating, and laying their eggs. The largest dragonflies alive today have wingspans that can be covered by a human hand. Three hundred million years ago, however, dragonflies such as *Meganeuropsis permiana* had wingspans of more than 70 centimeters—well over 2 feet, matching or exceeding the wingspans of many modern birds of prey. These dragonflies were the largest flying predators of their time.

No flying insects alive today are anywhere near this size. But during the Carboniferous and Permian geological periods, 350–250 million years ago, many groups of flying insects contained gigantic species. *Meganeuropsis* probably ate huge mayflies and other giant flying insects that shared its home in the Permian swamps. These enormous insects were themselves eaten by giant amphibians. None of these insects or amphibians would be able to survive on Earth today. The oxygen concentrations in Earth's atmosphere were about 50 percent higher than they are now, and those high oxygen concentrations are thought to have been necessary to support giant insects and their huge amphibian predators.

Paleontologists have uncovered fossils of *Meganeuropsis permiana* in the rocks of Kansas. How do we know the age of these fossils, and how can we know how much oxygen that long-vanished atmosphere contained? The layering of rocks allows us to tell their

Dragonflies as Big as Hawks

Meganeuropsis permiana is shown here in an artist's reconstruction from fossils. Except for its size, this giant from the Permian period was similar to modern dragonflies (depicted in the inset at the same scale).

ages relative to one another, but it does not by itself indicate a given layer's absolute age.

One of the remarkable scientific achievements of the twentieth century was the development of sophisticated techniques that use the decay rates of various radioisotopes, the ratios of certain molecules in rocks and fossils, and changes in Earth's magnetic field to infer conditions and events in the remote past and to date them accurately. It is those methods that allow us to age the fossils of *Meganeuropsis* and to calculate the concentration of oxygen in Earth's atmosphere at the time.

Earth is about 4.5 billion years old, and life has existed on it for about 3.8 billion of those years. That means human civilizations have occupied Earth for less than 0.0003 percent of the history of life. Discovering what happened before humans were around is an ongoing and exciting area of science.

Can modern experiments test hypotheses about the evolutionary impact of ancient environmental changes?

See answer on p. 522.

TABLE 25.1
Earth's Geological History

Eon	Era	Period	Onset	Major Physical Changes on Earth
Phanerozoic (~0.5 billion years long)	Cenozoic	Quaternary (Q)	2.6 mya	Cold/dry climate; repeated glaciations
		Tertiary (T)	65.5 mya	Continents near current positions; climate cools
	Mesozoic	Cretaceous (K)	145.5 mya	Laurasian continents attached to one another; Gondwana begins to drift apart; meteorite strikes near current Yucatán Peninsula at end of period
		Jurassic (J)	201.6 mya	Two large continents form: Laurasia (north) and Gondwana (south); climate warm
		Triassic (Tr)	251.0 mya	Pangaea begins to drift apart; hot/humid climate
	Paleozoic	Permian (P)	299 mya	Extensive lowland swamps; O ₂ levels 50% higher than present; by end of period continents aggregate to form Pangaea, and O ₂ levels drop rapidly
		Carboniferous (C)	359 mya	Climate cools; marked latitudinal climate gradients
		Devonian (D)	416 mya	Continents collide at end of period; giant meteorite probably strikes Earth
		Silurian (S)	444 mya	Sea levels rise; two large land masses emerge; hot/humid climate
		Ordovician (O)	488 mya	Massive glaciation; sea level drops 50 meters
		Cambrian (C)	542 mya	Atmospheric O ₂ levels approach current levels
Proterozoic	Collectively called the Precambrian (~4 billion years long)		2.5 bya	Atmospheric O ₂ levels increase from negligible to about 18%; "snowball Earth" from about 750 to 580 mya
Archean			3.8 bya	Earth accumulates more atmosphere (still almost no O ₂); meteorite impacts greatly reduced
Hadean			4.5–4.6 bya	Formation of Earth; cooling of Earth's surface; atmosphere contains almost no free O ₂ ; oceans form; Earth under almost continuous bombardment from meteorites

Note: mya, million years ago; bya, billion years ago.

25.1 How Do Scientists Date Ancient Events?

Some evolutionary changes happen rapidly enough to be studied directly and manipulated experimentally. Plant and animal breeding by agriculturalists and the evolution of surface proteins in influenza viruses are examples of rapid, short-term evolution that we have discussed in previous chapters. Other evolutionary changes, such as the appearance of new species and evolutionary lineages, usually take place over a **geological time scale** (Table 25.1).

To understand long-term patterns of evolutionary change, we must not only think in time scales spanning many millions of years, but also consider events and conditions very different from those we observe today. Earth of the distant past was so unlike our present Earth that it would seem like a foreign planet inhabited by strange organisms. The continents were not where they are now, and climates were sometimes dramatically different from those of today. We know this because much of Earth's history is recorded in its rocks.

We cannot tell the ages of rocks just by looking at them, but we can determine the ages of rocks *relative to one another*. The

first person to formally recognize this method of relative dating was the seventeenth century Danish physician Nicolaus Steno. Steno realized that in undisturbed sedimentary rocks (rocks formed by the accumulation of sediments), the oldest layers of rock, or **strata** (singular *stratum*), lie at the bottom, and successively higher strata are progressively younger.

Geologists subsequently combined Steno's insight with their observations of fossils contained in sedimentary rocks to establish the following principles of **stratigraphy**:

- Fossils of similar organisms are found in widely separated places on Earth.
- Certain fossils are always found in younger strata, and certain other fossils are always found in older strata.
- Organisms found in younger strata are more similar to modern organisms than are those found in older strata.

These patterns revealed much about the relative ages of sedimentary rocks and the fossils they contained, as well as patterns in the evolution of life. But geologists still could not tell the absolute age of these rocks. A method for *absolute* dating of rocks—that is, determining their actual age rather than just their age relative to one another—did not become available

Major Events in the History of Life
Humans evolve; many large mammals become extinct Diversification of birds, mammals, flowering plants, and insects
Dinosaurs continue to diversify; mass extinction at end of period (~76% of species lost) Diverse dinosaurs; radiation of ray-finned fishes; first fossils of flowering plants
Early dinosaurs; first mammals; marine invertebrates diversify; mass extinction at end of period (~65% of species lost)
Reptiles diversify; giant amphibians and flying insects present; mass extinction at end of period (~96% of species lost) Extensive fern/horsetail/giant club moss forests; first reptiles; insects diversify
Jawed fishes diversify; first insects and amphibians; mass extinction at end of period (~75% of marine species lost) Jawless fishes diversify; first ray-finned fishes; plants and animals colonize land
Mass extinction at end of period (~75% of species lost) Rapid diversification of multicellular animals; diverse photosynthetic protists
Origin of photosynthesis, multicellular organisms, and eukaryotes
Origin of life; prokaryotes flourish
Life not yet present

until after radioactivity was discovered at the beginning of the twentieth century.

Radioisotopes provide a way to date fossils and rocks

Radioactive isotopes of elements—**radioisotopes**—decay in a predictable pattern over long periods (see Section 2.1). Over a specific time interval, known as a **half-life**, half of the atoms in a radioisotope decay to become a different, stable (nonradioactive) isotope (Figure 25.1A). The use of this knowledge to date fossils and rocks is known as **radiometric dating**.

To use a radioisotope to date a past event, we must know or estimate the concentration of that isotope at the time of that event, and we must know the radioisotope’s half-life. For example, the production of carbon-14 (¹⁴C, a radioisotope of carbon) in the upper atmosphere—by the reaction of neutrons with nitrogen-14 (¹⁴N, a stable isotope of nitrogen)—just balances the natural radioactive decay of ¹⁴C into ¹⁴N. Therefore the ratio of ¹⁴C to the more common stable isotope of carbon, carbon-12 (¹²C), is relatively constant in living organisms and in their environment. As soon as an organism dies, however, it ceases to exchange carbon compounds with its environment.

25.1 Radioactive Isotopes Allow Us to Date Ancient Rocks The decay of radioactive isotopes into stable isotopes happens at a steady rate. A half-life is the time it takes for half of the remaining atoms to decay in this way. (A) The graph demonstrates the principle of half-life using carbon-14 (¹⁴C) as an example. The half-life of ¹⁴C is 5,700 years. (B) Different radioisotopes have different characteristic half-lives that allow us to estimate the ages of rocks.

Its decaying ¹⁴C is no longer replenished, and the ratio of ¹⁴C to ¹²C in its remains decreases over time. Paleontologists can use the ratio of ¹⁴C to ¹²C in fossil material to date fossils that are less than 60,000 years old (and thus the sedimentary rocks that contain those fossils). If fossils are older than that, so little ¹⁴C remains that the limits of detection using this particular isotope are reached.

Radiometric dating methods have been expanded and refined

Sedimentary rocks are formed from materials that existed for varying lengths of time before being weathered, fragmented, and transported, sometimes over long distances, to the site of their deposition. Therefore the radioisotopes in sedimentary rock do not contain reliable information about the date of its formation. Radiometric dating of rocks older than 60,000 years requires estimating radioisotope concentrations in **igneous rock**, which is formed when molten material cools. To date sedimentary strata, geologists search for places where volcanic ash or lava flows have intruded into the sedimentary rock.

A preliminary estimate of the age of an igneous rock determines which radioisotopes can be used to date it (Figure 25.1B). The decay of potassium-40 (which has a half-life of 1.3 billion years) to argon-40, for example, has been used to date many of the ancient events in the evolution of life. Fossils

in the adjacent sedimentary rock that are similar to those in other rocks of known ages provide additional clues to the rock's age.

Scientists have used several methods to construct a geological time scale

Radiometric dating of rocks, combined with fossil analysis, is the most powerful method of determining geological age. But in places where sedimentary rocks do not contain suitable igneous intrusions and few fossils are present, paleontologists turn to other dating methods.

One method, known as paleomagnetic dating, relates the ages of rocks to patterns in Earth's magnetism, which change over time. Earth's magnetic poles move and occasionally reverse themselves. Both sedimentary and igneous rocks preserve a record of Earth's magnetic field at the time they were formed, and that record can be used to determine the ages of those rocks. Other methods of dating events in life's history use information about continental drift, information about sea level changes, and molecular clocks (a method that was described in Section 22.3).

Geologists used all of these methods to develop a geological time scale (see Table 25.1). They divided the broad history of life into four **eons**. The Hadean eon refers to the time on Earth before life evolved. The early history of life occurred in the Archean eon, which ended about the time that photosynthetic organisms first appeared on Earth. Prokaryotic life diversified rapidly in the Proterozoic eon, and the first eukaryotes in the fossil record date from this time. These three eons are sometimes referred to collectively as Precambrian time, or simply the **Precambrian**. The Precambrian lasted for approximately four billion years and thus accounts for the vast majority of geological time. It was in the Phanerozoic eon, however—a mere 542-million-year time span—that multicellular eukaryotes rapidly diversified. To emphasize the events of the Phanerozoic, Table 25.1 shows the subdivision of this eon into eras and periods. The boundaries between these divisions of time are based largely on the striking differences geologists observe in the assemblages of fossil organisms contained in successive strata. This geological record of life reveals a remarkable story of a world in which the continents and biological communities are constantly changing.

RECAP 25.1

Fossils in sedimentary rock strata enabled geologists to determine the relative ages of organisms, but absolute dating was not possible until the discovery of radioactivity. Geologists divide the history of life into eons, eras, and periods, based on assemblages of fossil organisms found in successive layers of rocks.

- What observations suggested that fossils could be used to determine the relative ages of rocks? [See p. 506](#)
- How is the rate of decay of radioisotopes used to estimate the absolute ages of rocks? [See p. 507 and Figure 25.1](#)

As geologists began to develop accurate ways to measure the age of Earth, they began to understand that Earth is far older than anyone had previously understood. During its 4.5-billion-year history, Earth has undergone massive physical changes. These changes have influenced the evolution of life, and life, in its turn, has influenced Earth's physical environment.

25.2

How Have Earth's Continents and Climates Changed over Time?

As we saw in the previous section, the Phanerozoic eon has been notable for the rapid diversification of multicellular eukaryotes. But the diversity of multicellular organisms has not simply increased steadily through time. New species have arisen, and species have gone extinct, throughout the history of life. But there have been times during which extinction rates have increased dramatically over the background levels (**Figure 25.2**). These mass extinction events are the cause of some of the striking differences in fossil assemblages that geologists use to divide the Phanerozoic eon into eras and periods. After each mass extinction, the diversity of life rebounded, although recovery took millions of years. In this section we will discuss some of the physical changes on Earth that have resulted in such dramatic changes in life's diversity.

25.2 Periodic Mass Extinctions Mark Many Geologic Boundaries

Five sharp rises (marked by red dots) above the background extinction rate have occurred throughout the Phanerozoic. The most sweeping of these events, the end-Permian extinction, was associated with dramatic drops in sea level (see Figure 25.4), global temperature, and atmospheric oxygen level (see Figure 25.8).

25.3 Plate Tectonics and Continental Drift (A)

The heat of Earth's core generates convection currents in the viscous mantle material of the asthenosphere. These currents push the continental plates, along with the land masses they carry, together or apart. Where plates collide, one may slide under the other, creating mountain ranges and often volcanoes. (B) The Cascade Range of the Pacific Northwest of North America is an example of a mountain chain produced by subduction of an oceanic plate under a continental plate.

Life10e.com/mc25.1

The continents have not always been where they are today

The globes and maps that adorn our walls, shelves, and books give an impression of a static Earth. It would be easy for us to assume that the continents have always been where they are. But we would be wrong. The idea that Earth's land masses have changed their positions over the millennia, and that they continue to do so, was put forth in 1912 by the German meteorologist and geophysicist Alfred Wegener. His idea, known as **continental drift**, was initially met with skepticism and resistance. By the 1960s, however, physical evidence and increased understanding of **plate tectonics**—the geophysics of the movement of major land masses—had convinced virtually all geologists of the reality of Wegener's vision. Plate tectonics provided the geological mechanism that explained Wegener's hypothesis of continental drift.

Earth's crust consists of several solid plates, which collectively make up the solid **lithosphere** ("stone sphere"). Thick continental and thinner oceanic lithospheric plates overlie a viscous, malleable layer of Earth's mantle, known as the **asthenosphere** ("weak sphere"). Heat produced by radioactive decay deep in Earth's core sets up large-scale convection currents in the mantle. New crust is formed as mantle material rises between diverging plates, pushing them apart.

Where oceanic plates and continental plates converge, the thinner oceanic plate is forced underneath the thicker continental plate, a process known as **subduction**. Subduction results in volcanism and mountain building on the continental boundary (Figure 25.3A). For example, in the Pacific Northwest of North America, a series of volcanoes formed the Cascade mountain range as the Juan de Fuca oceanic plate has been subducted beneath a portion of the continental North American Plate (Figure 25.3B). When two oceanic plates collide, one is also subducted below the other, producing a deep oceanic trench and associated volcanic activity. The deepest part of the world's oceans—the Mariana Trench in the western Pacific—formed where two oceanic plates collided. Volcanic activity associated with the subduction at the Mariana Trench produced the nearby Mariana Islands.

When two thick continental plates collide, neither plate is subducted. Instead, the plates push up against one another, forming high mountain chains. The highest mountain chain in the world, the Himalayas, was formed this way when the

(B)

Indian Plate collided with the Eurasian Plate. When continental plates diverge, new crust forms in the intervening spaces, resulting in deep clefts called rift valleys in which large freshwater lakes typically form. The Great Rift Valley lakes of eastern Africa, including Lake Malawi (discussed at the opening of Chapter 23), were formed in this way. Two plates can also slide past one another, forming a transform fault boundary (such as the San Andreas Fault that produces violent seismic activity in parts of California).

Many physical conditions on Earth have oscillated in response to plate tectonic processes. We now know that the movement of the plates has sometimes brought continents together and at other times has pushed them apart, as seen in the maps across the top of Figure 25.14. The positions and sizes of the continents influence oceanic circulation patterns, global climates, and sea levels. Sea level is influenced directly by plate tectonic processes (which can influence the depth of ocean basins) and indirectly by oceanic circulation patterns, which affect patterns of glaciation. As climates cool, glaciers form and tie up water over land masses; as climates warm, glaciers melt and release water.

Movement of the Continents

Life10e.com/at25.1

25.4 Sea Levels Have Changed Repeatedly Rapid drops in sea level are associated with periods of globally cooler temperatures and increased glaciation. Most mass extinctions of marine organisms have coincided with low sea levels.

Earth's climate has shifted between hot and cold conditions

Through much of its history, Earth's climate was considerably warmer than it is today, and temperatures decreased more gradually toward the poles. At other times, Earth was colder than it is today. Rapid drops in sea level near the ends of the Ordovician, Devonian, Permian, Triassic, and Cretaceous periods, and most recently in the Quaternary period, resulted mainly from increased global glaciation (**Figure 25.4**). Many of these drops in sea level were accompanied by mass extinctions—particularly of marine organisms, which could not survive the disappearance of the shallow seas that covered vast areas of the continental shelves.

Earth's cold periods were separated by long periods of milder climates. Because we are living in one of the colder periods, it is difficult for us to imagine the mild climates that were found at high latitudes during much of the history of life. The Quaternary period has been marked by a series of glacial advances, interspersed with warmer interglacial intervals during which the glaciers retreated.

"Weather" refers to the daily events at a given location, such as individual storms and the high and low temperatures on a given day. "Climate" refers to long-term average expectations over the various seasons at a given location. Weather often changes rapidly; climates typically change slowly. However, major climate shifts have taken place over periods as short as 5,000 to 10,000 years, primarily as a result of changes in Earth's orbit around the sun. A few climate shifts have been even more rapid: during one Quaternary interglacial period, the ice-locked Antarctic Ocean became nearly ice-free in less than 100 years. Some climate changes have been so rapid that the extinctions caused by them appear to be nearly instantaneous in the fossil record. Such rapid changes are usually caused by sudden shifts in ocean currents.

We are currently living in a time of rapid climate change thought to be caused by a buildup of atmospheric CO_2 , primarily from the burning of fossil fuels by human populations. We are reversing the energy transformations that occurred with the massive burial and decomposition of organic material that occurred (especially) in the Carboniferous, Permian, and Triassic, which gave rise to the fossil fuels we are using today. But we are burning these fuels over a few hundred years, rather than the many millions of years over which those deposits accumulated. The current rate of increase in atmospheric CO_2 is unprecedented in Earth's history. A doubling of the atmospheric CO_2 concentration—which may happen during the current century—is expected to increase the average temperature of Earth, change rainfall patterns, melt glaciers and ice caps, and raise sea levels.

Volcanoes have occasionally changed the history of life

Most volcanic eruptions produce only local or short-lived effects, but a few large volcanic eruptions have had major consequences for life. When Krakatau (a volcanic island in the Sunda Strait off Indonesia) erupted in 1883, it ejected more than 25 cubic kilometers of ash and rock as well as large quantities of sulfur dioxide gas (SO_2). The SO_2 was ejected into the stratosphere and carried by high-altitude winds around the planet. Its presence led to high concentrations of sulfurous acid (H_2SO_3) in high-altitude clouds, creating a "parasol effect" that reduced the amount of sunlight reaching Earth's surface. Global temperatures dropped by 1.2°C in the year following the eruption, and global weather patterns showed strong effects for another 5 years. More recently, the eruption of Mount Pinatubo in the Philippines in 1991 (**Figure 25.5**) temporarily reduced global temperatures by about 0.5°C .

Although these individual volcanoes had only relatively short-term effects on global temperatures, they suggest that the simultaneous eruption of many volcanoes could have a much stronger effect on Earth's climate. What would cause many volcanoes to erupt at the same time? The collision of

25.5 Volcanic Eruptions Can Cool Global Temperatures When Mount Pinatubo erupted in 1991, it increased the concentrations of sulfurous acid in high-altitude clouds, which temporarily lowered global temperatures by about 0.5°C.

continents during the Permian period, about 275 million years ago (mya), formed a single, gigantic land mass and caused a multitude of massive volcanic eruptions. Emissions from these eruptions blocked considerable sunlight, contributing to the advance of glaciers and a consequent drop in sea level (see Figure 25.4). Thus volcanic eruptions were probably at least part of the explanation for the greatest mass extinction in Earth's history.

Extraterrestrial events have triggered changes on Earth

At least 30 meteorites of sizes between tennis balls and soccer balls strike Earth each year. Collisions with larger meteorites or comets are rare, but such collisions have probably been responsible for several mass extinctions. Several types of evidence tell us about these collisions. Their craters, and the dramatically disfigured rocks that result from their impact, are found in many places. Geologists have discovered compounds in these rocks that contain helium and argon with isotope ratios characteristic of meteorites, which are very different from the ratios found elsewhere on Earth.

A meteorite caused or contributed to a mass extinction at the end of the Cretaceous period (about 65.5 mya). The first clue that a meteorite was responsible came from the abnormally high concentrations of the element iridium found in a thin layer separating rocks deposited during the Cretaceous from rocks deposited during the Tertiary (**Figure 25.6**). Iridium is abundant in some meteorites, but it is exceedingly rare on Earth's surface. When scientists discovered a circular crater 180 km in diameter buried beneath the northern coast of Mexico's Yucatán Peninsula, they constructed the following

25.6 Evidence of a Meteorite Impact The white layers of rock are Cretaceous in age; the layers at the upper left were deposited in the Tertiary. Between the two is a thin, dark layer of clay that contains large amounts of iridium, a metal common in some meteorites but rare on Earth. Its high concentration in this sediment layer, deposited about 65.5 million years ago, suggests the impact of a large meteorite at that time.

scenario. When the meteorite that formed that crater collided with Earth, it released energy equivalent to that of 100 million megatons of high explosives, creating great tsunamis. A massive plume of debris rose into the atmosphere, spread around Earth, and descended. The descending debris heated the atmosphere to several hundred degrees and ignited massive fires. It also blocked the sun, preventing plants from photosynthesizing. The settling debris formed the iridium-rich layer. About a billion tons of soot with a composition matching that of smoke from forest fires were also deposited. These events had devastating effects on biodiversity. Many fossil species (including non-avian dinosaurs) that are found in Cretaceous rocks are not found in the Tertiary rocks of the next stratum.

Oxygen concentrations in Earth's atmosphere have changed over time

As the continents have moved over Earth's surface, the world has experienced other physical changes, including large increases and decreases in atmospheric oxygen concentrations. The atmosphere of early Earth probably contained little or no free oxygen gas (O_2). The increase in atmospheric O_2 came in two big steps more than a billion years apart.

The first step occurred about 2.5 billion years ago (bya), when certain bacteria gained the ability to use water as the source of hydrogen ions for photosynthesis. By chemically splitting H_2O , these bacteria generated O_2 as a waste product. They also made electrons available for reducing CO_2 to form the carbohydrate end-products of photosynthesis (see Section 10.3). The O_2 they produced dissolved in water and reacted with dissolved iron. The reaction product then precipitated

25.7 Banded Iron Formations Indicate Early Photosynthesis The alternating red and dark layers in this 2.25-billion-year-old sedimentary rock formation from Lake Superior resulted from a reaction between dissolved iron and the atmospheric oxygen produced by Earth's first photosynthetic organisms. The chemical reaction produced nearly pure iron oxide, or hematite, which forms the gray, metallic layers in this sample. The red bands are jasper tinged with much smaller amounts of iron oxide.

as iron oxide, which accumulated in alternating layers of red and dark rock known as banded iron formations (**Figure 25.7**). These formations provide evidence for the earliest photosynthetic organisms. As photosynthetic organisms continued to release O_2 , oxygen gas began to accumulate in the atmosphere.

The second step occurred about a billion years later, when some of these photosynthetic bacteria became endosymbionts within eukaryotic cells, leading to the eventual evolution of chloroplasts in plants and other photosynthetic eukaryotes. This change resulted in continued accumulation of O_2 in Earth's atmosphere (**Figure 25.8**).

One group of photosynthetic bacteria, the cyanobacteria, formed rocklike structures called stromatolites, which are abundantly preserved in the fossil record. To this day, cyanobacteria still form stromatolites in a few very salty bodies of water (**Figure 25.9**). Cyanobacteria liberated enough O_2 to open the way for the evolution of oxidation reactions as the energy source for the synthesis of ATP.

Thus the evolution of life irrevocably changed the physical nature of Earth. Those physical changes, in turn, influenced the evolution of life. When it first appeared in the atmosphere, O_2 was toxic to most of the anaerobic prokaryotes that inhabited Earth at the time. Over millennia, however, prokaryotes that evolved the ability to tolerate and use O_2 not only survived but gained the advantage. Aerobic metabolism proceeds more rapidly, and harvests energy more efficiently, than anaerobic metabolism. Organisms with aerobic metabolism replaced anaerobes in most of Earth's environments.

An atmosphere rich in O_2 also made possible larger and more complex organisms. Small single-celled aquatic organisms can obtain enough oxygen by simple diffusion even when dissolved oxygen concentrations in the water are very low. Larger single-celled organisms, however, have lower surface area-to-volume ratios; to obtain enough oxygen by simple diffusion, they must live in an environment with a relatively high oxygen concentration. Bacteria can thrive at 1 percent of the current oxygen concentration; eukaryotic cells require levels that are at least 2–3 percent of the current concentration. For concentrations of dissolved oxygen in the oceans to have reached these levels, much higher atmospheric concentrations were needed.

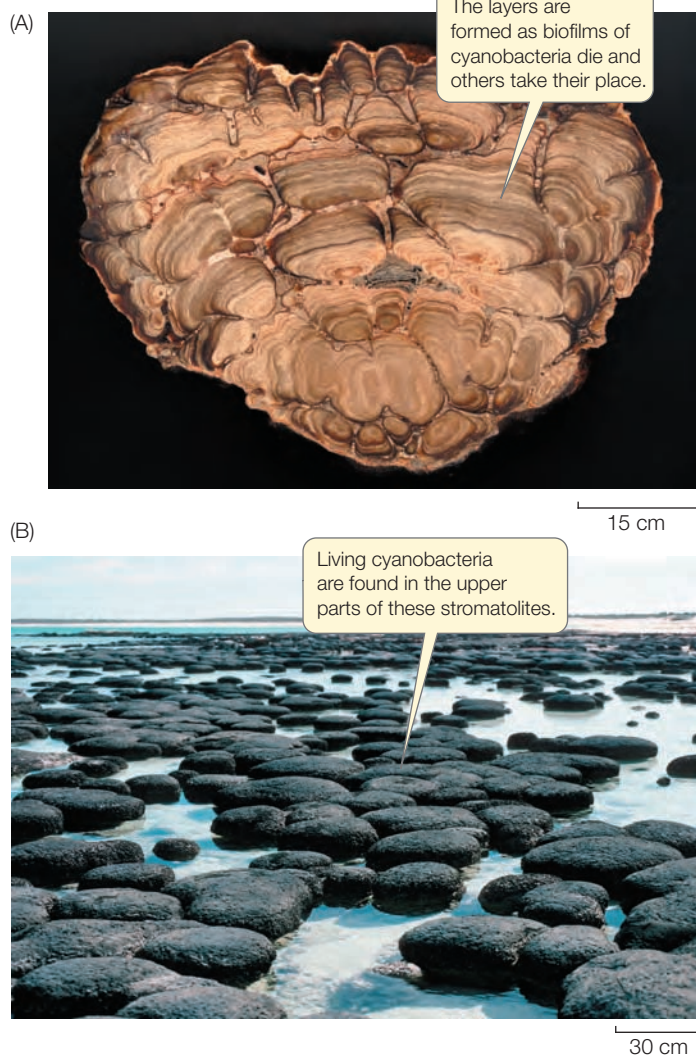

Probably because it took many millions of years for Earth to develop an oxygenated atmosphere, only single-celled prokaryotes lived on Earth for more than 2 billion years. About 1.5 bya, atmospheric O_2 concentrations became high enough for larger eukaryotic cells to flourish. Further increases in atmospheric O_2 concentrations in the late Precambrian enabled several groups of multicellular organisms to evolve (see **Figure 25.8**).

Oxygen concentrations increased again during the Carboniferous and Permian periods because of the evolution of large vascular plants. These plants lived in the expansive low-land swamps that existed at the time (see **Table 25.1**). Massive amounts of organic material were buried in these swamps as the plants died, leading to the formation of Earth's vast coal deposits. Because the buried organic material was not subject to oxidation as it decomposed, and because the living plants were producing large quantities of O_2 , atmospheric O_2 increased to

25.8 Atmospheric Oxygen Concentrations Have Changed over Time

Changes in atmospheric oxygen concentrations have strongly influenced, and have been influenced by, the evolution of life. (Note that the horizontal axis of the graph is on a logarithmic scale.)

25.9 Stromatolites (A) A vertical section through a fossil stromatolite. (B) These rocklike structures are living stromatolites that thrive in the very salty waters of Shark Bay in Western Australia.

concentrations that have not been reached again in Earth's history (see Figure 25.8). As mentioned at the opening of this chapter, these high concentrations of atmospheric O_2 allowed the evolution of giant flying insects and large amphibians that could not survive in today's atmosphere.

The drying of the lowland swamps at the end of the Permian reduced burial of organic matter as well as the production of O_2 , so atmospheric O_2 concentrations dropped rapidly. Over the past 200 million years, with the diversification of flowering plants, O_2 concentrations have again increased, but not to the levels that characterized the Carboniferous and Permian periods.

Biologists have conducted experiments that demonstrate the changing selection pressures that can accompany changes in atmospheric O_2 concentrations. When fruit flies (*Drosophila*) were raised in hyperoxic conditions (i.e., with artificially increased atmospheric concentrations of O_2), they evolved larger body sizes in just a few generations (Figure 25.10). The present atmospheric O_2 concentrations appear to constrain body size in these flying insects; increases in O_2 appear to relax those constraints. This experiment demonstrates that the stabilizing

INVESTIGATINGLIFE

25.10 Atmospheric Oxygen Concentrations and Body Size in Insects

C. Jaco Klok and his colleagues asked whether insects raised in hyperoxic conditions would evolve to be larger than their counterparts raised under today's atmospheric conditions. They raised strains of fruit flies (*Drosophila melanogaster*) under both conditions to test the effects of increased O_2 concentrations on the evolution of body size.^a

HYPOTHESIS In hyperoxic conditions, increased partial pressure of oxygen results in evolution of increased body size in flying insects.

Method

1. Separate a population of fruit flies into multiple lineages.
2. Raise half the lineages in current atmospheric (control) conditions; raise the other lineages in hyperoxic (experimental) conditions. Continue all lineages for seven generations.
3. Raise the F_8 individuals of all lineages under identical (current) atmospheric conditions.
4. Weigh 50 flies from each of the replicate lines and test for statistical differences in body weight.

Results

The average body mass of F_8 individuals of both sexes raised under hyperoxic conditions was significantly ($P < 0.001$) greater than that of individuals in the control lineages.

CONCLUSION Increased O_2 concentrations led to evolution of larger body size in fruit flies, consistent with the trends seen among other flying insects in the fossil record.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

^aKlok, C. J. et al. 2009. *Journal of Evolutionary Biology* 22: 2496–2504.

selection on body size at present O_2 concentrations can quickly switch to directional selection when environmental conditions change (see Section 21.3).

RECAP 25.2

Physical conditions on Earth have changed dramatically over time. Changes in Earth's climate and sea levels have had major effects on biological evolution. Continental drift, volcanic eruptions, and large meteorite strikes have contributed to major climate changes during Earth's history, and many of these climate shifts have resulted in mass extinction events. Changes in atmospheric concentrations of O_2 have also influenced the evolution of life.

- How have plate tectonic processes, volcanic eruptions, and meteorite strikes resulted in mass extinction events?
See pp. 510–511 and Figure 25.4
- Describe how increases in atmospheric concentrations of O_2 affected the evolution of multicellular organisms.
See pp. 511–512 and Figure 25.8

Analyze the Data

In the data shown in Figure 25.10, the body mass of individuals in the experimental population of *Drosophila* increased, on average, about 2 percent per generation under hyperoxic conditions (although the rate of increase was not constant over the experiment). Here you will extrapolate from Harrison et al.'s study to determine whether the observed rate of increase in body mass per generation these researchers observed in *Drosophila* is sufficient to account for the giant dragonflies of the Permian period.

QUESTION 1

Assume that the average rate of increase in dragonfly size during the Permian was much slower than the rate observed in the experiment in Figure 25.10. We'll assume that the actual rate of increase for dragonflies was just 0.01 percent per generation, rather than the 2 percent observed over a few generations for *Drosophila*. We'll assume further that dragonflies complete only one generation per year (as opposed to 40 or more generations for *Drosophila*). Starting with an average body mass of 1 gram, calculate the projected increase in dragonfly body mass over 50,000 years.*

QUESTION 2

What percent of the Permian period does 50,000 years represent? Use Table 25.1 for your calculation.

QUESTION 3

Given your calculations, do you think that increased O₂ concentrations during the Permian were sufficient to account for the evolution of giant dragonflies? Why or why not?

*This calculation is similar to computing compound interest for a savings account. Use the formula $W = S(1 + R)^N$ where W = the final mass, S = the starting mass, R = the rate of increase per generation (0.0001 in this case), and N = the number of generations.)

Go to **BioPortal** for all **WORKING WITH DATA** exercises

The many dramatic physical events in Earth's history have influenced the nature and timing of evolutionary changes among Earth's living organisms. We now will look more closely at some of the major events that characterize the history of life on Earth.

25.3

What Are the Major Events in Life's History?

How do we know about the effects of the physical changes described in the previous section on the evolution of life? To reconstruct life's history, scientists rely heavily on the fossil record. As we have seen, geologists divided Earth's history into eons, eras, and periods based on distinct fossil assemblages (see Table 25.1). Biologists refer to the assemblage of all organisms of all kinds living at a particular time or place as a **biota**. All of the plants living at a particular time or place are its **flora**; all of the animals are its **fauna**.

About 300,000 species of fossil organisms have been described and named, and the number steadily grows. The number of named species, however, is only a tiny fraction of the species that have ever lived. We do not know how many species lived in the past, but we have ways of making reasonable estimates. Of the present-day biota, about 1.8 million species have been named. The actual number of living species is estimated to be in the tens of millions, and possibly much higher, because many species have not yet been discovered and

described by biologists. So the number of described fossil species is only about 3 percent of the estimated minimum number of living species. Life has existed on Earth for about 3.8 billion years. Many species last only a few million years before undergoing speciation or going extinct; therefore Earth's biota must have turned over many times during geological history. So the total number of species that have lived over evolutionary time must vastly exceed the number living today. Why have only about 300,000 of these tens of millions of species been described from fossils to date?

Several processes contribute to the paucity of fossils

Only a tiny fraction of organisms ever become fossils, and only a tiny fraction of fossils are ever discovered by paleontologists. Most organisms live and die in oxygen-rich environments, in which they quickly decompose. Organisms are not likely to become fossils unless they are transported by wind or water to sites that lack oxygen, where decomposition proceeds slowly or not at all. Furthermore, geological processes transform many rocks, destroying the fossils they contain, and many fossil-bearing rocks are deeply buried and inaccessible. Paleontologists have studied only a tiny fraction of the sites that contain fossils, although they find and describe many new ones every year.

The fossil record is most complete for marine animals that had hard skeletons (which resist decomposition). Among the nine major animal groups with hard-shelled members, approximately 200,000 species have been described from

25.11 Insect Fossils Chunks of amber—fossilized tree resin—often contain insects such as this fly. Insects were preserved when they became trapped in the sticky resin.

fossils—roughly twice the number of living marine species in these same groups. Paleontologists lean heavily on these groups in their interpretations of the evolution of life. Insects and spiders are also relatively well represented in the fossil record because they are numerically abundant and have hard exoskeletons (Figure 25.11). The fossil record, though incomplete, is good enough to document clearly the factual history of the evolution of life.

By combining evidence of physical changes during Earth's history with evidence from the fossil record, scientists have composed portraits of what Earth and its inhabitants may have

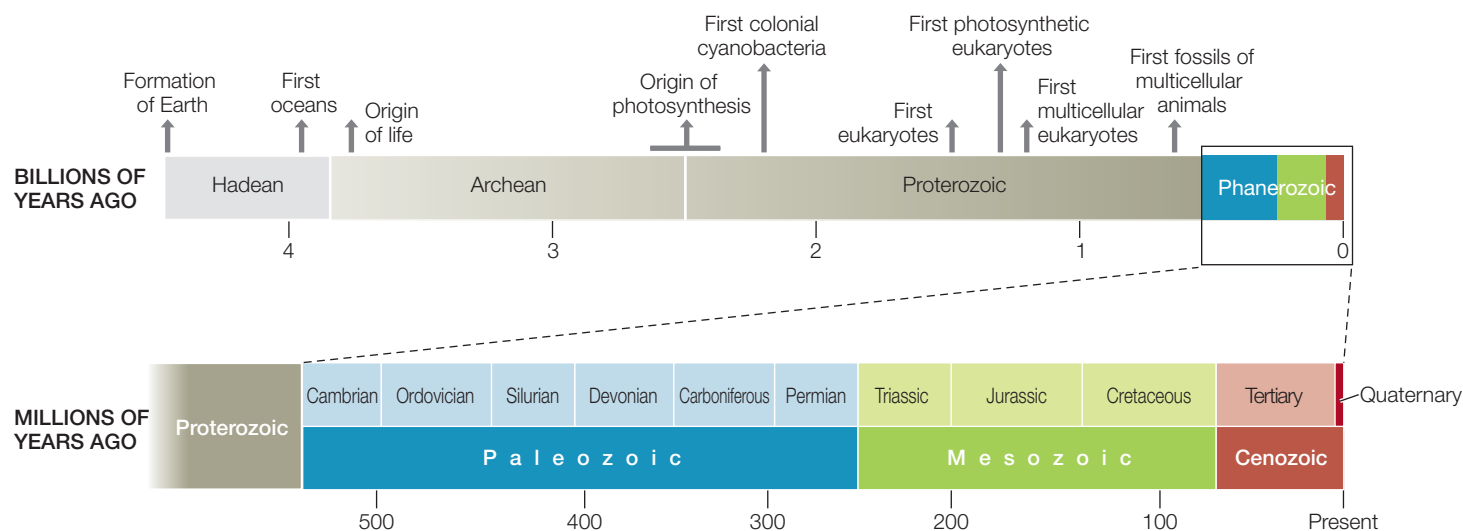

looked like at different times. We know in general where the continents were and how life changed over time, but many of the details are poorly known, especially for events in the more remote past.

Precambrian life was small and aquatic

Life first appeared on Earth about 3.8 bya (Figure 25.12). The fossil record of organisms that lived prior to the Phanerozoic is fragmentary, but it is good enough to establish that the total number of species and individuals increased dramatically in the late Precambrian.

For most of its history, life was confined to the oceans, and all organisms were small. For more than 3 billion years, all organisms lived in shallow seas. These seas slowly began to teem with microscopic prokaryotes. After the first eukaryotes appeared about 1.5 billion years ago, during the Proterozoic, unicellular eukaryotes and small multicellular animals fed on the microorganisms. Small floating organisms, known collectively as **plankton**, were strained from the water and eaten by slightly larger filter-feeding animals. Other animals ingested sediments on the seafloor and digested the remains of organisms within them. But it still took nearly a billion years before eukaryotes began to diversify rapidly into the many different morphological forms that we know today.

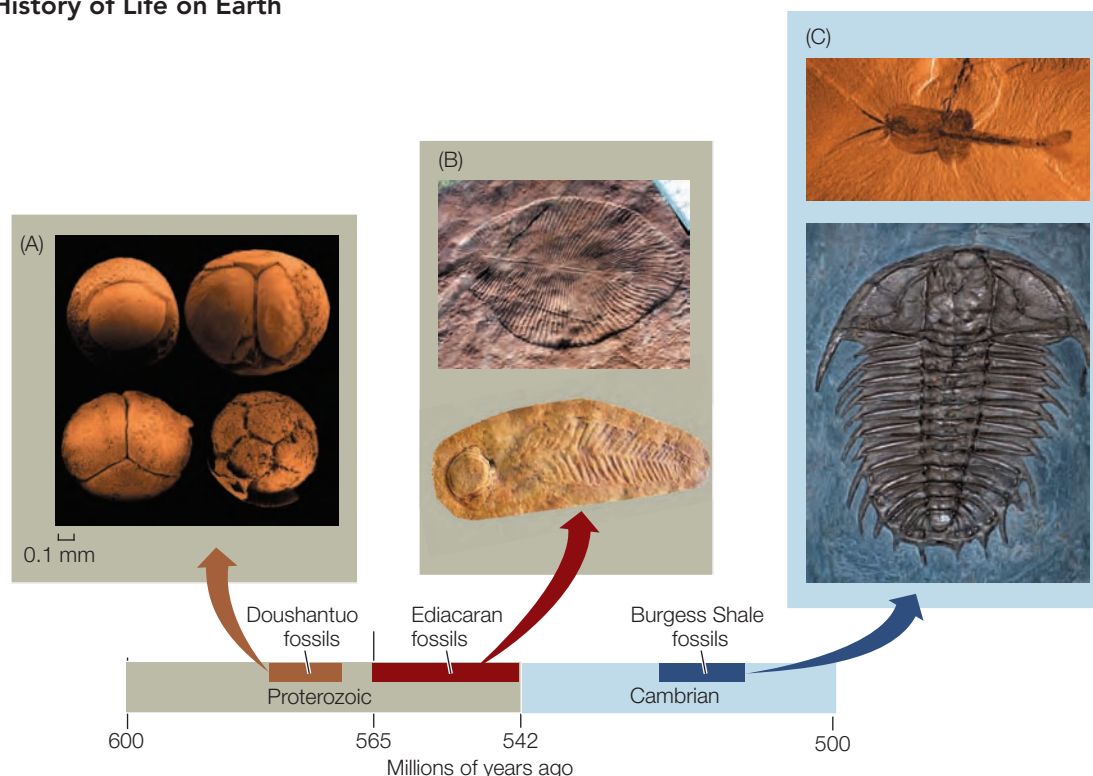

What limited the diversity of multicellular eukaryotes (in terms of their size and shape) for much of their early existence? It is likely that a combination of factors was responsible. We have already noted that O_2 levels increased throughout the Proterozoic, and it is likely that high atmospheric and dissolved O_2 concentrations were needed to support large multicellular organisms. In addition, geologic evidence points to a series of intensely cold periods during the late Proterozoic, which would have resulted in seas that were largely covered by

25.12 A Sense of Life's Time The top timeline shows the 4.5-billion-year history of Earth. Most of this history is accounted for by the Precambrian, a 3.4-billion-year time span that saw the origin of life and the evolution of cells, photosynthesis, and multicellularity. The final 600 million years are expanded in the bottom timeline and detailed in Figure 25.14.

25.13 Diversification of Multicellular Organisms: The “Cambrian Explosion”

Shortly after the end of Proterozoic glaciations (about 580 mya), several major radiations of multicellular organisms appear in the fossil record. (A) These microscopic fossils from the Doushantuo rock formation of China are the remains of tiny one-, two-, four-, and eight-celled stages of multicellular organisms. (B) Unusual soft-bodied marine invertebrates, unlike any animals alive at present, characterize the fossilized fauna preserved at Ediacara in southern Australia. (C) By the early Phanerozoic, fossilized faunas such as those preserved in Canada’s Burgess Shale include extinct representatives of some of the major animal groups alive today.

ice and continents that were covered by glaciers. The “snowball Earth” hypothesis suggests that cold conditions confined life to warm places such as hot springs, deep thermal vents, and perhaps a few equatorial oceans that avoided ice cover. The last of these Proterozoic glaciations ended about 580 million years ago, just before several major radiations of multicellular eukaryotes appear in the fossil record (**Figure 25.13**). Many of the multicellular organisms known from the late Proterozoic and early Phanerozoic were very different from any animals living today and may be members of groups that left no living descendants.

Life expanded rapidly during the Cambrian period

The Cambrian period (542–488 mya) marks the beginning of the Paleozoic, the first era of the Phanerozoic. The O_2 concentration in the Cambrian atmosphere was approaching the current level, and the glaciations of the late Proterozoic had ended nearly 40 million years earlier. Earth’s land masses had come together to form several large continents. A rapid diversification of life took place that is called the **Cambrian explosion**. This name is somewhat misleading, as the series of radiations it refers to actually began before the start of the Cambrian and continued for about 60 million years into the early Cambrian (see **Figure 25.13**). Nonetheless, 60 million years represents a relatively short amount of time, especially considering that the first eukaryotes had appeared about a billion (= 1,000 million) years earlier. Many of the major animal groups represented by species alive today first appeared during these evolutionary radiations. **Figure 25.14** provides an overview of the numerous continental and biotic innovations that have characterized the Phanerozoic.

For the most part, fossils tell us only about the hard parts of organisms, but in three known Cambrian fossil beds—the

Burgess Shale in British Columbia, Sirius Passet in northern Greenland, and the Chengjiang site in southern China—the soft parts of many animals were preserved. Crustacean arthropods (crabs, shrimps, and their relatives) are the most diverse group in the Chinese fauna; some of them were large carnivores. Multicellular life was largely or completely aquatic during the Cambrian. If there was life on land at this time, it was probably restricted to microorganisms.

Many groups of organisms that arose during the Cambrian later diversified

Geologists divide the remainder of the Paleozoic era into the Ordovician, Silurian, Devonian, Carboniferous, and Permian periods. Each period is characterized by the diversification of specific groups of organisms. Mass extinctions marked the ends of the Ordovician, Devonian, and Permian.

THE ORDOVICIAN (488–444 MYA) During the Ordovician period, the continents, which were located primarily in the Southern Hemisphere, still lacked multicellular life. Evolutionary radiation of marine organisms was spectacular during the early Ordovician, especially among animals, such as brachiopods and mollusks, that lived on the seafloor and filtered small prey

25.14 A Brief History of Multicellular Life on Earth The geologically rapid “explosion” of life shortly before and during the Cambrian saw the rise of many major animal groups that have representatives surviving today. The following three pages depict life’s history through the Phanerozoic. The movements of the major continents during the past half-billion years are shown in the maps of Earth, and associated biotas for each time period are depicted. The artists’ reconstructions are based on fossils such as those shown in the photographs.

Cambrian

Marrella splendens

Ottoia sp.

Anomalocaris canadensis (claw only)

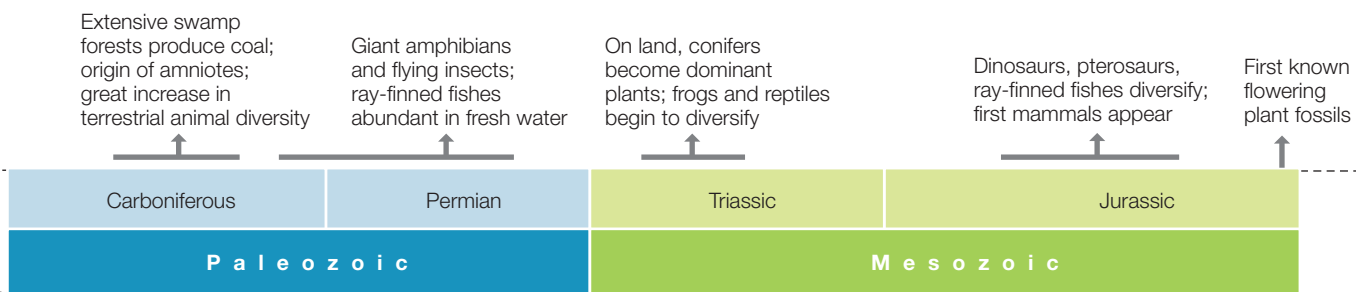

Devonian

Archaeopteris

Eusthenopteron foordi

300

200

Extinction of 96% of Earth's species; oxygen levels drop rapidly

Permian

Megatypus schucherti (wing)

Walchia piniformis

Triassic

Phleboteris smithii

Plateosaurus sp.

Cretaceous

Chasmosaurus belli

Sapindopsis belviderensis (leaves)

Tertiary

Hyracotherium leporinum

Plesiadapis fordinatus (jaw)

25.15 Evidence of Insect Diversification The margins of this fossil fern leaf from the Carboniferous have been chewed by insects.

from the water. At the end of the Ordovician, as massive glaciers formed over the southern continents, sea levels dropped about 50 meters, and ocean temperatures dropped. About 75 percent of all animal species became extinct, probably because of these environmental changes.

THE SILURIAN (444–416 MYA) During the Silurian period, the continents began to cluster together. Marine life rebounded from the mass extinction at the end of the Ordovician. Animals able to swim in open water and feed above the ocean floor appeared for the first time. Jawless fishes diversified, and the first fishes with supporting rays in their fins appeared. The tropical sea was uninterrupted by land barriers, and most marine organisms were widely distributed. On land, the first vascular plants evolved late in the Silurian (about 420 mya). The first terrestrial arthropods—scorpions and millipedes—evolved at about the same time.

THE DEVONIAN (416–359 MYA) Rates of evolutionary change accelerated in many groups of organisms during the Devonian period. The major land masses continued to move slowly toward each other. In the oceans there were great evolutionary radiations of corals and of shelled, squidlike cephalopod mollusks. Fishes diversified as jawed forms replaced jawless ones and as bony armor gave way to the less rigid scales of modern fishes.

Terrestrial communities changed dramatically during the Devonian. Club mosses, horsetails, and ferns became common; some attained the size of large trees. Their roots accelerated the weathering of rocks, resulting in the development of the first forest soils. The first plants to produce seeds appeared in the Devonian. The earliest fossil centipedes, spiders, mites, and insects date to this period, as do the earliest terrestrial vertebrates.

A mass extinction of about 75 percent of all marine species marked the end of the Devonian. Paleontologists are uncertain about its cause, but two large meteorites that collided with Earth at about that time (one in present-day Nevada, the

other in Western Australia) may have been responsible, or at least a contributing factor. The continued coalescence of the continents, with the corresponding reduction in the area of continental shelves, may have also contributed to this mass extinction.

THE CARBONIFEROUS (359–299 MYA) Large glaciers formed over high-latitude portions of the southern land masses during the Carboniferous period, but extensive swamp forests grew on the tropical continents. These forests were dominated by giant tree ferns and horsetails with small leaves. Their fossilized remains formed the coal we now mine for energy. In the seas, crinoids (sea lilies and feather stars) reached their greatest diversity, forming “meadows” on the seafloor.

The diversity of terrestrial animals increased greatly during the Carboniferous. Snails, scorpions, centipedes, and insects were abundant and diverse. Insects evolved wings, becoming the first animals to fly. Flight gave herbivorous insects easy access to tall plants; plant fossils from this period show evidence of chewing by insects (**Figure 25.15**). The terrestrial vertebrates split into two lineages. The amphibians became larger and better adapted to terrestrial existence, while the sister lineage led to the amniotes: vertebrates with well-protected eggs that can be laid in dry places.

THE PERMIAN (299–251 MYA) During the Permian period, the continents coalesced into a single supercontinent called **Pangaea**. Permian rocks contain representatives of many of the major groups of insects we know today. By the end of the period the amniotes had split into two lineages: the reptiles, and a second lineage that would lead to the mammals. Ray-finned fishes became common in the fresh waters of Pangaea.

Toward the end of the Permian, conditions for life deteriorated. Massive volcanic eruptions resulted in outpourings of lava that covered large areas of Earth. The ash and gases produced by the volcanoes blocked sunlight and cooled the climate. The death and decay of the massive Permian forests rapidly used up atmospheric oxygen, and the loss of

photosynthetic organisms meant that relatively little new atmospheric oxygen was produced. In addition, much of Pangaea was located close to the South Pole by the end of the Permian. All of these factors combined to produce the most extensive continental glaciers since the “snowball Earth” times of the late Proterozoic. Atmospheric oxygen concentrations gradually dropped from about 30 percent to 15 percent. At such low concentrations, most animals would have been unable to survive at elevations above 500 meters; thus about half of the land area would have been uninhabitable at the end of the Permian. The combination of these changes resulted in the most drastic mass extinction in Earth’s history. Scientists estimate that about 96 percent of all multicellular species became extinct at the end of the Permian.

Geographic differentiation increased during the Mesozoic era

The few organisms that survived the Permian mass extinction found themselves in a relatively empty world at the start of the Mesozoic era (251 mya). As Pangaea slowly began to break apart, the biotas of the newly separated continents began to diverge. The oceans rose and once again flooded the continental shelves, forming huge, shallow inland seas. Atmospheric oxygen concentrations gradually rose. Life once again proliferated and diversified, but different groups of organisms came to the fore. The three groups of phytoplankton (photosynthetic floating organisms) that dominate today’s oceans—dinoflagellates, coccolithophores, and diatoms—became ecologically important at this time, and their remains are the primary origin of the world’s oil deposits. Seed-bearing plants replaced the trees that had ruled the Permian forests.

The Mesozoic era is divided into three periods: the Triassic, Jurassic, and Cretaceous. The Triassic and Cretaceous were terminated by mass extinctions, probably caused by meteorite impacts.

THE TRIASSIC (251–201.6 MYA) Pangaea began to break apart during the Triassic period. Many invertebrate groups diversified, and many burrowing animals evolved from groups living on the surfaces of seafloor sediments. On land, conifers and seed ferns were the dominant trees. The first frogs and turtles appeared. A great radiation of reptiles began, which eventually gave rise to crocodilians, dinosaurs, and birds. The end of the Triassic was marked by a mass extinction that eliminated about 65 percent of the species on Earth.

THE JURASSIC (201.6–145.5 MYA) During the Jurassic period, Pangaea became completely divided into two large continents: **Laurasia**, which drifted northward, and **Gondwana** in the south. Ray-finned fishes rapidly diversified in the oceans. The first lizards appeared, and flying reptiles (pterosaurs) evolved. Most of the large terrestrial predators and herbivores of the period were dinosaurs. Several groups of mammals made their first appearance, and the earliest known fossils of flowering plants are from late in this period.

THE CRETACEOUS (145.5–65.5 MYA) By the early Cretaceous period, Laurasia and Gondwana had begun to break apart into the continents we know today. A continuous sea encircled the tropics. Sea levels were high, and Earth was warm and humid. Life proliferated both on land and in the oceans. Marine invertebrates increased in diversity. On land, the reptile radiation continued as dinosaurs diversified further and the first snakes appeared. Early in the Cretaceous, flowering plants began the radiation that led to their current dominance of the land. By the end of the period, many groups of mammals had appeared.

As described in Section 25.2, another meteorite-caused mass extinction took place at the end of the Cretaceous. In the seas, many planktonic organisms and bottom-dwelling invertebrates became extinct. On land, almost all animals larger than about 25 kg in body weight became extinct. Many species of insects died out, perhaps because the growth of their food plants was greatly reduced following the impact. Some species in northern North America and Eurasia survived in areas that were not subjected to the devastating fires that engulfed most low-latitude regions.

Modern biotas evolved during the Cenozoic era

By the early Cenozoic era (65.5 mya), the positions of the continents resembled those of today, but Australia was still attached to Antarctica, and the Atlantic Ocean was much narrower. The Cenozoic was characterized by an extensive radiation of mammals, but other groups were also undergoing important changes.

Flowering plants diversified extensively and came to dominate world forests except in the coolest regions, where the forests were composed primarily of gymnosperms. Mutations of two genes in one group of plants (the legumes) allowed these plants to use atmospheric nitrogen directly by forming symbioses with a few species of nitrogen-fixing bacteria. The evolution of this symbiosis, which can be thought of as the first “green revolution,” dramatically increased the amount of nitrogen available for terrestrial plant growth; this symbiosis remains fundamental to the ecological base of life as we know it today.

The Cenozoic era is divided into the Tertiary and the Quaternary periods, which are commonly subdivided into **epochs** (Table 25.2).

TABLE 25.2 Subdivisions of the Cenozoic Era		
Period	Epoch	Onset (mya)
Quaternary	Holocene (Recent)	0.01 (~10,000 years ago)
	Pleistocene	2.6
Tertiary	Pliocene	5.3
	Miocene	23
	Oligocene	34
	Eocene	55.8
	Paleocene	65

THE TERTIARY (65.5–2.6 MYA) During the Tertiary period, Australia began its northward drift. By 20 mya it had nearly reached its current position. The early Tertiary was a hot and humid time, and the ranges of many plants shifted into higher latitudes. The tropics were probably too hot to support rainforest vegetation and instead were clothed in low-lying vegetation. In the middle of the Tertiary, however, Earth's climate became considerably cooler and drier. Many lineages of flowering plants evolved herbaceous (nonwoody) forms, and grasslands spread over much of Earth.

By the start of the Cenozoic era, invertebrate faunas had already come to resemble those of today. It is among the terrestrial vertebrates that evolutionary changes during the Tertiary were most rapid. Frogs, snakes, lizards, birds, and mammals all underwent extensive radiations during this period. Three waves of mammals dispersed from Asia to North America across one of the several land bridges that have intermittently connected the two continents during the past 55 million years. Rodents, marsupials, primates, and hoofed mammals appeared in North America for the first time.

THE QUATERNARY (2.6 MYA TO PRESENT) We are living in the Quaternary period. It is commonly subdivided into two epochs, the Pleistocene and the Holocene (also known as the Recent).

The Pleistocene was a time of drastic cooling and climatic fluctuations. During 4 major and about 20 minor “ice ages,” massive glaciers spread across the continents, and the ranges of animal and plant populations shifted toward the equator. The last of these glaciers retreated from temperate latitudes less than 15,000 years ago. Organisms are still adjusting to this change. Many high-latitude ecological communities have occupied their current locations for no more than a few thousand years.

It was during the Pleistocene epoch that divergence within one group of mammals, the primates, resulted in the evolution of the hominoid lineage. Subsequent hominoid radiation eventually led to the species *Homo sapiens*—modern humans. Many large bird and mammal species became extinct in Australia and in the Americas when *H. sapiens* arrived on those continents

about 45,000 and 15,000 years ago, respectively. Many paleontologists believe these extinctions were the result of hunting and other influences of *Homo sapiens*.

The tree of life is used to reconstruct evolutionary events

The fossil record reveals broad patterns in life's evolution. To reconstruct major events in the history of life, biologists also rely on the phylogenetic information in the tree of life. We can use phylogeny, in combination with the fossil record, to reconstruct the timing of such major events as the acquisition of mitochondria in the ancestral eukaryotic cell, the several independent origins of multicellularity, and the movement of life onto dry land. We can also follow major changes in the genomes of organisms, and we can even reconstruct many gene sequences of species that are long extinct, as described in Section 22.3.

Changes in Earth's physical environment have clearly influenced the diversity of organisms we see on the planet today. To study the evolution of that diversity, biologists examine the evolutionary relationships among species. Deciphering phylogenetic relationships is an important step in understanding how life has diversified on Earth. The next part of this book will explore the major groups of life and the different solutions these groups have evolved to meet major challenges such as reproduction, energy acquisition, dispersal, and escape from predation.

RECAP 25.3

Life evolved in the oceans about 3.8 billion years ago. It diversified as atmospheric oxygen approached its current level. Numerous climate changes and rearrangements of the continents, as well as meteorite impacts, contributed to five major mass extinctions.

- Why have so few of the multitudes of organisms that have existed over millennia become fossilized? **See pp. 514–515**
- What do we mean when we refer to the “Cambrian explosion”? **See p. 516**
- What are the major changes that have occurred in terrestrial biotic communities over the course of the Phanerozoic? **See pp. 516, 520–522 and Figure 25.14**

Can modern experiments test hypotheses about the evolutionary impact of ancient environmental changes?

ANSWER

Several experiments have been conducted to test the link between O₂ concentrations and evolution of body size in flying insects (one of these is discussed in Figure 25.10). Results of these experiments are consistent with the evolution of larger body size in flying insects in hyperoxic (high-oxygen) environments.

Experiments have also been conducted under hypoxic (low-oxygen) conditions, such as existed at the end of the Permian. Results of these experiments suggest that the evolution of

body size is constrained under hypoxic conditions, even under strong artificial selection for larger body size. These latter results are consistent with the extinction of many of the large flying insects at the end of the Permian, the result of rapidly decreasing O₂ concentrations. Giant flying insects simply could not have survived the lower O₂ concentrations that existed at that time. The mass extinction at the end of the Permian is the only known mass extinction that involved considerable loss of insect diversity.

CHAPTERSUMMARY 25

25.1 How Do Scientists Date Ancient Events?

- The relative ages of organisms can be determined by the **strata** of **sedimentary rocks** in which their fossils are found.
- Paleontologists use a variety of **radioisotopes** with different **half-lives** to date events at different times in the remote past. **Review Figure 25.1**
- Geologists divide the history of life into **eons**, **eras**, and **periods**. These divisions are based largely on major differences in the fossil assemblages found in successive layers of rocks. **Review Table 25.1**

25.2 How Have Earth's Continents and Climates Changed over Time?

- **Plate tectonic** processes result in **continental drift** as well as volcanism and mountain building. Changes in the positions and sizes of the continents affect oceanic circulation patterns, climate, and sea levels. **Review Figure 25.3, ANIMATED TUTORIAL 25.1**
- Major physical events on Earth, such as the collision of continents that formed the single gigantic land mass **Pangaea**, have affected Earth's surface, climate, and atmosphere. In addition, extraterrestrial events such as meteorite strikes have created sudden and dramatic climate shifts. Some dramatic changes in physical conditions on Earth have caused mass extinctions. **Review Figure 25.4**
- Oxygen-generating cyanobacteria released enough O_2 to open the door to oxidation reactions in metabolic pathways. Aerobic prokaryotes were able to harvest more energy than anaerobic organisms and began to predominate. Increases in atmospheric

O_2 levels also supported the evolution of large eukaryotic cells. **Review Figure 25.8**

25.3 What Are the Major Events in Life's History?

- Paleontologists use the fossil record and evidence of geological changes to determine what Earth and its **biota** may have looked like at different times. **Review Figure 25.12**
- During most of its history, life was confined to the oceans. Multicellular life diversified extensively during the **Cambrian explosion**. **Review Figure 25.13**
- The remaining periods of the Paleozoic era were each characterized by the diversification of specific groups of organisms. The Paleozoic ended with the most drastic mass extinction in Earth's history, at the end of the Permian. **Review Figure 25.14**
- During the Mesozoic era, distinct terrestrial biotas evolved on each continent. Dinosaurs diversified to become the dominant large predators and herbivores. The era ended with a mass extinction event caused by the collision of a giant meteorite with Earth.
- The Cenozoic era is divided into the Tertiary and the Quaternary periods, which in turn are subdivided into **epochs**. This era saw the emergence of the modern biota as mammals radiated extensively and the angiosperms (flowering plants) became dominant. **Review Table 25.2**

CHAPTERREVIEW

REMEMBERING

1. In undisturbed strata of sedimentary rock, the oldest rocks
 - a. lie at the top.
 - b. lie at the bottom.
 - c. are in the middle.
 - d. are distributed among the strata of younger rocks.
 - e. None of the above
2. The concentration of oxygen in Earth's atmosphere
 - a. has increased steadily over time.
 - b. has decreased steadily over time.
 - c. has been both higher and lower in the past than at present.
 - d. was lower during most of the Permian than at present.
 - e. was at its highest levels in the Cambrian.
3. Many of the coal beds we now mine for energy are largely the remains of
 - a. plants that grew in swamps during the Carboniferous period.
 - b. algae that grew in marshes during the Devonian period.
 - c. giant insects and amphibians of the Permian period.
 - d. plants that grew in the oceans during the Carboniferous period.
 - e. None of the above
4. The mass extinction at the end of the Ordovician period was probably caused by
 - a. the collision of Earth with a large meteorite.
 - b. massive volcanic eruptions.
 - c. massive glaciation on the southern continents and associated climate changes.
 - d. the coming together of the continents to form Pangaea.
 - e. changes in Earth's orbit.
5. The cause of the mass extinction at the end of the Mesozoic era probably was
 - a. continental drift.
 - b. the collision of Earth with a large meteorite.
 - c. changes in Earth's orbit.
 - d. massive glaciation.
 - e. changes in the salt concentration of the oceans.
6. Which of the following times was marked by the largest mass extinction of life in the history of Earth?
 - a. The end of the Cretaceous
 - b. The end of the Devonian
 - c. The end of the Permian
 - d. The end of the Triassic
 - e. The end of the Silurian

UNDERSTANDING & APPLYING

7. Scientists date ancient events using a variety of methods, but nobody was present to witness or record those events. Accepting those dates requires us to understand the accuracy and appropriateness of indirect measurement techniques. What other basic scientific concepts are also based on the results of indirect measurement techniques?
8. Why is it useful to be able to date past events absolutely as well as relatively?
9. What conditions may have favored the evolution of multicellular groups of organisms near the end of the Precambrian?

ANALYZING & EVALUATING

10. The experiment in Figure 25.10 showed that the body size of insects may evolve quickly following changes in atmospheric oxygen concentrations. What other experiments could you devise to test the effects of changing atmospheric oxygen concentrations?

Bacteria, Archaea,
and Viruses

CHAPTER OUTLINE

- 26.1** Where Do Prokaryotes Fit into the Tree of Life?
- 26.2** Why Are Prokaryotes So Diverse and Abundant?
- 26.3** How Do Prokaryotes Affect Their Environments?
- 26.4** How Do Viruses Relate to Life's Diversity and Ecology?

Bacteria Seen from Space A satellite image reveals vast expanses of bioluminescence in the Indian Ocean. Spreading over thousands of square kilometers, this glowing “milky sea” is produced by dense populations of *Vibrio* bacteria.

ONE NIGHT IN JANUARY of 1995, the British merchant vessel *Lima* was off the coast of Somalia, near the Horn of Africa. This area is infamous for bands of pirates, so the crew was keeping a watchful eye on the seas when they spotted an eerie, whitish glow on the horizon. It was directly in their path, and there was no way to avoid it. Was this strange sight the result of some strange trick of piracy?

Within 15 minutes of first sighting the glow, the *Lima* was surrounded by shining waters for as far as her crew could see. The ship's log recorded that “it appeared as though the ship was sailing over a field of snow or gliding over the clouds.” Fortunately for the crew, the glow had nothing to do with pirates.

For centuries, mariners in this part of the world had reported occasional “milky seas” in which the sea surface produced a strange glow at night, extending from horizon to horizon. Scientists up to that point had never been able to confirm the reality or the cause of such phenomena. It was well established, however, that many organisms emit light by bioluminescence, a complex, enzyme-catalyzed biochemical reaction that emits light but not heat.

What kind of organism could cause the vast expanse of bioluminescence observed by the *Lima*? Some marine organisms emit flashes of light when they are disturbed, but they could not have produced the sustained and uniform glow seen in milky seas. The only organisms known to produce the level of sustained bioluminescence consistent with milky seas are certain prokaryotes, such as bacteria of the genus *Vibrio*. Using information supplied by the *Lima*, biologists scanned satellite images of the Indian Ocean for the specific light wavelengths emitted by *Vibrio*. The satellite images clearly identified thousands of square kilometers of *Vibrio*-produced milky seas.

Vibrio's bioluminescence requires a critical concentration of a specific chemical signal produced by the bacteria, so at low densities, free-living *Vibrio* populations do not glow. But as a colony establishes itself on phytoplankton, the bacteria's population density increases and concentrations of the luminescence signal build up. Eventually bacterial density—and concentrations of the signal—become high enough for the huge colony to produce light at a rate of about 10^3 photons per second per *Vibrio* cell. Such chemical-induced action among bacterial cells is referred to as quorum sensing.

What adaptive advantage does bioluminescence provide to *Vibrio* bacteria?

See answer on p. 546.

26.1 Where Do Prokaryotes Fit into the Tree of Life?

You may think that you have little in common with a bacterium. But all multicellular eukaryotes—including you—share many attributes with bacteria and archaea, together called **prokaryotes**. For example, all organisms, whether eukaryotes or prokaryotes,

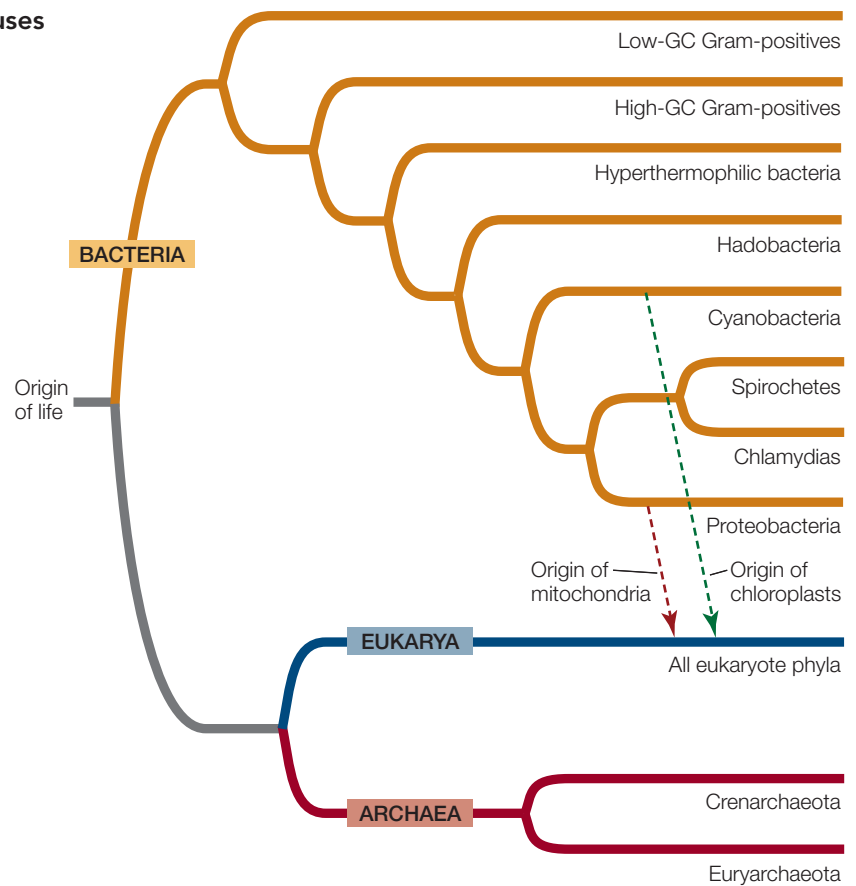

- have plasma membranes and ribosomes (see Chapters 5 and 6).
- have a common set of metabolic pathways (see Chapters 8 and 9).
- replicate DNA semiconservatively (see Chapter 13).
- use DNA as the genetic material to encode proteins, and use similar genetic codes to produce those proteins by transcription and translation (see Chapter 14).

These shared features support the conclusion that all living organisms share a common ancestor. If life had multiple origins, there would be little reason to expect all organisms to use overwhelmingly similar genetic codes or to share structures as unique as ribosomes. Furthermore, similarities in the DNA sequences of universal genes (such as those that encode the structural components of ribosomes) confirm the monophyly of life.

Despite these commonalities, major differences have also evolved across the diversity of life. Based on the differences in cell structure and biochemical functioning that they have observed, many biologists now recognize three domains (primary divisions) of life, two prokaryotic and one eukaryotic (**Figure 26.1**).

All prokaryotic organisms are unicellular, although they may form large, coordinated colonies or communities consisting of many individuals. The domain Eukarya, by contrast, encompasses both unicellular and multicellular life forms. As we saw in Chapter 5, prokaryotic cells differ from eukaryotic cells in some important ways:

- *Prokaryotic cells do not divide by mitosis.* Instead, after replicating their DNA, prokaryotic cells divide by their own method, binary fission (see Section 11.1).
- *The organization of the genetic material differs.* The DNA of the prokaryotic cell is not organized within a membrane-enclosed nucleus. DNA molecules in prokaryotes are often circular. Many (but not all) prokaryotes have only one main chromosome and are effectively haploid, although many have additional smaller DNA molecules, called plasmids (see Section 12.6).
- *Prokaryotes have none of the membrane-enclosed cytoplasmic organelles that are found in most eukaryotes.* However, the cytoplasm of a prokaryotic cell may contain a variety of infoldings of the plasma membrane and photosynthetic membrane systems that are not found in eukaryotes.

26.1 The Three Domains of the Living World This summary classification of the domains Bacteria and Archaea shows their relationships to each other and to Eukarya. The relationships among the many clades of bacteria, not all of which are listed here, are incompletely resolved at this time.

Go to Animated Tutorial 26.1
The Evolution of the Three Domains
Life10e.com/at26.1

Although the study and classification of eukaryotic organisms goes back centuries, much of our knowledge of the evolutionarily ancient prokaryotic domains is extremely recent. Not until the final quarter of the twentieth century did advances in molecular genetics and biochemistry enable the research that revealed the deep-seated distinctions between the domains Bacteria and Archaea.

The two prokaryotic domains differ in significant ways

A glance at **Table 26.1** will show you that there are major differences between the two prokaryotic domains (most of which cannot be seen even under an electron microscope). In some ways archaea are more like eukaryotes; in other ways they are more like bacteria. (Note that we use lowercase when referring to members of these domains and initial capitals when referring to the domains themselves.) The basic unit of an archaeon (the term for a single archaeal organism) or bacterium (a single bacterial organism) is the prokaryotic cell. Each single-celled prokaryote contains a full complement of genetic and protein-synthesizing systems, including DNA, RNA, and all

TABLE 26.1
The Three Domains of Life

Characteristic	Domain		
	Bacteria	Archaea	Eukarya
Membrane-enclosed nucleus	Absent	Absent	Present
Membrane-enclosed organelles	Few	Absent	Many
Peptidoglycan in cell wall	Present	Absent	Absent
Membrane lipids	Ester-linked	Ether-linked	Ester-linked
	Unbranched	Branched	Unbranched
Ribosomes ^a	70S	70S	80S
Initiator tRNA	Formylmethionine	Methionine	Methionine
Operons	Yes	Yes	Rare
Plasmids	Yes	Yes	Rare
Number of RNA polymerases ^b	One	One	Three
Ribosomes sensitive to chloramphenicol and streptomycin	Yes	No	No
Ribosomes sensitive to diphtheria toxin	No	Yes	Yes

^a70S ribosomes are smaller than 80S ribosomes.^bThe structure of archaeal RNA polymerase is similar to that of eukaryotic polymerases.

the enzymes needed to transcribe and translate genetic information into proteins. The prokaryotic cell also contains at least one system for generating the ATP it needs.

Genetic studies clearly indicate that all three domains of life had a single common ancestor. Across a large portion of their genome, eukaryotes share a more recent common ancestor with archaea than they do with bacteria (see Figure 26.1). However, the mitochondria of eukaryotes (as well as the chloroplasts of photosynthetic eukaryotes, such as plants) originated through endosymbiosis with bacteria (see Section 5.5). Some biologists prefer to view the origin of eukaryotes as a fusion of two equal partners (one ancestor that was related to modern archaea and another that was more closely related to modern bacteria). Others view the divergence of the early eukaryotes from the archaea as an event separate from and earlier than the later endosymbioses. In either case, some eukaryote genes are most closely related to those of archaea, whereas others are most closely related to those of bacteria. The tree of life therefore contains some merging of lineages as well as the predominant divergence of lineages.

The last common ancestor of the three domains probably lived about 3 billion years ago. It probably had DNA as its genetic material, as well as machinery for transcription and translation that produced RNAs and proteins, respectively. This ancestor almost certainly had a circular chromosome. Archaea, Bacteria, and Eukarya are all the products of billions of years of mutation, natural selection, and genetic drift, and they are all well adapted to present-day environments. The earliest prokaryote fossils, which date back at least 3.5 billion years, indicate that there was considerable diversity among the prokaryotes even during those earliest days of life.

The small size of prokaryotes has hindered our study of their evolutionary relationships

Until about 300 years ago, nobody had even *seen* an individual prokaryote; these organisms remained invisible to humans until the invention of the first simple microscope. Prokaryotes are so small, however, that even the best light microscopes don't reveal much about them. It took advanced microscopic equipment and modern molecular techniques to open up the microbial world. (Microscopic organisms—both prokaryotes and eukaryotes—are often collectively referred to as “microbes.”)

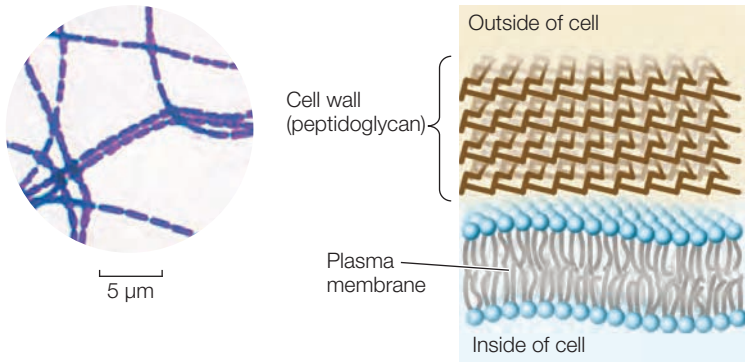

Before DNA sequencing became practical, taxonomists based prokaryote classification on observable phenotypic characters such as shape, color, motility, nutritional requirements, and sensitivity to antibiotics. One of the characters most widely used to classify prokaryotes is the structure of their cell walls.

The cell walls of almost all bacteria contain **peptidoglycan**, a cross-linked polymer of amino sugars that produces a firm, protective, meshlike structure around the cell. Peptidoglycan is a substance unique to bacteria; its absence from the cell walls of archaea is a key difference between the two prokaryotic domains. Peptidoglycan is also an excellent target for combating pathogenic (disease-causing) bacteria because it has no counterpart in eukaryotic cells. Antibiotics such as penicillin and ampicillin, as well as other agents that specifically interfere with the synthesis of peptidoglycan-containing cell walls, tend to have little, if any, effect on the cells of humans and other eukaryotes.

The **Gram stain** is a technique that can be used to separate most types of bacteria into two distinct groups. A smear of bacterial cells on a microscope slide is soaked in a violet dye and treated with iodine; it is then washed with alcohol and counterstained with a red dye called safranin. **Gram-positive bacteria** retain the violet dye and appear blue to purple (**Figure**

(A)

Gram-positive bacteria have a uniformly dense cell wall consisting primarily of peptidoglycan.

(B)

Gram-negative bacteria have a very thin peptidoglycan layer and an outer membrane, which together make up the cell envelope.

Go to Activity 26.1
Gram Stain and Bacteria
Life10e.com/ac26.1

26.2 The Gram Stain and the Bacterial Cell Wall When treated with Gram-staining reagents, the cell walls of bacteria react in one of two ways. (A) Gram-positive bacteria have a thick peptidoglycan cell wall that retains the violet dye and appears deep blue or purple. (B) Gram-negative bacteria have a thin peptidoglycan layer that does not retain the violet dye, but picks up the counterstain and appears pink to red.

26.2A). The alcohol washes the violet stain out of **Gram-negative bacteria**, which then pick up the safranin counterstain and appear pink to red (**Figure 26.2B**). For most bacteria, the effect of the Gram stain is determined by the chemical structure of the cell wall:

- A *Gram-negative cell wall* usually has a thin peptidoglycan layer, which is surrounded by a second, outer membrane quite distinct in chemical makeup from the plasma membrane. Together the cell wall and the outer membrane are called the **cell envelope**. Between the plasma membrane and the outer membrane is a **periplasmic space**. This space contains proteins that are important in digesting some materials, transporting others, and detecting chemical gradients in the environment.
- A *Gram-positive cell wall* usually has about five times as much peptidoglycan as a Gram-negative cell wall. Its thick

peptidoglycan layer is a meshwork that may serve some of the same purposes as the periplasmic space of the Gram-negative cell envelope.

Shape is another phenotypic characteristic that is useful for the basic identification of bacteria. The three most common shapes are spheres, rods, and spiral forms (**Figure 26.3**). Many bacterial names are based on these shapes. A spherical bacterium is called a **coccus** (plural *cocci*). Cocci may live singly or may associate in two- or three-dimensional arrays such as chains, plates, blocks, or clusters of cells. A rod-shaped bacterium is called a **bacillus** (plural *bacilli*). A spiral bacterium (shaped like a corkscrew) is called a **spirillum** (plural *spirilla*). Bacilli and spirilla may be single, form chains, or gather in regular clusters. Among the other bacterial shapes are long filaments and branched filaments.

Less is known about the shapes of archaea because many of these organisms have never been seen. Many archaea are known only from samples of DNA from the environment. However, the species whose morphologies are known include cocci, bacilli, and even triangular and square species; the last grow on surfaces, arranged like sheets of postage stamps.

The nucleotide sequences of prokaryotes reveal their evolutionary relationships

Analyses of the nucleotide sequences of ribosomal RNA (rRNA) genes provided the first comprehensive evidence of evolutionary relationships among prokaryotes. Comparisons of rRNA genes from a great many organisms have revealed probable phylogenetic relationships throughout the tree of life. Databases such as GenBank contain rRNA gene sequences from hundreds of thousands of species—more than any other type of gene sequence.

For several reasons, rRNA is particularly useful for phylogenetic studies of living organisms:

- rRNA was present in the common ancestor of all life and is therefore evolutionarily ancient.
- No free-living (i.e., not parasitic) organism lacks rRNA, so rRNA genes can be compared across the tree of life.
- rRNA plays a critical role in translation in all organisms, so lateral transfer of rRNA genes among distantly related species is unlikely.
- rRNA has evolved slowly enough that gene sequences from even distantly related species can be aligned and analyzed.

Although studies of rRNA genes reveal much about the evolutionary relationships of prokaryotes, they don't always reveal the entire evolutionary history of these organisms. In some groups of prokaryotes, analyses of multiple gene sequences

26.3 Bacterial Cell Shapes This composite, colorized micrograph shows the three most common bacterial shapes. Spherical cells are called cocci; those pictured are a species of *Enterococcus* from the mammalian gut. Rod-shaped cells are called bacilli; these *Escherichia coli* also reside in the gut. The helix-shaped spirilla are *Leptospira interrogans*, a human pathogen.

have suggested several different phylogenetic patterns. How could such differences among gene sequences arise in the same organisms? Studies of whole prokaryotic genomes have revealed that even distantly related prokaryotes sometimes exchange genetic material.

Lateral gene transfer can lead to discordant gene trees

As noted earlier, prokaryotes reproduce by binary fission. If we could follow these divisions back through evolutionary time, we would be tracing the complete tree of life for bacteria and archaea. This underlying tree of evolutionary relationships

(represented in highly abbreviated form in Appendix A) is called the organismal (or species) tree. Because binary fission is an asexual process that replicates whole genomes, we would expect phylogenetic trees constructed from most gene sequences (see Chapter 22) to reflect these same relationships.

There are other processes, however—including transformation, conjugation, and transduction—that allow the exchange of genetic information between some prokaryotes without reproduction. Thus prokaryotes can exchange and recombine their DNA with that of other individuals (this is sex in the genetic sense of the word), but this genetic exchange is not directly linked to reproduction, as it is in most eukaryotes.

From early in evolution to the present day, some genes have been moving “sideways” from one prokaryote species to another, a phenomenon known as **lateral gene transfer**. Lateral gene transfers are well documented among closely related species, and some have been documented even across the domains of life. Consider, for example, the genome of *Thermotoga maritima*, a bacterium that can survive extremely high temperatures. By comparing the 1,869 gene sequences of *T. maritima* with sequences encoding the same proteins in other species, investigators found that some of this bacterium’s genes have their closest relationships not with the genes of other bacterial species, but with the genes of archaea that live in similar extreme environments.

When genes involved in lateral transfer events are sequenced and analyzed, the resulting *gene trees* will not match the organismal tree in every respect (**Figure 26.4**). The gene trees will vary because the history of lateral transfer events may be different for different genes. Biologists can reconstruct the underlying organismal phylogeny by comparing multiple genes to produce a consensus tree, or by concentrating only on genes that are unlikely to be involved in lateral gene transfer

26.4 Lateral Gene Transfer Complicates Phylogenetic Relationships

(A) The phylogeny of four hypothetical prokaryote species, two of which have been involved in a lateral transfer of gene x. (B) A tree based only on gene x shows the phylogeny of the laterally transferred gene, rather than the organismal phylogeny. (C) A consensus tree based on multiple genes is more likely to reflect the true organismal phylogeny, especially if those genes come from a stable core of genes involved in fundamental processes.

events. For example, genes that are involved in fundamental cellular processes (such as the rRNA genes discussed above) are unlikely to be replaced by the same genes from other species because functional, locally adapted copies of these genes are already present.

What kinds of genes are most likely to be involved in lateral gene transfer? Genes that result in a new adaptation that confers higher fitness on a recipient species are most likely to be retained. For example, genes that produce antibiotic resistance are often transferred among bacterial species on plasmids, especially under strong selection pressure such as that imposed by modern antibiotic medications. Improper or overly frequent use of antibiotics can select for resistant strains of pathogenic bacteria that are much harder to treat. This phenomenon explains why informed physicians have become more careful in prescribing antibiotics.

It is debatable whether lateral gene transfer has seriously complicated our attempts to resolve the tree of prokaryotic life. Recent work suggests that it has not; although lateral gene transfer complicates studies in some individual species (and makes the boundaries of “species” of bacteria difficult to determine), it need not present problems at higher taxonomic levels. It is now possible to make nucleotide sequence comparisons of entire genomes, and these studies are revealing a stable core of fundamental genes whose phylogenies are uncomplicated by lateral gene transfer. Gene trees based on this stable core more accurately reveal the organismal phylogeny. The problem that remains is that only a very small proportion of the prokaryotic world has been described and studied.

The great majority of prokaryote species have never been studied

Most prokaryotes have defied all attempts to grow them in pure culture, causing biologists to wonder how many species, and possibly even large groups of species, we might be missing. A window onto this problem was opened with the introduction of a new way of examining nucleic acid sequences. When biologists are unable to work with the whole genome of a single prokaryote species, they can instead examine individual genes collected from a random sample of the environment. This technique is known as **environmental genomics**.

Biologists now routinely isolate gene sequences, or even whole genomes, from environmental samples such as soil and seawater. Comparing such sequences with previously known ones has revealed that an extraordinary number of the sequences represent new, previously unrecognized species. Biologists have described only about 10,000 species of bacteria and only a few hundred species of archaea (see Figure 1.7). The results of some environmental genomic studies suggest that there may be millions—perhaps hundreds of millions—of prokaryote species. Other biologists put the estimate much lower, arguing that the high dispersal ability of many bacterial species greatly reduces endemism (i.e., the number of species restricted to a small geographic area). Only the magnitude of these estimates differs, however; all sides agree that we have just begun to uncover Earth’s bacterial and archaeal diversity.

RECAP 26.1

Bacteria and Archaea are distinct prokaryotic domains of the tree of life. The small size of prokaryotes, combined with their potential for lateral gene transfer, has hindered our ability to understand their evolutionary relationships. Environmental genomic studies have suggested a much higher diversity of prokaryotes than previous studies had revealed.

- What findings led to the establishment of Bacteria and Archaea as separate domains? **See pp. 526–527 and Table 26.1**
- How did biologists classify bacteria before it became possible to determine their nucleotide sequences? **See pp. 527–528 and Figures 26.2 and 26.3**
- Why are nucleotide sequences of rRNA genes particularly useful for phylogenetic studies of prokaryotes? **See p. 528**
- How does lateral gene transfer complicate phylogenetic studies of prokaryotes? **See pp. 528–529 and Figure 26.4**

Despite the challenges of reconstructing prokaryote phylogeny, taxonomists are starting to establish evolutionary classification systems for these organisms. With the understanding that new information will necessitate periodic revision of these classifications, we next apply one current system to our discussion of prokaryote diversity.

26.2

Why Are Prokaryotes So Diverse and Abundant?

The prokaryotes were alone on Earth for a very long time, adapting to new and changing environments. They are still with us, in massive numbers and incredible diversity, and they are found everywhere. If success is measured by numbers of individuals, the prokaryotes are the most successful organisms on Earth. Individual bacteria and archaea in the oceans have been estimated to number more than 3×10^{28} —perhaps 100 million times more than the number of stars in the visible universe. Closer to home, the individual bacteria living in your intestinal tract outnumber all the humans who have ever lived.

Given our still-fragmentary knowledge of prokaryote diversity, it is not surprising that there are several different hypotheses about the relationships of the major groups of prokaryotes. In this book we use a widely accepted classification system that has considerable support from nucleotide sequence data. In this section we will discuss the eight bacterial groups that have the broadest phylogenetic support and have received the most study (see Figure 26.1). We will then describe the archaea, whose diversity is even less well studied than that of the bacteria.

The low-GC Gram-positives include some of the smallest cellular organisms

The **low-GC Gram-positives**, also known as Firmicutes, derive the first part of their name from the relatively low ratio of G-C to A-T nucleotide base pairs in their DNA. The second part of their name is less accurate: some of the low-GC Gram-positives

26.5 A Structure for Waiting Out Bad Times Under harsh conditions, some low-GC Gram-positive bacteria can replicate their DNA and encase it in an endospore. The parent cell then breaks down, and the endospore survives in a dormant state until conditions improve.

are in fact Gram-negative, and some have no cell wall at all. Despite these differences, phylogenetic analyses of DNA sequences support the monophyly of this bacterial group.

One group of low-GC Gram-positives can produce resting structures called **endospores** (Figure 26.5). When a key nutrient such as nitrogen or carbon becomes scarce, the bacterium replicates its DNA and encapsulates one copy, along with some of its cytoplasm, in a tough cell wall heavily thickened with peptidoglycan and surrounded by a spore coat. The parent cell then breaks down, releasing the endospore. Endospore production is not a reproductive process; the endospore merely replaces the parent cell. The endospore, however, can survive harsh environmental conditions that would kill the parent cell, such as high or low temperatures or drought, because it is dormant—its normal metabolic activity is suspended. Later, if it encounters favorable conditions, the endospore becomes metabolically active and divides, forming new cells that are descendants of the parent cell. Members of this endospore-forming group of low-GC Gram-positives include the many species of *Clostridium* and *Bacillus*. Some of their endospores can be reactivated after more than a thousand years of dormancy. There are even credible claims of reactivation of *Bacillus* endospores millions of years old.

Endospores of *Bacillus anthracis* are the cause of anthrax. Anthrax is primarily a disease of cattle and sheep, but it can be fatal in humans. When the endospores sense macrophages in mammalian blood, they reactivate and release toxins into the bloodstream. *Bacillus anthracis* has been used as a bioterrorism agent because it is relatively easy to transport large quantities of its endospores and release them among human populations, where they may be inhaled or ingested.

26.6 Staphylococci “Grape clusters” are the usual arrangement of these low-GC Gram-positive coccal bacteria, often the cause of skin or wound infections.

Low-GC Gram-positives of the genus *Staphylococcus*—the **staphylococci** (Figure 26.6)—are abundant on the human body surface; they are responsible for boils and many other skin problems. *Staphylococcus aureus* is the best-known human pathogen in this genus; it is present in 20 to 40 percent of normal adults (and in 50 to 70 percent of hospitalized adults). In addition to skin diseases, *S. aureus* can cause respiratory, intestinal, and wound infections.

Another interesting group of low-GC Gram-positives, the **mycoplasmas**, lack cell walls, although some have a stiffening material outside the plasma membrane. The mycoplasmas are among the smallest cellular organisms known (Figure 26.7). The smallest mycoplasmas have a diameter of about 0.2 μm. They are small in another crucial sense as well: they have less than half as much DNA as most other prokaryotes. It has been speculated

26.7 Tiny Cells With about one-fifth as much DNA as *E. coli*, mycoplasmas are among the smallest known bacteria.

that the DNA in a mycoplasma, which codes for fewer than 500 proteins, may be close to the minimum amount required to encode the essential properties of a living cell (see Figure 17.6).

Some high-GC Gram-positives are valuable sources of antibiotics

High-GC Gram-positives, also known as actinobacteria, have a higher ratio of G–C to A–T nucleotide base pairs than do the low-GC Gram-positives. These bacteria develop an elaborately branched system of filaments (**Figure 26.8**) that resembles the filamentous growth habit of fungi, albeit at a smaller scale. Some high-GC Gram-positives reproduce by forming chains of spores at the tips of the filaments. In species that do not form spores, the branched, filamentous growth ceases and the structure breaks up into typical cocci or bacilli, which then reproduce by binary fission.

The high-GC Gram-positives include several medically important bacteria. *Mycobacterium tuberculosis* causes tuberculosis, which kills 3 million people each year. Genetic data suggest that this bacterium arose 3 million years ago in East Africa, making it the oldest known human bacterial pathogen. The genus *Streptomyces* produces streptomycin as well as hundreds of other antibiotics. We derive most of our antibiotics from members of the high-GC Gram-positives.

Hyperthermophilic bacteria live at very high temperatures

Several lineages of bacteria and archaea are **extremophiles**: they thrive under extreme conditions that would kill most other organisms. The hyperthermophilic bacteria, for example, are thermophiles (Greek, “heat-lovers”). Genera such as *Aquifex* live near volcanic vents and in hot springs, sometimes

at temperatures near the boiling point of water. Some species of *Aquifex* need only hydrogen, oxygen, carbon dioxide, and mineral salts to live and grow. Species of the genus *Thermotoga* live deep underground in oil reservoirs as well as in other high-temperature environments.

Biologists have hypothesized that high temperatures characterized the ancestral conditions for life, given that most environments on early Earth were much hotter than those of today. Reconstructions of ancestral bacterial genes have supported this hypothesis by showing that the ancestral sequences functioned best at elevated temperatures. The monophyly of the hyperthermophilic bacteria, however, is not well established.

Hadobacteria live in extreme environments

The **hadobacteria**, including such genera as *Deinococcus* and *Thermus*, are another group of thermophilic extremophiles. The group’s name is derived from Hades, the ancient Greek name for the underworld. *Deinococcus* are resistant to radiation and can consume nuclear waste and other toxic materials. They can also survive extremes of cold as well as hot temperatures. Another member of this group, *Thermus aquaticus*, was the source of the thermally stable DNA polymerase that was critical for the development of the polymerase chain reaction. *Thermus aquaticus* was originally isolated from a hot spring, but it can be found wherever hot water occurs (including many residential hot water heaters).

Cyanobacteria were the first photosynthesizers

Cyanobacteria, sometimes called *blue-green bacteria* because of their pigmentation, are photosynthetic. They use chlorophyll *a* for photosynthesis and release oxygen gas (O_2); many species also fix nitrogen. The production of oxygen by these bacteria transformed the atmosphere of early Earth (see Section 25.2).

Cyanobacteria carry out the same type of photosynthesis that is characteristic of eukaryotic photosynthesizers. They contain elaborate and highly organized internal membrane systems called **photosynthetic lamellae**. As mentioned in Section 26.1, the chloroplasts of photosynthetic eukaryotes are derived from an endosymbiotic cyanobacterium.

Cyanobacteria may live free as single cells or associate in multicellular colonies. Depending on the species and on growth conditions, these colonies may range from flat sheets one cell thick to filaments to spherical balls of cells. Some filamentous colonies of cyanobacteria differentiate into three specialized cell types: vegetative cells, spores, and heterocysts (**Figure 26.9**). **Vegetative cells** photosynthesize, **spores** are resting stages that can survive harsh environmental conditions and eventually develop into new filaments, and **heterocysts** are cells specialized for nitrogen fixation. All of the known cyanobacteria with heterocysts fix nitrogen. Heterocysts also have a role in reproduction: when filaments break apart to reproduce, the heterocyst may serve as a breaking point.

26.8 Actinobacteria Are High-GC Gram-Positives The tangled, branching filaments seen in this scanning electron micrograph are typical of this medically important bacterial group.

(A) *Anabaena* sp.(B) *Nostoc punctiforme*

A thick wall separates the cytoplasm of the nitrogen-fixing heterocyst from the surrounding environment.

(C)

26.9 Cyanobacteria (A) Some cyanobacteria form filamentous colonies containing three cell types. (B) Heterocysts are specialized for nitrogen fixation and may serve as a breaking point when filaments reproduce. (C) This pond in Finland has experienced eutrophication: phosphorus and other nutrients generated by human activity have accumulated, feeding an immense green mat (commonly referred to as "pond scum") that is made up of several species of free-living cyanobacteria.

Spirochetes move by means of axial filaments

Spirochetes are Gram-negative, motile bacteria characterized by unique structures called axial filaments (**Figure 26.10A**), which are modified flagella running through the periplasmic space. The cell body is a long cylinder coiled into a helix (**Figure 26.10B**). The axial filaments begin at either end of the cell and overlap in the middle. Motor proteins connect the axial filaments to the cell wall, enabling the corkscrew-like movement of the bacterium. Many spirochetes are parasites of humans; a few are pathogens, including those that cause syphilis and Lyme disease. Others live free in mud or water.

Chlamydias are extremely small parasites

Chlamydias are among the smallest bacteria (0.2–1.5 μm in diameter). These tiny, Gram-negative cocci can live

only as parasites in the cells of other organisms. It was once believed that their obligate parasitism resulted from an inability to produce ATP—that chlamydias were "energy parasites." However, genome sequencing indicates that chlamydias have the genetic capacity to produce at least some ATP. They can augment this capacity by using an enzyme called a translocase, which allows them to take up ATP from the cytoplasm of their host in exchange for ADP from their own cells.

Chlamydias are unique among prokaryotes because of their complex life cycle, which involves two different forms of cells, elementary bodies and reticulate bodies (**Figure 26.11**). Various strains of chlamydias cause eye infections, sexually transmitted diseases, and some forms of pneumonia in humans.

26.10 Spirochetes Get Their Shape from Axial Filaments

(A) A spirochete from the gut of a termite, seen in cross section, shows the axial filaments these helical prokaryotes use to produce a corkscrew-like movement. (B) This spirochete species causes syphilis in humans.

26.11 Chlamydias Change Form Elementary bodies and reticulate bodies are the two cell forms of the chlamydia life cycle.

The proteobacteria are a large and diverse group

By far the largest bacterial group, in terms of numbers of described species, is the **proteobacteria**. The proteobacteria include many species of Gram-negative photoautotrophs that use light-driven reactions to metabolize sulfur, as well as dramatically diverse bacteria that bear no phenotypic resemblance to the photoautotrophic species. Genetic and morphological evidence indicates that the mitochondria of eukaryotes were derived from a proteobacterium by endosymbiosis.

Among the proteobacteria are some nitrogen-fixing genera such as *Rhizobium*, and other bacteria that contribute to the global nitrogen and sulfur cycles. *Escherichia coli*, one of the most studied organisms on Earth, is a proteobacterium. So too are many of the most famous human pathogens, such as *Yersinia pestis* (the cause of bubonic plague), *Vibrio cholerae* (cholera), and *Salmonella typhimurium* (gastrointestinal disease; **Figure 26.12**).

Go to Media Clip 26.2
A Swarm of *Salmonella*
Life10e.com/mc26.2

The bioluminescent *Vibrio* we discussed at the opening of this chapter are also proteobacteria. There are many potential applications of the genes that encode bioluminescent proteins in bacteria; these genes are already being inserted into the genomes of other species, with the resulting bioluminescence used as a marker of gene expression. Futuristic proposals for making use of bioluminescence in bioengineered organisms include crop plants that glow when they become water-stressed and need to be irrigated; and glowing trees that could illuminate highways, replacing electric lights.

Although most plant diseases are caused by fungi and viruses, about 200 known plant diseases are of bacterial origin. *Crown gall*, with its characteristic tumors, is one of the most striking (**Figure 26.13**). The causal agent of crown gall

26.12 Proteobacteria Include Human Pathogens These conjugating cells of *Salmonella typhimurium* are exchanging genetic material. This pathogen causes a wide range of gastrointestinal illnesses in humans.

is *Agrobacterium tumefaciens*, a proteobacterium that harbors a plasmid often used in recombinant DNA studies as a vehicle for inserting genes into new plant hosts.

Gene sequencing enabled biologists to differentiate the domain Archaea

The original identification of Archaea as a domain separate from Bacteria and Eukarya was based on phylogenetic relationships determined from rRNA gene sequences. This separation was supported when biologists sequenced the first complete archaeal genome, which consisted of 1,738 genes—more than half of which were unlike any genes ever found in the other two domains.

26.13 Crown Gall Crown gall, a type of tumor shown here growing on the trunk of a white oak, is caused by the proteobacterium *Agrobacterium tumefaciens*.

INVESTIGATINGLIFE

26.14 What Is the Highest Temperature Compatible with Life?

Can any organism thrive at temperatures above 120°C? This is the temperature used for sterilization, known to destroy all previously described organisms. Kazem Kashefi and Derek Lovley isolated an unidentified prokaryote from water samples taken near a hydrothermal vent and found it survived and even multiplied at 121°C. The organism was dubbed “Strain 121,” and its gene sequencing results indicate that it is an archaeal species.^a

HYPOTHESIS Some prokaryotes can survive at temperatures above the 120°C threshold of sterilization.

- Method**
1. Seal samples of unidentified, iron-reducing, thermal vent prokaryotes in tubes with a medium containing Fe^{3+} as an electron acceptor. Control tubes contain Fe^{3+} but no organisms.
 2. Hold both tubes in a sterilizer at 121°C for 10 hours. If the iron-reducing organisms are metabolically active, they will reduce the Fe^{3+} to Fe^{2+} (as magnetite, which can be detected with a magnet).

Results

The solids are attracted to the magnet, indicating that the organisms in this solution are alive and engaged in iron-reducing biochemical reactions.

CONCLUSION Archaea of “Strain 121” can survive at temperatures above the previously defined sterilization limit.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

^aKashefi, K. and D. R. Lovley. 2003. *Science* 301: 934.

Archaea are known for living in extreme habitats such as those with high salinity (salt content), low oxygen concentrations, high temperatures, or high or low pH (**Figure 26.14**). Many archaea are not extremophiles, however—they are common in soil, for example. Perhaps the largest numbers of archaea live in the ocean depths.

One current classification scheme divides Archaea into two principal groups, **Crenarchaeota** and **Euryarchaeota**. Less is known about two more recently discovered groups, **Korarchaeota** and **Nanoarchaeota**. In fact, we know relatively little about the phylogeny of archaea, in part because the study of these prokaryotes is still in its early stages.

Two characteristics shared by all archaea are the absence of peptidoglycan in their cell walls and the presence of lipids of distinctive composition in their cell membranes (see Table 26.1). The unusual lipids in the membranes of archaea are found in all archaea and in no bacteria or eukaryotes. Most lipids in bacterial and eukaryotic membranes contain

WORKING WITHDATA:

A Relationship between Temperature and Growth in an Archaeon

Original Paper

Kashefi, K. and D. R. Lovley. 2003. Extending the upper temperature limit for life. *Science* 301: 934.

Analyze the Data

After Strain 121 was isolated, its growth was examined at various temperatures. The table below shows generation time (time between cell divisions) at nine temperatures.

Temperature (°C)	Generation time (hr)
85	10
90	4
95	3
100	2.5
105	2
110	4
115	6
120	20
130	No growth, but cells not killed

QUESTION 1

Make a graph from these data showing time as a function of temperature.

QUESTION 2

Which temperature appears to be closest to optimum for the growth of Strain 121?

QUESTION 3

Note that no growth occurred at 130°C, but that the cells were not killed. How would you demonstrate that these cells were still alive?

Go to **BioPortal** for all **WORKING WITHDATA** exercises

unbranched long-chain fatty acids connected to glycerol molecules by **ester linkages**:

In contrast, some lipids in archaeal membranes contain long-chain hydrocarbons connected to glycerol molecules by **ether linkages**:

These ether linkages are a synapomorphy of archaea. In addition, the long hydrocarbon chains in the lipids of archaea are branched. One class of archaeal lipids, with hydrocarbon chains 40 carbon atoms in length, contains glycerol at *both* ends of the hydrocarbons (**Figure 26.15**). These lipids form a *lipid monolayer* structure that is unique to archaea. They still fit into a biological membrane because they are twice as long as the typical lipids in the bilayers of other membranes. Lipid monolayers

Some archaea have long-chain hydrocarbons that span the membrane (a lipid monolayer).

Other archaeal hydrocarbons fit the same template as those of bacteria and eukaryotes (a lipid bilayer).

26.15 Membrane Architecture in Archaea The long-chain hydrocarbons of many archaeal lipids have glycerol molecules at both ends, so that the membranes they form consist of a lipid monolayer. In contrast, the membranes of other archaea, bacteria, and eukaryotes consist of a lipid bilayer.

and bilayers are both found among the archaea. The effects, if any, of these structural features on membrane performance are unknown. In spite of this striking difference in their lipids, the membranes of all three domains have similar overall structures, dimensions, and functions.

Most crenarchaeotes live in hot or acidic places

Most known crenarchaeotes are either thermophilic, acidophilic (acid loving), or both. Members of the genus *Sulfolobus* live in hot sulfur springs at temperatures of 70°C to 75°C. They become metabolically inactive at 55°C (131°F). Hot sulfur springs are also extremely acidic. *Sulfolobus* grows best in the range from pH 2 to pH 3, but some members of this genus readily tolerate pH values as low as 0.9. Most acidophilic thermophiles maintain an internal pH of 5.5 to 7 (close to neutral) in spite of their acidic environment. These and other crenarchaeotes thrive where very few other organisms can even survive (Figure 26.16).

Euryarchaeotes are found in surprising places

Some species of Euryarchaeota are **methanogens**: they produce methane (CH₄) by reducing carbon dioxide as the key step in their energy metabolism. All of the methanogens are obligate anaerobes (see Section 26.3). Comparison of their rRNA gene sequences has revealed a close evolutionary relationship among these methanogenic species, which were previously assigned to several different groups of bacteria.

Methanogenic euryarchaeotes release approximately 2 billion tons of methane gas into Earth's atmosphere each year, accounting for 80 to 90 percent of the methane that enters the atmosphere, including that produced in some mammalian digestive systems. Approximately a third of this methane comes from methanogens living in the guts of ruminants such as cattle, sheep, and deer, and another large fraction comes from methanogens living in the guts of termites and cockroaches. Methane is increasing in Earth's atmosphere by about 1 percent per year and contributes to the greenhouse effect (see Section 58.3). Part of that increase is due to increases in cattle and rice farming and the methanogens associated with both.

26.16 Some Crenarchaeotes Like It Hot Thermophilic crenarchaeotes can thrive in the intense heat of volcanic hot sulfur springs such as these in Nevada's Black Rock Desert.

Another group of euryarchaeotes, the **extreme halophiles** (salt lovers), live exclusively in very salty environments. Because they contain pink carotenoid pigments, these archaea are sometimes easy to see (Figure 26.17). Extreme halophiles grow in the Dead Sea and in brines of all types; the reddish pink spots that can occur on pickled fish are colonies of halophilic archaea. Few other organisms can live in the saltiest homes that the extreme halophiles occupy; most would “dry” to death, losing too much water to the hypertonic environment. Extreme halophiles have been found in lakes with pH values as high as 11.5—the most alkaline environment inhabited by living organisms, and almost as alkaline as household ammonia.

Some of the extreme halophiles have a unique system for trapping light energy and using it to form ATP—without using any form of chlorophyll—when oxygen is in short supply.

26.17 Extreme Halophiles Highly saline environments such as these commercial seawater evaporating ponds in San Francisco Bay are home to extreme halophiles. The archaea are easily visible here because of the rich red coloration of their carotenoid pigments.

26.18 A Nanoarchaeote Growing in Mixed Culture with a Crenarchaeote *Nanoarchaeum equitans* (red), discovered living near deep-sea hydrothermal vents, is the only representative of the nanoarchaeote group so far identified. This tiny organism lives attached to cells of the crenarchaeote *Ignicoccus* (green). For this confocal laser micrograph, the two species were visually differentiated by fluorescent dye “tags” that are specific to their distinct gene sequences.

They use the pigment retinal (also found in the vertebrate eye) combined with a protein to form a light-absorbing molecule called microbial rhodopsin.

Another member of the Euryarchaeota, *Thermoplasma*, has no cell wall. It is thermophilic and acidophilic, its metabolism is aerobic, and it lives in coal deposits. Its genome of 1,100,000 base pairs is among the smallest (along with that of the mycoplasmas) found in any free-living organism, although some parasitic organisms have even smaller genomes.

Korarchaeotes and nanoarchaeotes are less well known

The korarchaeotes are known only from DNA isolated directly from marine hydrothermal vents and freshwater hot springs. No korarchaeote has been successfully grown in pure culture.

Another distinctive archaeal lineage has been discovered at a deep-sea hydrothermal vent off the coast of Iceland. It is the first representative of the group christened Nanoarchaeota because of their minute size (Greek *nanos*, “dwarf”). This organism is a parasite that lives on cells of *Ignicoccus*, a crenarchaeote. Because of their association, the two species can be grown together in culture (**Figure 26.18**).

roles in ecosystems that reach far beyond human sickness and health.

Prokaryotes have diverse metabolic pathways

Bacteria and archaea outdo the eukaryotes in terms of metabolic diversity. Although they are much more diverse in size and shape, eukaryotes draw on fewer metabolic mechanisms for their energy needs. In fact, much of eukaryotes’ energy metabolism is carried out in organelles—mitochondria and chloroplasts—that are endosymbiotic descendants of bacteria. The long evolutionary history of bacteria and archaea, during which they have had time to adapt to a wide variety of habitats, has led to the extraordinary diversity of their metabolic “lifestyles”—their use or nonuse of oxygen, their varied sources of energy and carbon atoms, and the materials they release as waste products. This diversity of metabolic pathways, some of them unique to prokaryotes, makes prokaryotes a key component of the cycling of materials through ecosystems.

ANAEROBIC VERSUS AEROBIC METABOLISM The presence of oxygen is poisonous to some prokaryotes, so these **obligate anaerobes** can live only by anaerobic metabolism. At the other extreme from the obligate anaerobes, some prokaryotes are **obligate aerobes**. They require oxygen for cellular respiration and are unable to survive for extended periods in the *absence* of oxygen. Other prokaryotes can shift their metabolism between anaerobic and aerobic modes and thus are called **facultative anaerobes**. Many facultative anaerobes alternate between anaerobic metabolic processes (such as fermentation) and cellular respiration, as conditions dictate. **Aerotolerant anaerobes** are not damaged by oxygen when it is present, but they cannot conduct cellular respiration. By definition, an anaerobe does not use oxygen as an electron acceptor for respiration.

NUTRITIONAL CATEGORIES All organisms face the same two nutritional challenges: they must synthesize energy-rich compounds such as ATP to power their life-sustaining metabolic reactions, and they must obtain carbon atoms to build their

RECAP 26.2

Bacteria and Archaea are highly diverse groups that survive in almost every imaginable habitat on Earth. Many can survive and even thrive in habitats where no eukaryotes can live, including extremely hot, acidic, or saline conditions.

- How does the diversity of environments occupied by prokaryotes compare with the diversity of environments occupied by multicellular organisms with which you are familiar?
- Explain why Gram staining is of limited use in understanding the evolutionary relationships of bacteria. **See pp. 530–531**
- What makes the membranes of archaea unique? **See pp. 535–536 and Figure 26.15**

Prokaryotes are found almost everywhere on Earth and live in a wide variety of ecosystems. In the next section we will examine the contributions of prokaryotes to the functioning of those ecosystems.

26.3 How Do Prokaryotes Affect Their Environments?

Many people think of prokaryotes primarily as disease-causing organisms, but only a small percentage of bacteria, and no archaea, are known to be pathogens. Prokaryotes play

TABLE 26.2
How Organisms Obtain Their Energy and Carbon

Nutritional Category	Energy Source	Carbon Source
Photoautotrophs (some bacteria, some eukaryotes)	Light	Carbon dioxide
Photoheterotrophs (some bacteria)	Light	Organic compounds
Chemoautotrophs (some bacteria, many archaea)	Inorganic substances	Carbon dioxide
Chemoheterotrophs (found in all three domains)	Usually organic compounds; sometimes inorganic substances	Organic compounds

own organic molecules. Biologists recognize four broad nutritional categories of organisms: photoautotrophs, photoheterotrophs, chemoautotrophs, and chemoheterotrophs. Prokaryotes are represented in all four groups (Table 26.2).

Photoautotrophs perform photosynthesis. They use light as their energy source and carbon dioxide (CO_2) as their carbon source. The cyanobacteria, like green plants and other photosynthetic eukaryotes, use chlorophyll *a* as their key photosynthetic pigment and produce oxygen gas (O_2) as a by-product of noncyclic electron transport.

There are other photoautotrophs among the bacteria, but these organisms use bacteriochlorophyll rather than chlorophyll *a* as their key photosynthetic pigment, and they do not produce O_2 . Instead, some of these photosynthesizers produce particles of pure sulfur because hydrogen sulfide (H_2S), rather than H_2O , is their electron donor for photophosphorylation. Many proteobacteria fit into this category. Bacteriochlorophyll molecules absorb light of longer wavelengths than do the chlorophyll molecules used by other photosynthesizing organisms. As a result, bacteria using this pigment can grow in water under fairly dense layers of algae, using light of wavelengths that are not absorbed by the algae (Figure 26.19).

Photoheterotrophs use light as their energy source but must obtain their carbon atoms from organic compounds made by other organisms. Their “food” consists of organic compounds such as carbohydrates, fatty acids, and alcohols.

26.19 Bacteriochlorophyll Absorbs Long-Wavelength Light The green alga *Ulva* contains chlorophyll, which absorbs no light of wavelengths longer than 750 nm. Purple sulfur bacteria, which contain bacteriochlorophyll, can conduct photosynthesis using longer infrared wavelengths. As a result, these bacteria can grow under layers of algae.

For example, some photoheterotrophs take up compounds released from plant roots (as in rice paddies) or from decomposing photosynthetic bacteria in hot springs and metabolize them to form building blocks for other compounds. Sunlight provides them with the energy necessary for ATP formation through photophosphorylation.

Chemoautotrophs obtain their energy by oxidizing inorganic substances, and they use some of that energy to fix carbon. Some chemoautotrophs use reactions identical to those of the typical photosynthetic cycle, but others use alternative pathways for carbon fixation. Some bacteria oxidize ammonia or nitrite ions to form nitrate ions. Others oxidize hydrogen gas, hydrogen sulfide, sulfur, and other materials. Many archaea are chemoautotrophs.

Finally, **chemoheterotrophs** obtain carbon atoms from one or more complex organic compounds that have been synthesized by other organisms, and usually obtain energy from breaking down these organic compounds as well. Most known bacteria and archaea are chemoheterotrophs—as are all animals and fungi and many protists.

Although most chemoheterotrophs rely on the breakdown of organic compounds for energy, some chemoheterotrophic prokaryotes obtain their energy by breaking down inorganic substances. Organisms that obtain energy from oxidizing inorganic substances (both chemoautotrophs as well as some chemoheterotrophs) are also known as **lithotrophs** (Greek, “rock consumers”).

Prokaryotes play important roles in element cycling

The metabolic diversity of the prokaryotes makes them key players in the cycles that keep chemical elements moving through ecosystems. Many prokaryotes are **decomposers**: organisms that metabolize organic compounds in dead organic material and return the products to the environment as inorganic substances. Prokaryotes, along with fungi, return tremendous quantities of carbon to the atmosphere as carbon dioxide, thus carrying out a key step in the carbon cycle.

The key metabolic reactions of many prokaryotes involve nitrogen or sulfur. For example, some bacteria carry out respiratory electron transport without using oxygen as an electron acceptor. These organisms use oxidized inorganic ions such as nitrate, nitrite, or sulfate as electron acceptors. Examples include the **denitrifiers**, which release nitrogen to the atmosphere as nitrogen gas (N_2). These normally aerobic bacteria, mostly species of the genera *Bacillus* and *Pseudomonas*, use nitrate (NO_3^-) as an electron acceptor in place of oxygen under anaerobic conditions:

Denitrifiers play a key role in the cycling of nitrogen through ecosystems. Without denitrifiers, which convert nitrate ions into nitrogen gas, all forms of nitrogen would leach from the soil and end up in lakes and oceans; the resulting deficit of nitrogen on land would make terrestrial life much more difficult.

Nitrogen fixers convert atmospheric nitrogen gas into ammonia (NH_3), a chemical form that is usable by the nitrogen fixers themselves as well as by other organisms:

All organisms require nitrogen in order to build proteins, nucleic acids, and other important compounds. Nitrogen fixation is thus vital to life as we know it. This all-important biochemical process is carried out by a wide variety of archaea and bacteria (including cyanobacteria) but by no other organisms, so we depend on these prokaryotes for our very existence.

Ammonia is oxidized to nitrate in soil and in seawater by chemoautotrophic bacteria and archaea called **nitrifiers**. Bacteria of two genera, *Nitrosomonas* and *Nitrosococcus*, convert ammonia (NH_3) to nitrite ions (NO_2^-), and *Nitrobacter* oxidize nitrite to nitrate (NO_3^-), the form of nitrogen most easily used by many plants. What do the nitrifiers get out of these reactions? Their metabolism is powered by the energy released by the oxidation of ammonia or nitrite. For example, by passing the electrons from nitrite through an electron transport system, *Nitrobacter* can make ATP, and using some of this ATP, can also make NADH. With this ATP and NADH, the bacterium can convert CO_2 and H_2O into glucose.

We have already seen the importance of the cyanobacteria in the cycling of oxygen: in ancient times, the oxygen generated by their photosynthesis converted Earth's atmosphere from an anaerobic to an aerobic environment. Other prokaryotes—both bacteria and archaea—contribute to the cycling of sulfur. Deep-sea hydrothermal vent ecosystems depend on chemoautotrophic prokaryotes that are incorporated into large communities of crabs, mollusks, and giant worms, all living at a depth of 2,500 meters—below any hint of sunlight. These bacteria obtain energy by oxidizing hydrogen sulfide and other substances released in the near-boiling water flowing from volcanic vents in the ocean floor.

Many prokaryotes form complex communities

Prokaryotes do not usually live in isolation. Rather, they live in communities of many different microbial species, which often

include microscopic eukaryotes as well as myriad prokaryotic species. While some microbial communities are harmful to humans, others provide important services. For example, microbial communities help us digest our food, break down municipal waste, and recycle organic matter and chemical elements in the environment.

Some microbial communities form layers in sediments; others form clumps a meter or more in diameter. Many microbial communities form dense **biofilms**. Upon contacting a solid surface, the cells bind to that surface and secrete a sticky, gel-like, polysaccharide matrix that traps other cells (**Figure 26.20**). Once a biofilm forms, the cells become more difficult to kill.

Biofilms are found in many places, and in some of those places they cause problems for humans. The material on our teeth that we call dental plaque is a biofilm. Pathogenic bacteria are difficult for the immune system—and modern medicine—to combat once they form a biofilm, which may be impermeable to antibiotics. Worse, some drugs stimulate the bacteria in a biofilm to lay down more matrix, making the film even more impermeable. Biofilms may form on just about any available surface, including contact lenses and artificial joint replacements. They foul metal pipes and cause corrosion, a major problem in steam-driven electricity generation plants. Fossil stromatolites—large, rocky structures made up of alternating layers of fossilized biofilm and calcium carbonate—are among the oldest remnants of life on Earth (see Figure 25.9).

Some biologists are studying the chemical signals that prokaryotes use to communicate with one another and trigger density-linked activities such as biofilm formation. We saw one example of this type of communication—called **quorum sensing**—in the chapter-opening discussion of bioluminescent *Vibrio*. In the case of health-threatening bacteria, researchers hope to be able to block the quorum-sensing signals that lead to the production of the matrix polysaccharides, thus preventing pathological biofilms from forming.

Prokaryotes live on and in other organisms

Prokaryotes engage in many kinds of mutually beneficial relationships with eukaryotes. As we have seen, the mitochondria and chloroplasts of eukaryotes are descended from what were once free-living bacteria. Much later in evolutionary history, some plants became associated with bacteria to form cooperative nitrogen-fixing nodules on their roots.

Many animals harbor a variety of bacteria and archaea in their digestive tracts. Cattle depend on prokaryotes to perform important steps in digestion. Like most animals, cattle cannot produce cellulase, the enzyme needed to start the digestion of the cellulose that makes up the bulk of their plant food. However, bacteria living in a special section of the gut, called the rumen, produce enough cellulase to process the daily diet for the cattle. Human health also depends on many hundreds of species of symbiotic bacteria.

Microbiomes are critical to human health

Although only a few bacterial species are pathogens, popular notions of bacteria as “germs” and fear of the consequences

26.20 Forming a Biofilm (A) Free-living prokaryotes readily attach themselves to surfaces and form films that are stabilized and protected by a surrounding matrix. Once the population is large enough, the developing biofilm can send out chemical signals that attract other microorganisms. (B) Scanning electron microscopy reveals a biofilm of dental plaque. The bacteria (red) are embedded in a matrix consisting of proteins from both bacterial secretions and saliva.

of infection cause many people to assume that most bacteria are harmful. Increasingly, however, biologists are discovering that human health depends in many ways on the health of our **microbiomes**: communities of bacteria that live in and on our bodies (**Figure 26.21**).

Every surface of your body is covered with diverse communities of bacteria. A 2009 study identified more than 1,000 species of bacteria that live on human skin. Inside your body, your digestive system teems with bacteria. If you count up all the cells in a human body, only about 10 percent of them are human cells. The rest are microbes—mostly bacteria, along with some archaea and microscopic eukaryotes.

Biologists are discovering that many complex health problems are linked to the disruption of our microbiomes. These diverse microbial communities affect the expression of our genes and play a critical role in the development and maintenance of a healthy immune system. When our microbiomes contain an appropriate community of beneficial bacteria, our bodies function normally. But these communities are strongly affected by our life experiences, by the food we eat, by the medicines we take, and by our exposure to various environmental toxins. When our microbial communities are disrupted, they must be restored before the body can function normally. The recent rapid increase in occurrences of autoimmune diseases—diseases in which our immune systems begin to attack our bodies (see Chapter 42)—has been linked to the changing diversity and composition of our microbiomes.

The early acquisition of an appropriate microbiome is critical for lifelong health. Normally, a human infant acquires much of its microbiome at birth, from the microbiome in its mother's vagina. Other components of the microbiome are also acquired from the mother, especially through breast feeding. Recent studies have shown that babies born by cesarean section, as well as babies that are bottle-fed on artificial milk formula, typically acquire microbes from a wider variety of sources. Many of the bacteria acquired in this way are not well suited for human health. Biologists have discovered that the incidence of many autoimmune diseases is much higher in people who were born by cesarean section and in those who were fed on formula as infants, compared with individuals who were born vaginally and breast-fed. The difference appears to be related to the composition of the individual's original microbiome.

Our microbiomes may be related to many other health concerns. For example, physicians have long noted a connection between autism and gastrointestinal disorders. In 2012, microbiologists discovered that children with autism have high levels of bacteria of the genus *Sutterella* adhering to their intestinal walls. These bacteria are absent or rare in children without autism. It is not yet known if *Sutterella* bacteria cause the gastrointestinal problems or if they are merely its symptoms, but it appears clear that the intestinal microbiomes of children with autism are distinctive.

Humans use some of the metabolic products—especially vitamins B₁₂ and K—produced by the microorganisms living in the large intestine. Communities of bacteria line our intestines with a dense biofilm that is in intimate contact with the mucosal lining of the gut. This biofilm facilitates nutrient transfer from the intestine into the body, functioning like a specialized “tissue” that is essential to our health. This biofilm has a complex ecology that scientists have just begun to explore in

26.21 The Body's Microbiome Is Critical to the Maintenance of Health

Surveys of the human microbiome have shown that this community includes thousands of diverse bacterial species that are adapted to grow in or on various parts of the body. Although we now know that the composition of this microbiome is closely associated with many aspects of human health, most of the component species are poorly characterized and remain largely unstudied by biologists. What has become clear is that, although the “subcommunities” in different parts of the body share similarities, each is a site-specific assemblage of many distinctive species.

detail—including the possibility that the species composition of an individual’s gut microbiome may contribute to obesity (or the resistance to it).

A small minority of bacteria are pathogens

The tiny percentage of prokaryotes that are pathogens all fall into the domain Bacteria. Many archaea live in association with humans and other eukaryotes but are not known to cause any diseases. Why are there no pathogenic archaea? One clue is that different groups of viruses and plasmids infect bacteria than infect archaea, and pathogenesis in bacteria is largely coupled with traits carried by these plasmids and viruses. Differences in the external structures of bacteria and archaea make cross-domain infection by viruses and plasmids highly unlikely. Pathogenic traits may evolve relatively rarely, and they do not

appear to have evolved in the viruses or plasmids that infect archaea.

How can we know if a particular microbe is responsible for a disease? The late nineteenth century was a productive era in the history of medicine—a time when bacteriologists, chemists, and physicians proved that many diseases are caused by microbial agents. During this time, the German physician Robert Koch laid down a set of four rules for establishing that a particular microorganism causes a particular disease:

1. The microorganism is always found in individuals with the disease.
2. The microorganism can be taken from the host and grown in pure culture.
3. A sample of the culture produces the same disease when injected into a new, healthy host.
4. The newly infected host yields a new, pure culture of microorganisms identical to those obtained in the second step.

These rules, called **Koch’s postulates**, were important tools in a time when it was not widely understood that microorganisms cause disease. Although modern medical science has more powerful diagnostic tools, Koch’s postulates remain useful. For example, physicians were taken aback in the 1990s

26.22 Satisfying Koch's Postulates Robin Warren and Barry Marshall of the University of Western Australia won the 2005 Nobel Prize in Medicine for showing that ulcers are caused not by the action of stomach acid but by infection with the bacterium *Helicobacter pylori*.

Helicobacter pylori 1.5 μm

when stomach ulcers—long accepted and treated as the result of excess stomach acid—were shown by Koch's postulates to be caused by the bacterium *Helicobacter pylori* (Figure 26.22).

For an organism to be a successful pathogen, it must:

- arrive at the body surface of a potential host;
- enter the host's body;
- evade the host's defenses;
- reproduce inside the host; and
- infect a new host.

Failure to complete any of these steps ends the reproductive career of a pathogenic organism. Yet in spite of the many defenses available to potential hosts (see Chapters 39 and 42), pathogenic bacteria are often surprisingly difficult to combat, even with today's arsenal of antibiotics. One source of this difficulty, as we have seen, is their ability to form biofilms.

For the host, the consequences of a bacterial infection depend on several factors. One is the **invasiveness** of the pathogen: its ability to multiply in the host's body. Another is its **toxigenicity**, or ability to produce toxins (chemical substances that are harmful to the host's tissues). *Corynebacterium diphtheriae*, the agent that causes diphtheria, has low invasiveness and multiplies only in the throat, but its toxigenicity is so great that the entire body is affected. In contrast, *Bacillus anthracis*, which causes anthrax, has low toxigenicity, but is so invasive that the entire bloodstream ultimately teems with the bacteria.

There are two general types of bacterial toxins, exotoxins and endotoxins. **Endotoxins** are lipopolysaccharides (complexes consisting of a polysaccharide and a lipid component) that form part of the outer membrane of certain Gram-negative bacteria. They are released when these bacteria lyse (burst). Endotoxins are rarely fatal to the host; they normally cause fever, vomiting, and diarrhea. Among the endotoxin producers are some strains of the proteobacteria *Salmonella* and *Escherichia*.

Exotoxins are soluble proteins released by living, multiplying bacteria. They are highly toxic—often fatal—to the host. Human diseases induced by bacterial exotoxins include tetanus

Marshall and Warren set out to satisfy Koch's postulates:

Test 1

The microorganism must be present in every case of the disease.

Results: Biopsies from the stomachs of many patients revealed that the bacterium was always present if the stomach was inflamed or ulcerated.

Test 2

The microorganism must be cultured from a sick host.

Results: The bacterium was isolated from biopsy material and eventually grown in culture media in the laboratory.

Test 3

The isolated and cultured bacteria must be able to induce the disease.

Results: Marshall was examined and found to be free of bacteria and inflammation in his stomach. After drinking a pure culture of the bacterium, he developed stomach inflammation (gastritis).

Test 4

The bacteria must be recoverable from newly infected individuals.

Results: Biopsy of Marshall's stomach 2 weeks after he ingested the bacteria revealed the presence of the bacterium, now christened *Helicobacter pylori*, in the inflamed tissue.

Conclusion

Antibiotic treatment eliminated the bacteria and the inflammation in Marshall's stomach. The experiment was repeated on healthy volunteers, and many patients with gastric ulcers were cured with antibiotics. Thus Marshall and Warren demonstrated that the stomach inflammation leading to ulcers is caused by *H. pylori* infections in the stomach.

(*Clostridium tetani*), cholera (*Vibrio cholerae*), and bubonic plague (*Yersinia pestis*). Anthrax is caused by three exotoxins produced by *Bacillus anthracis*. Botulism is caused by exotoxins produced by the obligate anaerobe *Clostridium botulinum* that are among the most poisonous ever discovered. The lethal dose for humans of one exotoxin of *C. botulinum* is about one-millionth of a gram. Nonetheless, much smaller doses of this exotoxin are marketed under various trade names (the best known being Botox®) and are used to treat muscle spasms as well as for cosmetic purposes (temporary wrinkle reduction in the skin).

RECAP 26.3

Many prokaryotes are beneficial and even necessary to other forms of life. Most animals, including humans, depend on a complex community of prokaryotes—a microbiome—to maintain health, especially of the immune and digestive systems. Pathogenic bacteria are the direct causes of diseases.

- How are the four nutritional categories of prokaryotes distinguished? [See p. 539 and Table 26.2](#)
- Why is nitrogen metabolism in the prokaryotes vital to other organisms? [See p. 538](#)
- How do biofilms form, and why are they of special interest to researchers? [See p. 539 and Figure 26.20](#)

Before moving on to discuss the diversity of eukaryotic life, it is appropriate to consider another category of life that includes some pathogens: the viruses.

A negative-sense single-stranded RNA virus: Influenza virus H5N1, the “bird flu” virus. Surface view.

A positive-sense single-stranded RNA virus: Coronavirus of a type thought to be responsible for severe acute respiratory syndrome (SARS). Surface view.

An RNA retrovirus: One of the human immunodeficiency viruses (HIV) that causes AIDS. Cutaway view.

A double-stranded DNA virus: One of the many herpes viruses (Herpesviridae). Different herpes viruses are responsible for many human infections, including chicken pox, shingles, cold sores, and genital herpes (HSV1/2). Surface view.

A double-stranded DNA virus: Bacteriophage T4. Viruses that infect bacteria are referred to as bacteriophage (or simply phage). T4 attaches leglike fibers to the outside of its host cell and injects its DNA into the cytoplasm through its “tail” (pink structure in this rendition).

A double-stranded DNA mimivirus: This *Acanthamoeba polyphaga* mimivirus (APMV) has the largest diameter of all known viruses and a genome larger than some prokaryote genomes. It is named for its host, an amoeba. Cutaway view.

26.4

How Do Viruses Relate to Life's Diversity and Ecology?

Although they are not cellular, viruses are numerically among the most abundant forms of life on Earth, and their effects on other organisms are enormous. Where did viruses come from, and how do they fit into the tree of life? Biologists are still working to answer these questions.

Some biologists do not think of viruses as living organisms, primarily because they are not cellular and must depend on cellular organisms for basic life functions such as replication and metabolism (see Section 16.1). But viruses are derived from the cells of living organisms. They use the same forms of genetic information storage and transmission as do cellular organisms. Viruses infect all cellular forms of life—bacteria, archaea, and eukaryotes. They replicate, mutate, evolve, and interact with other organisms, often causing serious diseases in their hosts. Finally, viruses clearly evolve independently of other organisms, so it is almost impossible not to treat them as a part of life.

26.23 Viruses Are Diverse Relatively small genomes and rapid evolutionary rates make it difficult to reconstruct phylogenetic relationships among some classes of viruses. Instead, viruses are classified largely by general characteristics of their genomes. The images here are computer artists' reconstructions based on cryo-electron micrographs.

Several factors make viral phylogeny difficult to resolve. First, the tiny size of many viral genomes restricts the phylogenetic analyses that can be conducted to relate them to the genomes of cellular organisms. Second, their rapid mutation rate, which results in rapid evolution of viral genomes, tends to cloud their evolutionary relationships over long periods. Third, there are no known fossil viruses—viruses are too small and delicate to fossilize—so the paleontological record offers no clues to virus origins. Finally, viruses are highly diverse (**Figure 26.23**). Several lines of evidence support the hypothesis that viruses have evolved repeatedly within each of the major groups of life. The difficulty in resolving their deep evolutionary relationships makes a phylogeny-based classification of viruses difficult. Instead, viruses are placed in one of several groups

on the basis of the structure of their genomes, although most of these defined groups are not thought to represent monophyletic taxa.

Many RNA viruses probably represent escaped genomic components of cellular life

Although viruses are obligate parasites of cellular species, many viruses may once have been cellular components involved in basic cellular functions—that is, they may be “escaped” components of cellular life that now evolve independently of their hosts.

NEGATIVE-SENSE SINGLE-STRANDED RNA VIRUSES A case in point is a class of viruses whose genome is composed of single-stranded **negative-sense RNA**: RNA that is the complement of the mRNA needed for protein translation. Many of these negative-sense single-stranded RNA viruses have only a few genes, including one for an RNA-dependent RNA polymerase that allows them to make complementary mRNA from their negative-sense RNA genome. Modern cellular organisms cannot generate mRNA in this manner (at least in the absence of viral infections), but scientists speculate that single-stranded RNA genomes may have been common in the distant past, before DNA became the primary molecule for genetic information storage.

A self-replicating RNA polymerase gene that began to replicate independently of a cellular genome could conceivably acquire a few additional protein-coding genes through recombination with its host’s DNA. If one or more of these genes were to foster the development of a protein coat, the virus might then survive outside the host and infect new hosts. It is believed that this scenario has been repeated many times independently across the tree of life, given that many of the negative-sense single-stranded RNA viruses that infect organisms from bacteria to humans are not closely related to one another. In other words, negative-sense single-stranded RNA viruses do not represent a distinct taxonomic group, but rather exemplify a particular process of cellular escape that probably happened many different times.

Familiar examples of negative-sense single-stranded RNA viruses include the viruses that cause measles, mumps, rabies, and influenza (see Figure 26.23A).

POSITIVE-SENSE SINGLE-STRANDED RNA VIRUSES The genome of another type of single-stranded RNA virus is composed of positive-sense RNA. Positive-sense genomes are already set for translation; no replication of the genome to form a complement strand is needed before protein translation can take place. Positive-sense single-stranded RNA viruses (see Figure 26.23B) are the most abundant and diverse class of viruses. Most of the viruses that cause diseases in crop plants are members of this group. These viruses kill patches of cells in the leaves or stems of plants, leaving live cells amid a patchwork of discolored dead tissue (giving them the name of mosaic or mottle viruses; **Figure 26.24**). Other viruses in this group infect bacteria, fungi, and animals. Human diseases caused by positive-sense single-stranded RNA viruses include polio, hepatitis C, and the common cold. As is true of the other functionally defined groups of viruses, these

26.24 Mosaic Viruses Are a Problem for Agriculture Mosaic, or “mottle,” viruses are the most diverse class of viruses. This leaf is from an apple tree infected with a mosaic virus.

viruses appear to have evolved multiple times across the tree of life from different groups of cellular ancestors.

RNA RETROVIRUSES The RNA retroviruses are best known as the group that includes the human immunodeficiency viruses (HIV; see Figure 26.23C). Like the previous two categories of viruses, RNA retroviruses have genomes composed of single-stranded RNA and probably evolved as escaped cellular components.

Retroviruses are so named because they regenerate themselves by reverse transcription. When the retrovirus enters the nucleus of its vertebrate host, viral reverse transcriptase produces complementary DNA (cDNA) from the viral RNA genome, then replicates that single-stranded cDNA to produce double-stranded DNA. Another virally encoded enzyme, called integrase, catalyzes the integration of the new piece of double-stranded viral DNA into the host’s genome. The viral genome is then replicated along with the host cell’s DNA; the integrated retroviral DNA is known as a **provirus**.

Retroviruses are only known to infect vertebrates, although genomic elements that resemble portions of these viruses are a component of the genomes of a wide variety of organisms, including bacteria, plants, and many animals. Several retroviruses are associated with various forms of cancer, as cells infected with these viruses are likely to undergo uncontrolled replication.

DOUBLE-STRANDED RNA VIRUSES Double-stranded RNA viruses may have evolved repeatedly from single-stranded RNA ancestors—or perhaps vice versa. These viruses, which are not closely related to one another, infect organisms from throughout the tree of life. Many plant diseases are caused by double-stranded RNA viruses. Other viruses of this type cause many cases of infant diarrhea in humans.

Some DNA viruses may have evolved from reduced cellular organisms

Another class of viruses is composed of viruses that have a double-stranded DNA genome (see Figure 26.23D–F). This group is also almost certainly polyphyletic (with many independent origins). Many of the common phage that infect

bacteria are double-stranded DNA viruses, as are the viruses that cause smallpox and herpes in humans.

Some biologists think that at least some of the DNA viruses may represent highly reduced parasitic organisms that have lost their cellular structure as well as their ability to survive as free-living species. For example, the mimiviruses, which are some of the largest DNA viruses (see Figure 26.23F), have a genome in excess of a million base pairs of DNA that encodes more than 900 proteins. This genome is similar in size to the genomes of many parasitic bacteria and about twice as large as the genomes of the smallest bacteria (Figure 26.25). Phylogenetic analyses of these DNA viruses suggest that they have evolved repeatedly from cellular organisms. Furthermore, recombination among different viruses may have allowed the exchange of various genetic modules, further complicating the history and origins of these viruses.

Vertebrate genomes contain endogenous retroviruses

In introducing the RNA retroviruses, we noted that they insert their genomes into the genomes of their vertebrate hosts. As these incorporated retroviral genomes evolve over time, many become nonfunctional copies that are no longer expressed as functional viruses. These sequences may provide a record of ancient viral infections that plagued our ancestors. Humans, for example, carry about 100,000 fragments of endogenous retroviruses in our genome. These fragments make up about 8 percent of our DNA—a considerably larger fraction of our genome than the fraction that comprises all our protein-coding genes (about 1.2 percent of our genome).

In 2006 a French biologist named Thierry Heidmann examined the variants of one such endogenous retrovirus in a number of different people. He reasoned that each of these sequences might contain small numbers of changes from the original sequence. If so, then a consensus of the variants might resemble the original, functional sequence of a retrovirus. Heidmann constructed the consensus sequence in the lab and inserted it into human cells in culture. The cultured cells produced functional retroviruses, which could then infect other cells. Heidmann named this reconstructed virus “Phoenix” after the mythical bird that rose from the dead. Since then, biologists have resurrected other retroviruses from our genomes, and they have then identified and studied the genes that our cells use to disable these retroviral sequences and keep them from producing functional viruses. In this way, we are beginning to understand how our bodies fight retroviral infections.

Although many endogenous retroviral fragments in our genomes represent nonfunctional “ghost sequences,” in some cases we appear to have derived new functions from captured retroviral sequences. For example, when a developing fetus forms a placenta, the cells in the outer layer of the placenta fuse together. This fusion is accomplished by the expression of a protein on the cell’s surface, which allows the cells to attach and merge with one another. The protein that is responsible for this fusion is encoded in an endogenous retroviral sequence. Thus vertebrates appear to have co-opted some critical

26.25 Mimiviruses Have Genomes Similar in Size to Those of Many Parasitic Bacteria The genome of *Acanthamoeba polyphaga* mimivirus contains 1,181,404 base pairs and encompasses 911 protein-encoding genes. This observation is consistent with the hypothesis that this virus evolved from a parasitic bacterium.

functions from retroviral genomes that were inserted during ancient infections.

Viruses can be used to fight bacterial infections

Although some viruses cause devastating diseases, other viruses have been used to fight disease. Most bacterial diseases are treated today with antibiotics. But antibiotics were first discovered in the 1930s, and they were not widely used to treat bacterial diseases until the 1940s; antibiotics were not available during World War I, when bacterial infections plagued the battlefields. Battlefield wounds were often infected by bacteria, and in the absence of antibiotics, these infections often led to the loss of limbs and lives. While trying to find a way to combat this problem, a physician named Felix d’Herelle discovered the first evidence of viruses that attack bacteria. He named these viruses **bacteriophages**, or “eaters of bacteria.” d’Herelle extracted bacteriophages from the stool of infected patients. He then used these extracts to treat patients with deadly bacterial infections, including dysentery, cholera, and bubonic plague. This practice became known as phage therapy. After the war, phage therapy was widely used among the general public to treat bacterial infections of the skin and intestines.

Go to Media Clip 26.3

Bacteriophages Attack *E. coli*

Life10e.com/mc26.3

Phage therapy was mostly replaced by the use of antibiotics in the 1930s and 1940s as physicians grew concerned about treating patients with live viruses. Phage therapy continued to be used in the Soviet Union but largely disappeared from Western medical practice. Today, however, many antibiotics are losing their effectiveness as bacterial pathogens evolve resistance to these drugs. Phage therapy is once again an active area of research, and it is likely that bacteriophages will become increasingly important as weapons against bacterial diseases. One advantage that bacteriophages may have over

antibiotics is that, like bacteria, bacteriophages can evolve. As bacteria evolve resistance to a strain of bacteriophages, biologists can select for new strains of bacteriophages that retain their effectiveness against the pathogens. In this way, biologists are using their understanding of evolution to combat the problem of antibiotic-resistant bacteria.

Viruses are found throughout the biosphere

As biologists have learned to search for and recognize viruses, they have discovered that they occur in incredible abundance almost anywhere we look on Earth. They are abundant throughout the oceans of the world, for example, with an estimated 10^{30} individual viruses in marine environments. This means there are about 15 times more viruses in the oceans than there are cellular organisms, including all bacteria, archaea, and eukaryotes combined. Many of these viruses are bacteriophages, and they have an enormous effect on the ecology of the oceans. Every day, about half of the bacteria in the oceans are killed by viruses. Huge marine blooms of bacteria, such as the *Vibrio* bloom that produced the milky seas described at the opening of this chapter, do not last long because viral blooms soon follow the initial bacterial bloom. As the bacteriophages increase, they begin to kill bacteria faster than the bacteria can reproduce. Another species of *Vibrio* causes cholera in humans, and cholera epidemics also fade as bacteriophages increase and control these *Vibrio* population booms.

Many nutrient cycles, such as the carbon cycle (see Section 58.3), are strongly influenced by viral populations. Photosynthetic bacteria and algae produce about half of the oxygen in Earth's atmosphere. During photosynthesis, these organisms also take up carbon dioxide, which they use to produce organic carbon compounds. As these photosynthetic organisms are killed by viruses, their remains settle to the ocean bottom. These remains are a primary source of the vast oil reserves that occur under oceanic sediments. The constant growth and death of these photosynthetic organisms controlled largely by viruses. Because of their importance in controlling these populations, viruses have an enormous impact on Earth's climate and ecosystems.

RECAP 26.4

Viruses are highly diverse and appear to have evolved independently from many different cellular organisms within each of the major groups of life. Some viruses appear to have evolved from escaped components of cellular organisms, whereas other viruses may have evolved from parasitic cellular ancestors.

- Why is it difficult to place viruses precisely within the tree of life? **See p. 543**
- What are the two main hypotheses of viral origins? **See pp. 544–545**
- How can viruses be used to treat some human diseases? **See pp. 545–546**
- What are some of the ways that viruses can affect Earth's ecosystems? **See p. 546**

It may be best to view viruses as “spin-offs” from the various branches on the tree of life—sometimes evolving independently of cellular genomes, sometimes recombining with them. One way to think of viruses is as the “bark” on the tree of life: an important component all across the tree, but not quite like the main branches. The third of those main branches—the eukaryotes—will be our focus in the rest of Part 7.

What adaptive advantage does bioluminescence provide to *Vibrio* bacteria?

ANSWER

Although these marine *Vibrio* are able to live independently, they truly thrive inside the guts of fish and other marine animals. Inside a fish, *Vibrio* cells attach themselves to food particles, including phytoplankton, and are often expelled into the ocean as waste. How can they get back into their preferred environment? The bioluminescent glow produced by a dense colony of free-living *Vibrio* growing on phytoplankton attracts fish, which consume the phytoplankton and thus ingest the bacteria—which gets the bacteria into a new host fish.

Margaret McFall-Ngai and her colleagues have studied one species of bioluminescent *Vibrio*, *V. fischeri*, in which a symbiotic relationship with the Hawaiian bobtail squid (*Euprymna scolopes*) has evolved. Chemicals produced by a developing squid embryo specifically “recruit” *V. fischeri* from the surrounding seawater. The bacteria then preferentially migrate to specific tissues that develop into a bioluminescent “light organ” in the belly of the adult squid (**Figure 26.26**). The tiny (about 3 cm long) adult squid feed while floating near the sea surface at night. The soft glow produced by the bioluminescent bacteria mimics the moonlight above, so the squid are less visible to potential predators coming at them from below.

Vibrio fischeri live symbiotically inside the squid's light organ.

26.26 Bioluminescent Bacterial Symbionts *Vibrio* bacteria within the light organ emit bioluminescence downward as the Hawaiian bobtail squid floats near the ocean surface to feed. At night, this allows the squid to blend in with moonlight or starlight rather than becoming a target for a predator from below.

CHAPTERSUMMARY 26

26.1 Where Do Prokaryotes Fit into The Tree of Life?

- Two of life's three domains, Bacteria and Archaea, are prokaryotic. They are distinguished from Eukarya in several ways, including their lack of a nucleus and of membrane-enclosed organelles. **Review Table 26.1**
- Eukaryotes are related to both Archaea and Bacteria and appear to have originated through endosymbiosis between members of these two lineages. The last common ancestor of all three domains probably lived about 3 billion years ago. **Review Figure 26.1, ANIMATED TUTORIAL 26.1**
- Bacteria can be classified into two groups by the **Gram stain**. **Gram-negative bacteria** have a periplasmic space between the plasma membrane and a distinct outer membrane. **Gram-positive bacteria** have a thick cell wall containing about five times as much peptidoglycan as a Gram-negative wall. **Review Figure 26.2, ACTIVITY 26.1**
- The three most common bacterial shapes are **cocci** (spheres), **bacilli** (rods), and **spirilla** (helices). **Review Figure 26.3**
- Phylogenetic classification of prokaryotes is now based principally on the nucleotide sequences of rRNA and other genes involved in fundamental cellular processes.
- Although **lateral gene transfer** has occurred throughout prokaryotic evolutionary history, elucidation of many aspects of prokaryote phylogeny is still possible. **Review Figure 26.4**

26.2 Why Are Prokaryotes So Diverse and Abundant?

- Prokaryotes are the most numerous organisms on Earth.
- The **low-GC Gram-positives** include the **mycoplasmas**, which are among the smallest cellular organisms ever discovered.
- Some **high-GC Gram-positives** produce important antibiotics.
- The photosynthetic **cyanobacteria** release oxygen into the atmosphere. Cyanobacteria may live free as single cells or associate in multicellular colonies. **Review Figure 26.9**
- **Spirochetes** have unique structures called axial filaments that allow them to move in a corkscrew-like manner. **Review Figure 26.10**
- The **proteobacteria** embrace the largest number of known species of bacteria. Smaller groups include the **hyperthermophilic bacteria**, **hadobacteria**, and **chlamydias**.
- Many archaea are **extremophiles**. **Review Figure 26.14**

- **Ether linkages** in the branched long hydrocarbon chains of the lipids that make up the cell membranes are a synapomorphy of Archaea. **Review Figure 26.15**

26.3 How Do Prokaryotes Affect Their Environments?

- Prokaryotes form complex communities, of which **biofilms** are one example. **Review Figure 26.19**
- Prokaryote metabolism is very diverse. Some prokaryotes are anaerobic, others are aerobic, and still others can shift between these modes.
- Prokaryotes fall into four broad nutritional categories: **photoautotrophs**, **photoheterotrophs**, **chemoautotrophs**, and **chemoheterotrophs**. **Review Table 26.2**
- Prokaryotes play key roles in the cycling of elements such as nitrogen, oxygen, sulfur, and carbon.
- Diverse communities of bacteria and archaea live on and in most animals. The composition of these **microbiomes** is often closely associated with the animal's health. **Review Figure 26.21**
- **Koch's postulates** establish the criteria by which an organism may be classified as a pathogen. Relatively few bacteria—and no archaea—are known to be pathogens. **Review Figure 26.22**

26.4 How Do Viruses Relate to Life's Diversity and Ecology?

- Viruses have evolved many times from many different groups of cellular organisms. They are placed in groups according to the structure of their genomes, but these groups are not thought to represent monophyletic taxa. **Review Figure 26.23**
- Some viruses are probably derived from escaped components of cellular organisms; others are thought to have evolved as highly reduced parasites. **Review Figure 26.25**
- A large fraction of vertebrate (including human) genomes consists of incorporated remains of retroviral genomes.
- Bacteriophages have been used to treat bacterial infections in humans.
- Viruses are found in virtually all of Earth's environments and have a huge impact on the planet's ecosystems.

CHAPTERREVIEW

REMEMBERING

1. The division of the living world into three domains
 - a. is based on the number of cells in organisms of each group.
 - b. is based mostly on major morphological differences between archaea and bacteria.
 - c. emphasizes the greater importance of eukaryotes.
 - d. was proposed by the early microscopists.
 - e. is based on phylogenetic relationships determined from nucleotide sequences of rRNA and other genes.
2. Which statement about nitrogen metabolism is *not* true?
 - a. Certain prokaryotes reduce atmospheric N_2 to ammonia.
 - b. Some nitrifiers are soil bacteria.
 - c. Denitrifiers are obligate anaerobes.
 - d. Nitrifiers obtain energy by oxidizing ammonia and nitrite.
 - e. Without nitrifiers, terrestrial organisms would lack a nitrogen supply.

3. All photosynthetic bacteria
 - a. use chlorophyll *a* as their photosynthetic pigment.
 - b. use bacteriochlorophyll as their photosynthetic pigment.
 - c. release oxygen gas (O₂).
 - d. produce particles of sulfur.
 - e. are photoautotrophs.
4. Gram-negative bacteria
 - a. appear blue to purple following Gram staining.
 - b. appear pink to red following Gram staining.
 - c. are all either bacilli or cocci.
 - d. contain no peptidoglycan in their cell walls.
 - e. are all photosynthetic.

5. Archaea
 - a. have cytoskeletons.
 - b. have distinctive lipids in their plasma membranes.
 - c. survive only at moderate temperatures and near neutral pH.
 - d. all produce methane.
 - e. have substantial amounts of peptidoglycan in their cell walls.
6. Genetic evidence suggests that viruses
 - a. are most closely related to Bacteria.
 - b. are most closely related to Archaea.
 - c. are most closely related to Eukarya.
 - d. have evolved multiple times from many different cellular species.
 - e. evolved from the fusion of a bacterial and an archaeal species.

UNDERSTANDING & APPLYING

7. Why do systematic biologists find rRNA sequence data more useful than data on metabolism or cell structure for classifying prokaryotes?
8. The figure below shows an organismal tree in which gene *x* has undergone a lateral transfer event. Draw the phylogenetic tree you would expect based on gene *x*, as well as the phylogenetic tree you would expect based on a consensus of non-transferred genes.

9. Do you consider viruses to be living organisms? Why or why not?

ANALYZING & EVALUATING

10. Kashefi and Lovley were able to grow an unnamed archaeal species at temperatures above 120°C only because they used Fe₃⁺ as an electron acceptor—no other electron acceptor they tried allowed the archaean to grow (see Figure 26.14). How might you explore the same or other high-temperature environments for other hyperthermophilic organisms not detected by Kashefi and Lovley using Fe₃⁺?

The Origin and Diversification of Eukaryotes

CHAPTER OUTLINE

- 27.1** How Did the Eukaryotic Cell Arise?
- 27.2** What Features Account for Protist Diversity?
- 27.3** What Is the Relationship between Sex and Reproduction in Protists?
- 27.4** How Do Protists Affect Their Environments?

IN THE SUMMER of 2005, a devastating red tide crippled the shellfish industry along the Atlantic coast of North America from Canada to Massachusetts. This red tide was produced by a bloom of dinoflagellates of the genus *Alexandrium*. These protists produce a powerful toxin that accumulates in clams, mussels, and oysters. A person who eats a mollusk contaminated with the toxin can experience a syndrome known as paralytic shellfish poisoning. Many people were sickened by eating mollusks that were harvested before the problem was diagnosed, and losses to the shellfish industry in 2005 were estimated at \$50 million.

Several species of dinoflagellates produce toxic red tides in many parts of the world. Along the Gulf of Mexico, red tides caused by dinoflagellates of the genus *Karenia* produce a neurotoxin that affects the central nervous systems of fish, which become paralyzed and cannot respire effectively. Huge numbers of dead fish wash up on Gulf Coast beaches during a *Karenia* red tide. In addition, wave action can produce aerosols of the *Karenia* toxin, and these aerosols often cause asthma-like symptoms in humans on shore.

After the losses that resulted from the 2005 red tide, biologists at the Woods Hole Oceanographic Institution (WHOI) on Cape Cod began to monitor and model dinoflagellate populations off the New England coast. If biologists could accurately forecast future blooms, people in the area could be made aware of the problem in advance and adjust the shellfish harvest (and their eating habits) accordingly.

A Toxic Sea A bloom of dinoflagellates of the genus *Noctiluca* was responsible for this red tide in Puget Sound in the U. S. state of Washington.

Biologists from WHOI monitored counts of dinoflagellates in the water and in seafloor sediments. They also monitored river runoff, water currents, water temperature and salinity, winds, and tides. Another environmental factor they considered was the “nor’easter” storms common along the New England coast. By correlating their measurements of these environmental factors with dinoflagellate counts, biologists produced a model that predicted growth of dinoflagellate populations.

In spring 2008, the WHOI team determined that all the factors were in place to produce another red tide like the one of 2005—if a nor’easter occurred to blow the dinoflagellates toward the coast. A nor’easter did occur at just the wrong time, and another red tide materialized in summer 2008, just as predicted. But this time, people were warned. Shellfish harvesters adjusted their harvest, and many fewer people were harmed by eating toxic mollusks.

Can dinoflagellates be beneficial, as well as harmful, to marine ecosystems?

See answer on p. 566.

27.1 How Did the Eukaryotic Cell Arise?

We easily recognize trees, mushrooms, and insects as plants, fungi, and animals, respectively. But there is a dazzling assortment of other eukaryotic organisms—mostly microscopic—that do not fit into these three groups. Eukaryotes that are not plants, animals, or fungi have traditionally been called **protists**. But phylogenetic analyses reveal that many of the groups we commonly refer to as protists are not, in fact, closely related. Thus the term “protist” does not describe a formal taxonomic group, but is a convenience term for “all the eukaryotes that are not plants, animals, or fungi.”

The unique characteristics of the eukaryotic cell lead scientists to conclude that the eukaryotes are monophyletic and that a single eukaryotic ancestor diversified into the many different protist lineages as well as giving rise to the plants, fungi, and animals. As we saw in Section 26.1, eukaryotes are generally thought to be more closely related to Archaea than to Bacteria. The mitochondria and chloroplasts of eukaryotes, however, are clearly derived from bacterial lineages (see Figure 26.1).

Biologists traditionally hypothesized that the split of Eukarya from Archaea was followed by endosymbioses with bacterial lineages that led to the origin of mitochondria and chloroplasts. Some biologists prefer to view the origin of eukaryotes as the *fusion* of lineages from the two prokaryote groups. This difference is largely a semantic one that hinges on the point at which we deem the eukaryote lineage to have become definitively “eukaryotic.” In either case, we can make some reasonable inferences about the events that led to the evolution of a new cell type, bearing in mind that the environment underwent an enormous change—from low to high availability of atmospheric oxygen—during the course of these events.

The modern eukaryotic cell arose in several steps

At least five events were significant in the origin of the eukaryotic cell (Figure 27.1):

- The origin of a flexible cell surface
- The origin of a cytoskeleton
- The origin of a nuclear envelope, which enclosed a genome organized into chromosomes

27.1 A Hypothetical Sequence for the Evolution of the Eukaryotic Cell

The loss of a firm cell wall allowed the plasma membrane to fold inward and create more surface area, which facilitated the evolution of larger cells. As cells grew larger, cytoskeletal complexity increased, and the cell became increasingly compartmentalized. Endosymbioses involving bacteria gave rise to mitochondria and (in photosynthetic eukaryotes) to chloroplasts.

- The appearance of digestive vacuoles
- The acquisition of mitochondria and chloroplasts via endosymbiosis

FLEXIBLE CELL SURFACE We presume that ancient prokaryotic organisms, like most present-day prokaryotic cells, had firm cell walls. The first step toward the eukaryotic condition was the loss of the cell wall.

Consider the possibilities open to a flexible cell without a firm wall, starting with cell size. As a cell grows larger, its surface area-to-volume ratio decreases (see Figure 5.2). Unless the surface area can be increased, the cell's volume will reach an upper limit. If the cell's surface is flexible, however, it can fold inward, creating more surface area for gas and nutrient exchange. With a surface flexible enough to allow infolding, the cell can exchange materials with its environment rapidly enough to sustain a larger volume and more rapid metabolism (Figure 27.1, steps 1–2). Furthermore, a flexible surface can pinch off bits of the environment and bring them into the cell by endocytosis. These infoldings of the cell surface (which also exist in some modern prokaryotes) were important for the evolution of large eukaryotic cells.

CHANGES IN CELL STRUCTURE AND FUNCTION Other early steps that were important for the evolution of the eukaryotic cell are likely to have included three advances: the formation of ribosome-studded internal membranes, some of which surrounded the DNA; development of a complex cytoskeleton; and the evolution of digestive vacuoles (Figure 27.1, steps 3–7).

Until a few years ago, biologists thought that cytoskeletons were restricted to eukaryotes. Improved imaging technology and molecular analyses have now revealed homologs of many cytoskeletal proteins in prokaryotes, showing that simple cytoskeletons evolved before the origin of eukaryotes. The cytoskeleton of a eukaryote, however, is much more developed and complex than that of a prokaryote. This greater development of microfilaments and microtubules supports the eukaryotic cell and allows it to manage changes in shape, to distribute daughter chromosomes, and to move materials from one part of the large cell to other parts. In addition, the presence of microtubules in the cytoskeleton could have given rise in some cells to the characteristic eukaryotic flagellum.

The DNA of a prokaryotic cell is attached to a site on its plasma membrane. If that region of the plasma membrane were to fold into the cell, the first step would be taken toward the evolution of a nucleus, a primary feature of the eukaryotic cell.

The nuclear envelope appeared early in the eukaryote lineage. The next step was probably phagocytosis—the ability to engulf and digest other cells in digestive vacuoles. These digestive vacuoles eventually incorporated digestive enzymes to form lysosomes. Other infoldings of the plasma membrane developed into the endoplasmic reticulum and Golgi apparatus.

ENDOSYMBIOSIS At the same time the processes outlined above were taking place, cyanobacteria were generating oxygen gas as a product of photosynthesis. Increasing concentrations of O₂ in the oceans, and eventually in the atmosphere,

had disastrous consequences for most organisms of the time, which were unable to tolerate the newly oxidizing environment. But some prokaryotes evolved strategies to utilize the increasing oxygen and—fortunately for us—so did some of the new phagocytic eukaryotes.

At about this time, endosymbioses began to play a role in eukaryote evolution (Figure 27.1, steps 8–9). The theory of endosymbiosis proposes that certain organelles are the descendants of prokaryotes engulfed, but not digested, by early eukaryotic cells. One crucial event in the history of eukaryotes was the incorporation of a proteobacterium that evolved into the mitochondrion. Initially, the new organelle's primary function was probably to detoxify O₂ by reducing it to water. Later, this reduction became coupled with the formation of ATP in cellular respiration. Upon completion of this step, the essential modern eukaryotic cell was complete.

Photosynthetic eukaryotes are the result of yet another endosymbiotic step: the incorporation of a prokaryote related to today's cyanobacteria, which became the chloroplast.

Chloroplasts have been transferred among eukaryotes several times

Eukaryotes in several different groups possess chloroplasts, and groups with chloroplasts appear in several distantly related eukaryote clades. Some of these groups differ in the photosynthetic pigments their chloroplasts contain. And not all chloroplasts are limited to a pair of surrounding membranes like those found in plants—in some microbial eukaryotes, they are surrounded by three or more membranes. We now view these observations as evidence of a remarkable series of endosymbioses. This conclusion is supported by extensive evidence from electron microscopy and nucleic acid sequence comparisons.

All chloroplasts trace their ancestry back to the engulfment of one cyanobacterium by a larger eukaryotic cell. This event, the step that first gave rise to the photosynthetic eukaryotes, is known as **primary endosymbiosis** (Figure 27.2A). The cyanobacterium, a Gram-negative bacterium, had both an inner and an outer membrane (see Figure 26.2B). Thus the original chloroplasts had two surrounding membranes: the inner and outer membranes of the cyanobacterium. Remnants of the peptidoglycan-containing cell wall of the bacterium are present in the form of a bit of peptidoglycan between the chloroplast membranes of glaucophytes, the first eukaryote group to branch off following primary endosymbiosis (as we will see in Chapter 28). Primary endosymbiosis also gave rise to the chloroplasts of the red algae, green algae, and land plants. The red algal chloroplast retains certain pigments of the original cyanobacterial endosymbiont that are absent in green algal chloroplasts.

Almost all remaining photosynthetic eukaryotes are the result of additional rounds of endosymbiosis. For example, the photosynthetic euglenids derived their chloroplasts from **secondary endosymbiosis** (Figure 27.2B). Their ancestor took up a unicellular green alga, retaining its chloroplast and eventually losing the rest of the constituents of the alga. This history explains why the photosynthetic euglenids have the same photosynthetic pigments as the green algae and land plants. It also

27.2 Endosymbiotic Events in the Evolution of Chloroplasts

(A) A single instance of primary endosymbiosis ultimately gave rise to all of today's chloroplasts. (B) Secondary endosymbiosis—the uptake and retention of a chloroplast-containing cell by another eukaryotic cell—took place several times, independently.

Go to Animated Tutorial 27.1
Family Tree of Chloroplasts
Life10e.com/at27.1

accounts for the third membrane of the euglenid chloroplast, which is derived from the euglenid's plasma membrane (as a result of endocytosis). An additional round—**tertiary endosymbiosis**—occurred when a dinoflagellate apparently lost its chloroplast and took up another protist that had acquired its chloroplast through secondary endosymbiosis.

RECAP 27.1

The modern eukaryotic cell probably arose from an ancestral prokaryote in several steps, including the origin of a flexible cell surface, the enclosure of the genetic material in a nucleus, and endosymbiosis.

- What were the steps that led to the evolution of the eukaryotic cell? [See pp. 550–551 and Figure 27.1](#)
- Why was the development of a flexible cell surface a key event for eukaryote evolution? [See p. 551](#)
- Explain how increased availability of atmospheric oxygen (O_2) could have influenced the evolution of the eukaryotic cell. [See p. 551](#)

The features that eukaryotes gained from archaea and bacteria have allowed them to exploit many different environments. This led to the evolution of great diversity among eukaryotes, beginning with a radiation that started in the Precambrian.

27.2

What Features Account for Protist Diversity?

Most eukaryotes can be placed in one of eight major clades that began to diversify about 1.5 billion years ago: alveolates, stramenopiles, rhizaria, excavates, plants, amoebozoans, fungi, and animals (**Figure 27.3**). Plants, fungi, and animals each have close protist relatives (such as the choanoflagellate relatives of animals), which we will discuss along with those major multicellular eukaryote groups in Chapters 28–33.

Each of the five major groups of eukaryotes covered in this chapter consists of organisms with enormously diverse body forms and lifestyles. Some protists are motile, whereas others do not move; some are photosynthetic, others heterotrophic; most are unicellular, but some are multicellular. Most are microscopic, but a few are huge (giant kelps, for example, can grow to half the length of a football field). We refer to the unicellular species of protists as **microbial eukaryotes**, but keep in mind that there are large, multicellular protists as well.

Multicellularity has arisen dozens of times across the evolutionary history of eukaryotes. Four of the origins of multicellularity resulted in large organisms that are familiar to most people: plants, animals, fungi, and brown algae (the last are a group of stramenopiles). In addition, there are dozens of smaller and less familiar groups among the eukaryotes that include multicellular species. Recent experimental studies have shown that artificial selection for multicellularity can produce repeated, convergent evolution of multicellular forms over just a few months in some normally unicellular eukaryotic species. In addition, many unicellular species retain individual identities but nonetheless associate in large multicellular colonies.

There is a near-continuum between fully integrated, multicellular organisms on the one hand and loosely integrated multicellular colonies of cells on the other. Biologists do not always agree on where to draw the line between the two.

Biologists used to classify protists largely on the basis of their life histories and reproductive features. In recent years, however, electron microscopy and gene sequencing have revealed many new patterns of evolutionary relatedness among these groups. Analyses of slowly evolving gene sequences are making it possible to explore evolutionary relationships among eukaryotes in ever greater detail and with greater confidence. Nonetheless, some substantial areas of uncertainty remain, and lateral gene transfer may complicate our efforts to reconstruct the evolutionary history of protists (as is also true for prokaryotes; see Section 26.1). Today we recognize great diversity among the many distantly related protist clades.

Alveolates have sacs under their plasma membranes

Alveolates are so named because they possess sacs, called alveoli, just beneath their plasma membranes, which may play a role in supporting the cell surface. All alveolates are unicellular, and most are photosynthetic, but they are diverse in body form. The alveolate groups we will consider in detail here are the dinoflagellates, apicomplexans, and ciliates.

DINOFLAGELLATES Most **dinoflagellates** are marine and photosynthetic; they are important primary producers of organic matter in the oceans. Although fewer *species* of dinoflagellates live in fresh water, individuals can be abundant in freshwater environments. The dinoflagellates are of great ecological, evolutionary, and morphological interest. A distinctive mixture of

27.3 Precambrian Divergence of Major Eukaryote Groups

A phylogenetic tree shows one current hypothesis and estimated time line for the origin of the major groups of eukaryotes. The rapid divergence of major lineages between 1.5 and 1.4 billion years ago makes reconstruction of their precise relationships difficult. The major multicellular groups (tinted boxes) will be covered in subsequent chapters.

photosynthetic and accessory pigments gives their chloroplasts a golden brown color. Some dinoflagellate species cause red tides, as discussed at the opening of this chapter. Other species are photosynthetic endosymbionts that live within the cells of other organisms, including invertebrate animals (such as corals; see Figure 27.21) and other marine protists (see Figure 27.12A). Still others are nonphotosynthetic and live as parasites within other marine organisms.

Dinoflagellates have a distinctive appearance. They generally have two flagella, one in an equatorial groove around the cell, the other starting near the same point as the first and passing down a longitudinal groove before extending into the surrounding medium (**Figure 27.4**). Some dinoflagellates can take on different forms, including amoeboid ones, depending on environmental conditions. It has been claimed that the dinoflagellate *Pfiesteria piscicida* can occur in at least two dozen distinct forms, although this claim is highly controversial. In any case, this remarkable dinoflagellate, when present in large enough numbers, is harmful to fish and can both stun and feed on them.

APICOMPLEXANS The exclusively parasitic **apicomplexans** derive their name from the apical complex, a mass of organelles contained in the apical end (the tip) of the cell. These organelles help the apicomplexan invade its host's tissues. For example, the apical complex enables *Plasmodium*, the causative agent of malaria, to enter its target cells in the human body after transmission by a mosquito.

Peridinium sp.

27.4 A Dinoflagellate The presence of two flagella is characteristic of many dinoflagellates, although these appendages are contained within deep grooves and thus are seldom visible. One flagellum lies within the equatorial groove and provides forward thrust and spin to the organism. The second flagellum originates in the longitudinal groove and acts like the rudder of a boat.

Go to Media Clip 27.1

A Dinoflagellate Shows Off Its Flagellum

Life10e.com/mc27.1

Like many obligate parasites, apicomplexans have elaborate life cycles featuring asexual and sexual reproduction through a series of very dissimilar life stages (see Figure 27.20). In many species, these life stages are associated with two different types of host organisms, as is the case with *Plasmodium*. Another apicomplexan, *Toxoplasma*, alternates between cats and rats to complete its life cycle. A rat infected with *Toxoplasma* loses its

fear of cats, which makes it more likely to be eaten by, and thus transfer the parasite to, a cat.

CILIATES The **ciliates** are named for their numerous hairlike cilia, which are shorter than, but otherwise identical to, eukaryotic flagella. The ciliates are much more complex in body form than are most other unicellular eukaryotes (Figure 27.5). Their definitive characteristic is the possession of two types of nuclei (whose roles we will describe in Section 27.3 when we discuss protist reproduction). Almost all ciliates are heterotrophic, although a few contain photosynthetic endosymbionts.

Paramecium, a frequently studied ciliate genus, exemplifies the complex structure and behavior of ciliates (Figure 27.6). The slipper-shaped cell is covered by an elaborate pellicle, a structure composed principally of an outer membrane and an inner layer of closely packed, membrane-enclosed sacs (the alveoli) that surround the bases of the cilia. Defensive organelles called trichocysts are also present in the pellicle. In response to a threat, a microscopic explosion expels the trichocysts in a few milliseconds, and they emerge as sharp darts, driven forward at the tip of a long, expanding filament.

The cilia provide *Paramecium* with a form of locomotion that is generally more precise than locomotion by flagella. A *Paramecium* can coordinate the beating of its cilia to propel itself either forward or backward in a spiraling manner. It can also back off swiftly when it encounters a barrier or a negative stimulus. The coordination of ciliary beating is probably the result of a differential distribution of ion channels in the plasma membrane near the two ends of the cell.

Organisms living in fresh water are hypertonic to their environment. Many freshwater protists, including *Paramecium*, address this problem by means of specialized **contractile vacuoles** that excrete the excess water the organisms constantly take in by osmosis. The excess water collects in the contractile vacuoles, which then contract and expel the water from the cell.

(A) *Paramecium* sp.(B) *Didinium nasutum*(C) *Euplotes* sp.

27.5 Diversity among the Ciliates (A) A free-swimming organism, this *Paramecium* belongs to a ciliate group whose members have many cilia of uniform length. (B) The barrel-shaped *Didinium nasutum* feeds on other ciliates, including *Paramecium*. Its cilia occur in two separate bands. (C) Some of the cilia in *Euplotes* fuse into flat sheets that direct food particles into an oral groove.

27.6 Anatomy of *Paramecium* *Paramecium*, with its many specialized organelles, exemplifies the complex body form of ciliates.

Go to Activity 27.1 Anatomy of *Paramecium*

Life10e.com/ac27.1

Paramecium and many other protists engulf solid food by endocytosis, forming a **digestive vacuole** within which the food is digested (Figure 27.7). Smaller vesicles containing digested food pinch away from the digestive vacuole and enter the cytoplasm. These tiny vesicles provide a large surface area across which the products of digestion can be absorbed by the rest of the cell.

Go to Animated Tutorial 27.2

Digestive Vacuoles

Life10e.com/at27.2

Stramenopiles typically have two flagella of unequal length

A morphological synapomorphy of most **stramenopiles** is the possession of two flagella of unequal length, with rows of tubular hairs on the longer of the two. Some stramenopiles lack flagella, but they are descended from ancestors that possessed flagella. The stramenopiles include the diatoms and the brown algae, which are photosynthetic, and the oomycetes, which are not.

DIATOMS All of the **diatoms** are unicellular, although some species associate in filaments. Many have sufficient carotenoids in their chloroplasts to give them a yellow or brownish color. All of them synthesize carbohydrates and oils as photosynthetic storage products. Diatoms lack flagella except in male gametes.

Architectural magnificence on a microscopic scale is the hallmark of the diatoms. Almost all diatoms deposit silica (hydrated silicon dioxide) in their cell walls. The cell wall of a diatom is

INVESTIGATINGLIFE

27.7 The Role of Vacuoles in Ciliate Digestion An acidic environment is known to aid digestion in many multicellular organisms. Do ciliates also use acid to obtain nutrients?*

HYPOTHESIS The digestive vacuoles of *Paramecium* produce an acidic environment that allows the organism to digest food particles.

Method

1. Feed *Paramecium* yeast cells stained with Congo red, a dye that is red at neutral or basic pH but turns green at acidic pH.
2. Under a light microscope, observe the formation and degradation of digestive vacuoles within the *Paramecium*. Note time and sequence of color (i.e., acid level) changes.

Results

CONCLUSION Some ciliates acidify digestive vacuoles to assist in the breakdown of food.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

*Mast, S. O. 1947. *Biological Bulletin* 92: 31–72.

constructed in two pieces, with the top overlapping the bottom like the top of a petri dish. The silica-impregnated walls have intricate patterns unique to each species (Figure 27.8). Despite their remarkable morphological diversity, all diatoms are symmetrical—either bilaterally (with “right” and “left” halves) or radially (with the type of symmetry possessed by a circle).

Diatoms reproduce both sexually and asexually. Asexual reproduction by binary fission is somewhat constrained by the stiff cell wall. Both the top and bottom of the “petri dish” become tops of new “dishes” without changing appreciably in size; as a result, the new cell made from the former bottom is smaller than the parent cell. If this process continued indefinitely, one cell line would simply vanish, but sexual reproduction largely solves this

27.8 Diatom Diversity This bright-field micrograph illustrates the variety of species-specific forms found among the diatoms.

Diatoms In Action
Life10e.com/mc27.2

potential problem. Gametes are formed, shed their cell walls, and fuse. The resulting zygote then grows substantially in size before a new cell wall is laid down.

Diatoms are found in all the oceans and are frequently present in great numbers. They are major photosynthetic producers in coastal waters and are among the dominant organisms in the dense “blooms” of phytoplankton that occasionally appear in the open ocean (see Section 27.4). Diatoms are also common in fresh water and even occur on the wet surfaces of terrestrial mosses.

BROWN ALGAE The **brown algae** obtain their namesake color from the carotenoid **fucoxanthin**, which is abundant in their chloroplasts. The combination of this yellow-orange pigment with the green of chlorophylls *a* and *c* yields a brownish tinge. All brown algae are multicellular, and some are extremely large. Giant kelps such as those of the genus *Macrocystis* may be up to 60 meters long (see Figure 54.9).

 **Go to Media Clip 27.3**
A Kelp Forest
Life10e.com/mc27.3

The brown algae are almost exclusively marine. They are composed either of branched filaments (Figure 27.9A) or of leaflike growths (Figure 27.9B). Some float in the open ocean; the most famous example is the genus *Sargassum*, which forms dense mats in the Sargasso Sea in the mid-Atlantic. Most brown

27.9 Brown Algae (A) This seaweed illustrates the filamentous growth form of the brown algae. (B) Sea palms exemplify the leaf-like growth form of brown algae. Sea palms and many other brown algal species are “glued” to the rocks by tough, branched structures called holdfasts that can withstand the pounding of the surf.

algae, however, attach themselves to rocks near the shore. A few thrive only where they are regularly exposed to heavy surf. All of the attached forms develop a specialized structure, called a holdfast, that literally glues them to the rocks. The “glue” of the holdfast is alginic acid, a gummy polymer found in the walls of many brown algal cells. In addition to its function in holdfasts, alginic acid cements algal cells and filaments together. It is harvested and used by humans as an emulsifier in ice cream, cosmetics, and other products.

OOMYCETES The **oomycetes** are the water molds and their terrestrial relatives. Water molds are filamentous and stationary. They are **absorptive heterotrophs**—that is, they secrete enzymes that digest large food molecules into smaller molecules that they can absorb. They are all aquatic and **saprobic**—meaning they feed on dead organic matter. If you have seen a whitish, cottony mold growing on dead fish or dead insects in water, it was probably a water mold of the common genus *Saprolegnia* (Figure 27.10).

Some other oomycetes, such as the downy mildews, are terrestrial. Although most of the terrestrial oomycetes are harmless or helpful decomposers of dead matter, a few are plant parasites that attack crops such as avocados, grapes, and potatoes.

Oomycetes were once classified as fungi. However, we now know that their similarity to fungi is only superficial, and that the oomycetes are more distantly related to the fungi than are many other eukaryote groups, including humans (see Figure 27.3). For example, the cell walls of oomycetes are typically made of cellulose, whereas those of fungi are made of chitin.

Saprolegnia sp.

27.10 An Oomycete The filaments of a water mold radiate from the carcass of a beetle.

Rhizaria typically have long, thin pseudopods

The three primary groups of **Rhizaria**—cercozoans, foraminiferans, and radiolarians—are unicellular and mostly aquatic. The rhizaria have contributed their shells to ocean sediments, some of which have become terrestrial features over the course of geological history.

CERCOZOANS The **cercozoans** are a diverse group with many forms and habitats. Some are aquatic; others live in soil. One group of cercozoans possesses chloroplasts derived from a green alga by secondary endosymbiosis, and those chloroplasts contain a trace of the alga's nucleus.

(B)

*Hexacontium* sp.

27.11 Building Blocks of Limestone Some foraminiferans secrete calcium carbonate to form shells. The shells of different species have distinctive shapes. Over millions of years, the shells of foraminiferans have accumulated to form limestone deposits.

FORAMINIFERANS Some **foraminiferans** secrete external shells of calcium carbonate (**Figure 27.11**). These shells have accumulated over time to produce much of the world's limestone. Some foraminiferans live as plankton; others live on the seafloor. Living foraminiferans have been found 10,896 meters down in the western Pacific's Challenger Deep—the deepest point in the world's oceans. At that depth, however, they cannot secrete normal shells because the surrounding water is too poor in calcium carbonate.

In living planktonic foraminiferans, long, threadlike, branched pseudopods extend through numerous microscopic apertures in the shell and interconnect to create a sticky, reticulated net, which the foraminiferans use to catch smaller plankton. In some foraminiferan species, the pseudopods provide locomotion.

RADIOLARIANS **Radiolarians** are recognizable by their thin, stiff pseudopods, which are reinforced by microtubules (**Figure 27.12A**). These pseudopods greatly increase the surface area of the cell, and they help the cell stay afloat in its marine environment.

27.12 Radiolarians Exhibit Distinctive Pseudopods and Radial Symmetry (A) The radiolarians are distinguished by their thin, stiff pseudopods and by their radial symmetry. The pigmentation seen at the center of this radiolarian's glassy endoskeleton is imparted by endosymbiotic dinoflagellates. (B) The endoskeleton secreted by a radiolarian.

Radiolarians also are immediately recognizable by their distinctive radial symmetry. Almost all radiolarian species secrete glassy endoskeletons (internal skeletons). The skeletons of the different species are as varied as snowflakes, and many have elaborate geometric designs (Figure 27.12B). A few radiolarians are among the largest of the unicellular eukaryotes, measuring several millimeters across.

Excavates began to diversify about 1.5 billion years ago

The **excavates** include a number of diverse groups that began to split from one another soon after the origin of eukaryotes. Several groups of excavates lack mitochondria, an absence that once led to the view that these groups might represent early-diverging eukaryotes that diversified before the evolution of mitochondria. However, the discovery of genes in the nucleus that are normally associated with mitochondria suggests that the absence of mitochondria is a derived condition in these organisms. In other words, ancestors of these excavate groups probably possessed mitochondria that were lost or reduced over the course of evolution. The existence of these organisms today shows that eukaryotic life is possible without mitochondria.

DIPLOMONADS AND PARABASALIDS The **diplomonads** and the **parabasalids** are unicellular and lack mitochondria (although they have reduced organelles that are derived from mitochondria). The parasitic *Giardia lamblia*, a diplomonad, causes the intestinal disease giardiasis. *Giardia* infections may result from contact with contaminated water; in the United States, such infections are most common among hikers and campers using spring or stream water in recreational areas. This tiny organism has a cytoskeleton and multiple flagella, and contains two nuclei bounded by nuclear envelopes (Figure 27.13A).

In addition to flagella and a cytoskeleton, the parabasalids have undulating membranes that also contribute to the cell's locomotion. *Trichomonas vaginalis* (Figure 27.13B) is a parabasalid responsible for a sexually transmitted disease in humans. Infection of the male urethra, where it may occur without symptoms, is less common than infection of the vagina.

HETEROLOBOSEANS The amoeboid body form appears in several protist groups that are only distantly related to one another. The body forms of **heteroloboseans**, for example, resemble those of loboseans, an amoebozoan group that is not at all closely related to heteroloboseans (see the next section). Amoebas of the free-living heterolobosean genus *Naegleria*, some of which can enter the human body and cause a fatal disease of the nervous system, usually have a two-stage life cycle, in which one stage has amoeboid cells and the other flagellated cells.

EUGLENIDS AND KINETOPLASTIDS The **euglenids** and **kinetoplastids** together constitute a clade of unicellular excavates with flagella. Their mitochondria contain distinctive disc-shaped

(A) *Giardia* sp.

(B) *Trichomonas vaginalis*

27.13 Some Excavate Groups Lack Mitochondria (A) *Giardia*, a diplomonad, has flagella and two nuclei. (B) *Trichomonas*, a parabasalid, has flagella and undulating membranes. Neither of these organisms possesses mitochondria.

cristae, and their flagella contain a crystalline rod not found in other organisms. They reproduce primarily asexually.

The flagella of euglenids arise from a pocket at the anterior end of the cell. Spiraling strips of proteins under the plasma membrane control the cell's shape. Some euglenids are photosynthetic. Figure 27.14 depicts a typical cell of the genus *Euglena*. This common freshwater organism has a complex cell structure. It propels itself through the water with the longer of its two flagella, which may also serve as an anchor to hold the organism in place. The second flagellum is often rudimentary.

Go to Media Clip 27.4

Euglenids

Life10e.com/mc27.4

The euglenids have diverse nutritional requirements. Many species are always heterotrophic. Other species, including species of *Euglena*, are fully autotrophic in sunlight, using chloroplasts to synthesize organic compounds through photosynthesis. When kept in the dark, these euglenids lose their photosynthetic pigment and begin to feed exclusively on dissolved organic material in the water around them. A "bleached" *Euglena* resynthesizes its photosynthetic pigment when it is returned to the light and becomes autotrophic again. But *Euglena* cells treated with certain antibiotics or mutagens lose their photosynthetic pigment completely; neither they nor

27.14 A Photosynthetic Euglenid In the *Euglena* species illustrated in this drawing, the second flagellum is rudimentary. Note that the primary flagellum originates at the anterior of the organism and trails toward its posterior.

their descendants are ever autotrophs again. However, those descendants function well as heterotrophs.

The kinetoplastids are unicellular parasites with two flagella and a single, large mitochondrion. The mitochondrion contains a kinetoplast, a unique structure housing multiple circular DNA molecules and associated proteins. Some of these DNA molecules encode “guide proteins” that edit mRNA within the mitochondrion.

The kinetoplastids include several medically important species of pathogenic trypanosomes (Table 27.1). Some of these organisms are able to change their cell surface recognition molecules frequently. This ability allows them to evade our best attempts to kill them and thus eradicate the diseases they cause.

Amoebozoans use lobe-shaped pseudopods for locomotion

Amoebozoans appear to have diverged from other eukaryotes about 1.5 billion years ago (see Figure 27.3). It is not yet clear whether they are more closely related to opisthokonts (which include fungi and animals) or to other major groups of eukaryotes. The lobe-shaped pseudopods of amoebozoans are a hallmark of

Chaos carolinensis

the amoeboid body form (Figure 27.15). Amoebozoan pseudopods differ in form and function from the slender pseudopods of rhizaria. We consider three amoebozoan groups here: the loboseans and two groups known as slime molds.

	<i>Trypanosoma brucei</i>	<i>Trypanosoma cruzi</i>	<i>Leishmania major</i>
Human disease	Sleeping sickness	Chagas disease	Leishmaniasis
Insect vector	Tsetse fly	Assassin bugs (many species)	Sand fly
Vaccine or effective cure	None	None	None
Strategy for survival	Changes surface recognition molecules frequently	Causes changes in surface recognition molecules on host cell	Reduces effectiveness of macrophage hosts
Site in human body	Bloodstream; in final stages, attacks nerve tissue	Enters cells, especially muscle cells	Enters cells, primarily macrophages
Approximate number of deaths per year	50,000	45,000	60,000

Nebela collaris

27.16 Life in a Glass House This testate amoeba has built a lightbulb-shaped shell, or test, by gluing sand grains together. Its pseudopods extend through the single aperture in the test.

LOBOSEANS **Loboseans** are small amoebozoans that feed on other small organisms and particles of organic matter by phagocytosis, engulfing them with pseudopods. Many loboseans are adapted for life on the bottoms of lakes, ponds, and other bodies of water. Their creeping locomotion and their manner of engulfing food particles fit them for life close to a relatively rich supply of sedentary organisms or organic particles. Most loboseans exist as predators, parasites, or scavengers. Members of one group of loboseans, the testate amoebas, live inside shells. Some of these amoebas produce casings by gluing sand grains together (**Figure 27.16**); other testate amoebas have shells secreted by the organism itself.

PLASMODIAL SLIME MOLDS If the nucleus of an amoeba began rapid mitotic division, accompanied by a tremendous increase in cytoplasm and organelles, but no cytokinesis, the resulting organism would resemble the multinucleate mass of a **plasmodial slime mold**. During its vegetative (feeding, nonreproductive) stage, a plasmodial slime mold is a wall-less mass of cytoplasm with numerous diploid nuclei. This mass streams very slowly over its substrate in a remarkable network of strands called a plasmodium (**Figure 27.17A**). The plasmodium is an example of a **coenocyte**: many nuclei enclosed in a single plasma membrane. The outer cytoplasm of the plasmodium (closest to the environment) is normally less fluid than the interior cytoplasm and thus provides some structural rigidity.

Plasmodial slime molds provide a dramatic example of movement by **cytoplasmic streaming**. The outer cytoplasm

27.17 A Plasmodial Slime Mold (A) The plasmodial form of the slime mold *Hemitrachia serpula* covers rocks, decaying logs, and other objects as it engulfs bacteria and other food items; it is also responsible for the organism's common name of "pretzel mold." (B) Fruiting structures of *Hemitrachia*.

Go to Media Clip 27.6
Plasmodial Slime Mold Growth
Life10e.com/mc27.6

of the plasmodium becomes more fluid in places, and cytoplasm rushes into those areas, stretching the plasmodium. This streaming reverses its direction every few minutes as cytoplasm rushes into a new area and drains away from an older one, moving the plasmodium over its substrate. Sometimes an entire wave of plasmodium moves across a surface, leaving strands behind. Microfilaments and a contractile protein called myxomyosin interact to produce the streaming movement. As it moves, the plasmodium engulfs food particles by endocytosis—predominantly bacteria, yeasts, spores of fungi, and other small organisms as well as decaying animal and plant remains.

A plasmodial slime mold can grow almost indefinitely in its plasmodial stage as long as the food supply is adequate and other conditions, such as moisture and pH, are favorable. If conditions become unfavorable, however, one of two things can happen. In one case, the plasmodium can form an irregular mass of hardened, cell-like components called a **sclerotium**. This resting structure rapidly becomes a plasmodium again when favorable conditions are restored.

Alternatively, the plasmodium can transform itself into spore-bearing **fruiting structures** (Figure 27.17B). These stalked or branched structures rise from heaped masses of plasmodium. They derive their rigidity from walls that form and thicken between their nuclei. The diploid nuclei of the plasmodium divide by meiosis as the fruiting structure develops. One or more knobs, called sporangia, develop on the end of the stalk. Within a sporangium, haploid nuclei become surrounded by walls to form spores. Eventually, as the fruiting structure dries, it sheds its spores.

The spores germinate into wall-less, haploid cells called **swarm cells**, which can either divide mitotically to produce more haploid swarm cells or function as gametes. Swarm cells can live as separate individual cells that move by means of flagella or pseudopods, or they can become walled and resistant resting cysts when conditions are unfavorable; when conditions improve again, the cysts release swarm cells. Two swarm cells can also fuse to form a diploid zygote, which divides by mitosis (but without a wall forming between the nuclei) and thus forms a new coenocytic plasmodium.

CELLULAR SLIME MOLDS Whereas the plasmodium is the basic vegetative unit of the plasmodial slime molds, a single amoeboid cell is the vegetative unit of the **cellular slime molds** (Figure 27.18). Cells called **myxamoebas**, which have single haploid nuclei, swarm together as they engulf bacteria and other food particles by endocytosis and reproduce by mitosis and fission. This simple life cycle stage, consisting of swarms of independent, isolated cells, can persist indefinitely as long as food and moisture are available.

When conditions become unfavorable, the cellular slime molds form fruiting structures, as do their plasmodial counterparts. The individual myxamoebas aggregate into a mass called a **slug** or **pseudoplasmodium**. Unlike the true plasmodium of the plasmodial slime molds, this structure is not simply a giant sheet of cytoplasm with many nuclei; the individual myxamoebas within the slug retain their plasma membranes and therefore their identity.

A slug may migrate over a substrate for several hours before becoming motionless and reorganizing to construct a delicate, stalked fruiting structure. Cells at the top of the fruiting structure develop into thick-walled spores, which are eventually released. Later, under favorable conditions, the spores germinate, releasing myxamoebas.

The cycle from myxamoebas through slug and spores to new myxamoebas is asexual. Cellular slime molds also have a sexual cycle, in which two myxamoebas fuse. The product of

Dictyostelium discoideum

Go to Media Clip 27.7

Cellular Slime Mold Aggregation

Life10e.com/mc27.7

this fusion develops into a spherical structure that ultimately germinates, releasing new haploid myxamoebas.

RECAP 27.2

The major lineages of eukaryotes began to diverge about 1.5 billion years ago. Major groups of eukaryotes are highly diverse in their habitat, nutrition, locomotion, and body form. Many protists are photosynthetic autotrophs, but heterotrophic lineages have evolved repeatedly. Although most protists are unicellular, multicellularity has arisen independently many times.

- Contrast the major distinctive features of alveolates, excavates, stramenopiles, rhizaria, and amoebozoans.
- Give examples of alveolates, stramenopiles, and excavates that are important for medical or agricultural reasons.

See pp. 553–558 and Table 27.1.

The ancient origins of the major eukaryote lineages and the adaptation of these lineages to a wide variety of lifestyles and environments resulted in enormous protist diversity. It is not surprising, then, that reproductive modes among protists are also highly diverse.

27.19 Conjugation in *Paramecia* The exchange of micronuclei by two conjugating *Paramecium* individuals results in genetic recombination. After conjugation, the cells separate and continue their lives as two individuals.

27.3 What Is the Relationship between Sex and Reproduction in Protists?

Although most protists engage in both asexual and sexual reproduction, sexual reproduction has yet to be observed in some groups. In some protists, as in all prokaryotes, the acts of sex and reproduction are not directly linked. Several asexual reproductive processes have been observed among the protists:

- The equal splitting of one cell into two by mitosis followed by cytokinesis
- The splitting of one cell into multiple (i.e., more than two) cells
- The outgrowth of a new cell from the surface of an old one (known as **budding**)
- The formation of specialized cells (spores) that are capable of developing into new individuals (known as **sporulation**)

Asexual reproduction results in offspring that are genetically nearly identical to their parents (they differ only by new mutations that may arise during DNA replication). Such asexually reproduced groups of nearly identical organisms are known as **clonal lineages**, or **clones**.

Sexual reproduction among the protists takes various forms. In some protists, as in animals, the gametes are the only haploid cells. In others, the zygote is the only diploid cell. In still others, both diploid and haploid cells undergo mitosis, giving rise to alternating multicellular diploid and haploid life stages.

Some protists reproduce without sex and have sex without reproduction

As noted in Section 27.2, members of the genus *Paramecium* are ciliates, which commonly have two types of nuclei in a single cell (one macronucleus and from one to several micronuclei; see

Figure 27.6). The micronuclei are typical eukaryotic nuclei and are essential for genetic recombination. The macronucleus contains many copies of the genetic information, packaged in units containing only a few genes each. The macronuclear DNA is transcribed and translated to regulate the life of the cell.

When *paramecia* reproduce asexually, all of the nuclei are copied before the cell divides. *Paramecia* (and many other protists) also have an elaborate sexual behavior called **conjugation**, in which two individuals line up tightly against each other and fuse in the oral groove region of the body. Nuclear material is extensively reorganized and exchanged over the next several hours (Figure 27.19). Each cell ends up with two haploid micronuclei, one of its own and one from the other cell, which fuse to form a new diploid micronucleus. A new macronucleus develops from that micronucleus through a series of dramatic chromosomal rearrangements. The exchange of nuclei is fully reciprocal: each of the two *paramecia* gives and receives an equal amount of DNA. The two organisms then separate and go their own ways, each equipped with new combinations of alleles.

Conjugation in *Paramecium* is a sexual process (i.e., a process of genetic recombination), but it is not a reproductive process. Two cells begin conjugation and two cells are there at the end, so no new cells are created. As a rule, each asexual clone of *paramecia* must conjugate periodically. Experiments have shown that if some species are not permitted to conjugate, the clones can live through only about 350 cell divisions before dying out.

Some protist life cycles feature alternation of generations

Alternation of generations is a feature of the life cycles of many multicellular protists, all land plants, and some fungi. In these life cycles, a multicellular, diploid, spore-producing stage gives rise to a multicellular, haploid, gamete-producing stage (see Figure 28.6). When two haploid gametes fuse, a diploid organism is produced. The haploid organism, the diploid organism, or both may also reproduce asexually. Note that alternation of generations is distinct from the familiar reproductive system of animals, in which the only haploid stages are unicellular gametes produced by multicellular, diploid adults.

The two alternating (spore-producing and gamete-producing) generations differ genetically (one has diploid cells, the other haploid cells), but they may or may not differ morphologically. In **heteromorphic** alternation of generations, the two generations differ morphologically; in **isomorphic** alternation of generations, they do not. Examples of both heteromorphic and isomorphic alternation of generations are found among the brown algae.

The gamete-producing generation does not produce gametes by meiosis because the gamete-producing organism is already haploid. Instead, specialized cells of the diploid spore-producing organism, called **sporocytes**, divide meiotically to produce four haploid *spores*. The spores may eventually germinate and divide mitotically to produce the multicellular haploid generation, which then produces gametes by mitosis and cytokinesis.

Gametes, unlike spores, can produce new organisms only by fusing with other gametes. The fusion of two gametes produces a diploid zygote, which then undergoes mitotic divisions to produce a diploid organism. The diploid organism's sporocytes then undergo meiosis and produce haploid spores, starting the cycle anew.

RECAP 27.3

Protists reproduce both asexually and sexually, although sex occurs independently of reproduction in some species. Some multicellular protists exhibit alternation of generations, alternating between multicellular haploid and diploid life stages.

- Why is conjugation between paramecia considered a sexual process but not a reproductive process? [See p. 562 and Figure 27.19](#)
- Although most diploid animals have haploid stages (for example, eggs and sperm), their life cycles are not considered an example of alternation of generations. Why not? [See pp. 562–563](#)

Given the diversity of protists and of the environments in which they live, it is not surprising that they influence their environments in numerous ways.

27.4 How Do Protists Affect Their Environments?

As we have seen, many microbial eukaryotes are food for aquatic animals, while others poison those animals or act as pathogens. The remains of some form the sands of many modern beaches, and others are a major source of the oil that sometimes fouls those beaches.

Phytoplankton are primary producers

A single protist clade, the diatoms, performs about one-fifth of all photosynthetic carbon fixation on Earth—about the same amount as all of Earth's rainforests. These spectacular unicellular organisms (see Figure 27.8) are the predominant component of the oceanic phytoplankton, but the phytoplankton include

many other protists that also contribute heavily to global photosynthesis. Like green plants on land, these “floating photosynthesizers” are the gateway for energy from the sun into the rest of the living world; in other words, they are **primary producers**. These autotrophs are eaten by heterotrophs, including animals and many other protists. Those consumers, in turn, are eaten by other consumers. Most aquatic heterotrophs (with the exception of some species in the deep sea) depend on photosynthesis performed by phytoplankton for their energy supply.

Some microbial eukaryotes are deadly

Some microbial eukaryotes are pathogens that cause serious diseases in humans and other vertebrates. The best-known pathogenic protists are members of the genus *Plasmodium*, a highly specialized group of apicomplexans that spend part of their complex life cycle as parasites in human red blood cells. *Plasmodium* parasites cause malaria, one of the world's three most serious infectious diseases; it infects more than 350 million people, and kills more than 1 million people, each year. On average, about two people die from malaria every minute of every day—most of them in sub-Saharan Africa, although malaria occurs in more than 100 countries.

Mosquitoes of the genus *Anopheles* transmit *Plasmodium* to humans when an infected female mosquito penetrates the person's skin. The parasites enter the human bloodstream and travel to cells in the liver and the lymphatic system, where they change form, multiply, and reenter the bloodstream to invade red blood cells, where they continue to multiply. Eventually the blood cells lyse (burst), releasing new swarms of *Plasmodium*. These episodes of cell lysis coincide with the primary symptoms of malaria, which include fever, shivering, vomiting, joint pain, and convulsions.

If another *Anopheles* bites the victim, the mosquito ingests *Plasmodium* cells along with blood. Some of these cells develop into gametes that unite in the mosquito, forming zygotes. The zygotes lodge in the mosquito's gut, divide several times, and move into its salivary glands, from which they can be passed on to another human host ([Figure 27.20](#)). Thus *Plasmodium* is an extracellular parasite in the mosquito vector and an intracellular parasite in the human host. Such an organism—that is, a parasite that requires more than one host—is said to have a **complex life cycle**.

Plasmodium is a singularly difficult pathogen for humans to combat. Its life cycle is best broken by removing stagnant water, in which mosquitoes breed. Using insecticides to reduce the *Anopheles* population can also be effective, but the benefits must be weighed against the ecological, economic, and health risks posed by the insecticides themselves.

Even some of the phytoplankton that are such important primary producers can be deadly, as described at the opening of this chapter. Some diatoms and dinoflagellates reproduce in enormous numbers when environmental conditions are favorable for their growth. In the resulting “red tides,” the concentration of dinoflagellates may reach 60 million per liter of ocean water and produce potent nerve toxins that harm or kill many vertebrates, especially fish.

(A)

(B)

27.20 Life Cycle of the Malarial Parasite (A) Like many parasitic species, the apicomplexan *Plasmodium falciparum* has a complex life cycle, part of which is spent in mosquitoes of the genus *Anopheles* and part in humans. The sexual phase (gamete fusion) of this life cycle takes place in the insect, and the zygote is the only diploid stage. (B) Encysted *Plasmodium* zygotes (artificially colored blue) cover the stomach wall of a mosquito. Invasive sporozoites will hatch from the cysts and be transmitted to a human, in whom the parasite causes malaria.

Some microbial eukaryotes are endosymbionts

Endosymbiosis is common among the microbial eukaryotes. Many radiolarians harbor photosynthetic endosymbionts (see Figure 27.12A). As a result, these radiolarians, which are not photosynthetic themselves, appear greenish or golden, depending on the type of endosymbiont they contain. This arrangement is often mutually beneficial: the radiolarian can make use of the carbon compounds produced by its photosynthetic endosymbiont, and the endosymbiont may in turn make use of metabolites made by the host or receive physical protection. In some cases,

the endosymbiont is exploited for its photosynthetic products while receiving little or no benefit itself.

Dinoflagellates are common endosymbionts and can be found in both animals and other protists. Most, but not all, dinoflagellate

endosymbionts are photosynthetic. Some dinoflagellates live endosymbiotically in the cells of corals, contributing the products of their photosynthesis to the partnership. Their importance to the corals is demonstrated when the dinoflagellates die or are expelled by the corals as a result of changing environmental conditions such as rising water temperatures or increased water turbidity. This phenomenon, known as **coral bleaching**, reduces the corals' food supply. Unless the corals can acquire new endosymbionts, they are unlikely to survive (**Figure 27.21**).

We rely on the remains of ancient marine protists

Diatoms are lovely to look at, but their importance to us goes far beyond aesthetics, and even beyond their role as primary producers. Diatoms store oil as an energy reserve and to keep themselves afloat at the correct depth in the ocean. Over millions of years, untold numbers of diatoms have died and sunk to the ocean floor, where their bodies have undergone chemical changes. In this way, diatoms have become a major source of petroleum and natural gas, two of our most important fossil fuels and political concerns.

Because the silica-containing cell walls of dead diatoms resist decomposition, some sedimentary rocks are composed almost entirely of diatom skeletons that sank to the seafloor over time. Diatomaceous earth obtained from such rocks has many industrial uses, such as insulation, filtration, toothpaste, and metal polishing. It has also been used as an "Earth-friendly" insecticide that clogs the tracheae (breathing structures) of insects.

Other ancient marine protists have also contributed to the rocks of today. Some foraminiferans, as we have seen, secrete shells of calcium carbonate. After they reproduce (by mitosis and cytokinesis), the daughter cells abandon the parent shell and make new shells of their own. The discarded shells of ancient foraminiferans form a layer hundreds to thousands of meters deep over millions of square kilometers of ocean bottom. The extensive limestone deposits seen in various parts of the world are the result of tectonic processes that have raised these layers above sea level. Foraminiferan shells also make up much of the sand of some beaches. A single gram of such sand may contain as many as 50,000 foraminiferan shells and shell fragments.

The shells of individual foraminiferans are easily preserved as fossils in marine sediments. Each geological period is characterized by a distinctive assemblage of foraminiferan species. Because the shells of foraminiferan species have such distinctive shapes (see **Figure 27.11**) and, because they are so abundant, the remains of foraminiferans are especially valuable in classifying and dating sedimentary rocks. In addition, analyses of the chemical makeup of foraminiferan shells can be used to estimate the global temperatures prevalent at the time when the shells were formed.

INVESTIGATINGLIFE

27.21 Can Corals Reacquire Dinoflagellate Endosymbionts Lost to Bleaching? Some corals lose their chief nutritional source when their photosynthetic endosymbionts die, often as a result of changing environmental conditions. This experiment by Cynthia Lewis and Mary Alice Coffroth investigated the ability of corals to acquire new endosymbionts after bleaching.^a

HYPOTHESIS Bleached corals can acquire new photosynthetic endosymbionts from their environment.

Method

1. Count numbers of *Symbiodinium*, a photosynthetic dinoflagellate, living symbiotically in samples of a coral (*Briareum* sp.).
2. Stimulate bleaching by maintaining all *Briareum* colonies in darkness for 12 weeks.
3. After 12 weeks of darkness, count numbers of *Symbiodinium* in the coral samples; then return all colonies to light.
4. In some of the bleached colonies (the experimental group), introduce *Symbiodinium* strain B211—dinoflagellates that contain a unique molecular marker. Do not expose the others (the control group) to strain B211. Maintain both groups in the light for 6 weeks.

Results

Pre-bleach

Post-bleach

CONCLUSION Corals can acquire new endosymbionts from their environment following bleaching.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

WORKING WITH DATA:

Uptake of Endosymbionts After Coral Bleaching

Original Paper

Lewis, C. L. and M. A. Coffroth. 2004. The acquisition of exogenous algal symbionts by an octocoral after bleaching. *Science* 304: 1490–1492.

Analyze the Data

The data shown in the table at right come from DNA analyses of *Symbiodinium* strains found in the experimental and control colonies of corals (*Briareum*) before and after bleaching. *Symbiodinium* strain B211 (which was not present before bleaching) was introduced to the experimental colonies after bleaching. Use these data to answer the questions below.

QUESTION 1

Are new strains of *Symbiodinium* taken up only by coral colonies that have lost all their original endosymbionts?

QUESTION 2

Does the acquisition of a new *Symbiodinium* strain always result in survival of a recovering *Briareum* colony?

QUESTION 3

In week 3, only strain B211 was detected in the experimental colonies, but in week 6, non-B211 *Symbiodinium* were detected in 8 percent of the experimental colonies. Can you suggest an explanation for this observation?

	Symbiodinium strain present (% of colonies)			
	Non-B211	B211	None*	Colony died
Experimental colonies (strain B211 added)				
Pre-bleach	100	0	0	0
Post-bleach	58	0	42	0
Week 3	0	92	0	8
Week 6	8	58	8	25
Control colonies (no strain B211)				
Pre-bleach	100	0	0	0
Post-bleach	67	0	33	0
Week 3	67	0	33	0
Week 6	67	0	17	17

*Colonies remained alive but no *Symbiodinium* were detected.

RECAP 27.4

Protists have many effects, both positive and negative, on their environment. Some species are important primary producers, many are endosymbionts, and some are pathogens. Protists are among the most important producers of fossil fuels, and they are important components of sedimentary rocks.

- What is the role of female *Anopheles* mosquitoes in the transmission of malaria? See p. 563 and Figure 27.20
- Explain the roles of dinoflagellates in the two very different phenomena of coral bleaching and red tides. See pp. 549 and 564–565
- What are some of the ways in which diatoms are important to human society? See p. 565

The next six chapters will explore the major evolutionary radiations of multicellular eukaryotes, along with the protist ancestors from which they arose. Chapters 28 and 29 will describe the origin and diversification of plants, Chapter 30 will present the fungi, and Chapters 31–33 will provide a brief overview of the animals.

Can dinoflagellates be beneficial, as well as harmful, to marine ecosystems?

ANSWER

Not all dinoflagellate blooms produce problems for other species. Dinoflagellates are important components of many ecosystems, as we have seen throughout this chapter. Photosynthetic dinoflagellates also produce much of the atmospheric oxygen that most animals need to survive. Corals and many other species depend on symbiotic dinoflagellates for food (see Figure 27.21). In addition, as photosynthetic organisms, free-living planktonic dinoflagellates are among the most important primary producers in aquatic food webs. They are a major component of the phytoplankton and provide an important food source for many species (see Section 27.4). Some dinoflagellates produce a beautiful bioluminescence. Unlike the bioluminescent bacteria described at the start of Chapter 26, however, dinoflagellates cannot generate a steady bioluminescence, but produce flashes of light when disturbed, as people who swim in the ocean at night in certain regions often observe.

CHAPTERSUMMARY 27

27.1 How Did the Eukaryotic Cell Arise?

- The term **protist** does not describe a formal taxonomic group. It is shorthand for “all eukaryotes that are not plants, animals, or fungi.”
- Early events in the evolution of the eukaryotic cell probably included the loss of the firm cell wall and infolding of the plasma membrane. Such infolding probably led to segregation of the genetic material in a membrane-enclosed nucleus. **Review Figure 27.1**
- Mitochondria evolved by endosymbiosis with a proteobacterium.
- **Primary endosymbiosis** of a eukaryote and a cyanobacterium gave rise to the first chloroplasts. **Secondary endosymbiosis** and **tertiary endosymbiosis** between chloroplast-containing eukaryotes and other eukaryotes gave rise to the distinctive chloroplasts of euglenids, dinoflagellates, and other groups. **Review Figure 27.2, ANIMATED TUTORIAL 27.1**

27.2 What Features Account for Protist Diversity?

- Most eukaryotes can be placed in one of eight major clades that diverged about 1.5 billion years ago: alveolates, stramenopiles, rhizaria, excavates, plants, amoebozoans, fungi, and animals. **Review Figure 27.3**
- Most, but not all, protists are unicellular.
- **Alveolates** are unicellular organisms with sacs (alveoli) beneath their plasma membranes. Alveolate clades include the marine **dinoflagellates**, the parasitic **apicomplexans**, and the diverse, highly motile **ciliates**. **See ACTIVITY 27.1, ANIMATED TUTORIAL 27.2**
- **Stramenopiles** typically have two flagella of unequal length, the longer one bearing rows of tubular hairs. Among the stramenopiles are the unicellular **diatoms**, the multicellular **brown algae**, and the nonphotosynthetic **oomycetes**, many of which are **saprobic**.
- **Rhizaria** are unicellular and aquatic. They include the **cercozoans**; the **foraminiferans**, which secrete shells of calcium carbonate; and the **radiolarians**, which have thin, stiff pseudopods and glassy endoskeletons.

- The **excavates** include parasitic as well as free-living species. The **diplomonads** and **parabasalids** lack typical mitochondria. **Heteroloboseans** have an amoeboid body form and a two-stage life cycle. **Euglenids** have anterior flagella; some are photosynthetic. The **kinetoplastids**, which include several human pathogens, have a single, large mitochondrion.
- The **amoebozoans** move by means of lobe-shaped pseudopods. A **lobosean** consists of a single amoeboid cell. **Plasmodial slime molds** are amoebozoans whose vegetative stage is a **coenocyte** that moves by cytoplasmic streaming. In **cellular slime molds**, the individual cells maintain their identity at all times but aggregate to form fruiting structures.

27.3 What is the Relationship between Sex and Reproduction in Protists?

- Asexual reproduction gives rise to **clonal lineages** of organisms.
- **Conjugation** in *Paramecium* is a sexual process but not a reproductive one. **Review Figure 27.19**
- **Alternation of generations**, which includes a multicellular diploid stage and a multicellular haploid stage, is a feature of many multicellular protist life cycles (as well as those of some fungi and all land plants). The alternating generations may be **heteromorphic** or **isomorphic**.

27.4 How Do Protists Affect Their Environments?

- The diatoms are responsible for about one-fifth of the photosynthetic carbon fixation on Earth. They and other members of the phytoplankton are important **primary producers** in the marine environment. Ancient diatoms are a major source of today's petroleum and natural gas deposits.
- Some protists are pathogens of humans and other vertebrates. **Review Figure 27.20, ANIMATED TUTORIAL 27.3**
- Endosymbiotic relationships are common among microbial protists and typically benefit both the endosymbionts and their protist or animal partners. **Review Figure 27.21**

CHAPTERREVIEW

REMEMBERING

- Which statement about eukaryotic phytoplankton is *not* true?
 - Some are important primary producers.
 - Some contributed to the formation of petroleum.
 - Some form toxic “red tides.”
 - Some are food for marine animals.
 - They constitute a clade.
- The chloroplasts of photosynthetic protists
 - are structurally identical.
 - gave rise to mitochondria.
 - are all descended from a once free-living cyanobacterium.
 - all have exactly two surrounding membranes.
 - are all descended from a once free-living red alga.
- Reproduction in protists
 - is sexual in some species
 - is asexual in some species.
 - can occur through both asexual and sexual processes in some species.
 - can occur independently of sex in some species.
 - All of the above

UNDERSTANDING & APPLYING

- For each pair of groups below, describe how you could recognize members of the two groups and differentiate them from each another. Then describe features that the two groups in each pair share.
 - Foraminiferans and radiolarians
 - Ciliates and dinoflagellates
 - Diatoms and brown algae
 - Plasmodial slime molds and cellular slime molds
- Given that sex and reproduction are independent of each other in the ciliates, what does that suggest about the role of sex in maintenance of populations?

ANALYZING & EVALUATING

Background for Questions 6–7:

In most temperate regions of the oceans, there is a spring bloom of phytoplankton. Although the red tide blooms described at the opening of this chapter are harmful, phytoplankton blooms can also be beneficial for marine communities. In fact, many species of marine life depend on these blooms for their survival. The dates of spring phytoplankton blooms near the coast of Nova Scotia, Canada, were determined by examining remote satellite images. The table below presents these dates as deviations from the mean date of the spring bloom in this region; it also gives the survival index for larval haddock (an important commercial fish) for the year after each bloom. The survival index is the ratio of the mass of juvenile fish to the mass of mature fish; higher values indicate better survival of larval fish.

Year	Deviation in bloom date* (days)	Survival index
1	+5	1.9
2	+11	2.2
3	−15	6.8
4	+5	1.9
5	−4	4.9
6	−20	10.3
7	+6	2.1
8	+14	1.9

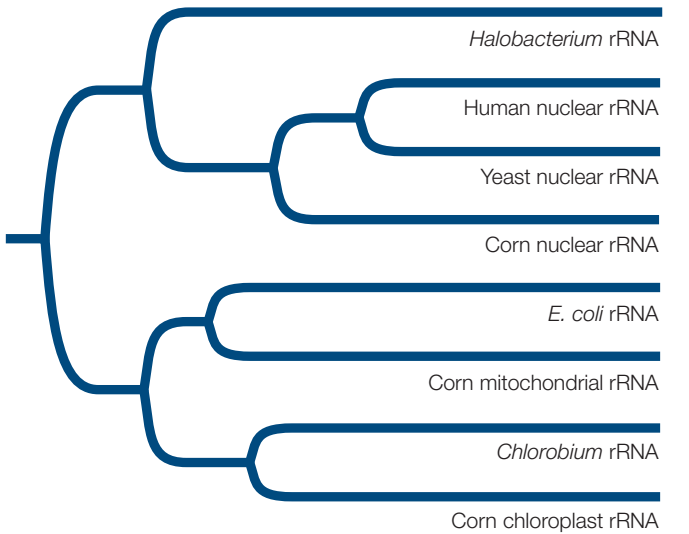

*Negative values indicate blooms occurring earlier than the mean date; positive values indicate later blooms.

- Plot the survival index of larval haddock against the deviation in the date of the spring phytoplankton bloom. Calculate a correlation coefficient for their relationship (see Appendix B).

- Formulate one or more hypotheses to explain your results. Keep in mind that larval haddock include phytoplankton in their diet, and that phytoplankton blooms also provide some cover in which larval fish can hide from potential predators.

Background for Questions 8–10:

Ribosomal RNA (rRNA) genes are present in the nuclear genome of eukaryotes. There are also rRNA genes in the genomes of mitochondria and chloroplasts. Therefore photosynthetic eukaryotes have three different sets of rRNA genes, which encode the structural RNA of three separate sets of ribosomes. Translation of each genome takes place on its own set of ribosomes. The gene tree shows the evolutionary relationships among rRNA gene sequences isolated from the nuclear genomes of humans, yeast, and corn; from an archaeon (*Halobacterium*), a proteobacterium (*E. coli*), and a cyanobacterium (*Chlorobium*); and from the mitochondrial and chloroplast genomes of corn. Use the gene tree to answer the following questions.

- Why aren't the three rRNA genes of corn one another's closest relatives?
- How would you explain the closer relationship of the mitochondrial rRNA gene of corn to the rRNA gene of *E. coli* than to the nuclear rRNA genes of other eukaryotes? Can you explain the relationship of the rRNA gene from the chloroplast of corn to the rRNA gene of the cyanobacterium?
- If you were to sequence the rRNA genes from human and yeast mitochondrial genomes, where would you expect these two sequences to fit on the gene tree?

Plants without Seeds: From Water to Land

CHAPTER OUTLINE

- 28.1** How Did Photosynthesis Arise in Plants?
- 28.2** When and How Did Plants Colonize Land?
- 28.3** What Features Allowed Land Plants to Diversify in Form?

IN THE GULF OF MEXICO, about 60 kilometers south of the Louisiana coast, the oil rig *Deepwater Horizon* was drilling an exploratory oil well in the seafloor beneath about 1,500 meters of water when, on April 20, 2010, an explosive blowout occurred and could not be contained. Over the next 3 months, almost 5 million barrels of petroleum flowed from the well into the Gulf, making this event the worst marine oil spill in history. The spill caused massive mortality among marine life, as well as considerable damage along the coast as the oil floated to the surface and washed ashore.

Why was oil to be found so deep beneath the Gulf, and what led geologists to expect to find oil there? Most people know that petroleum is a fossil fuel, meaning that it is derived from the ancient remains of once-living organisms. Fewer people know that most petroleum is derived largely from the remains of phytoplankton, including many species of green algae (as well as other microbial groups, as discussed in Chapter 27). These algae produce complex hydrocarbons through photosynthesis. They accumulate hydrocarbons both as an energy reserve and as a way to increase their buoyancy in water. When these algae die, they drop to the bottom of the ocean, and over many millions of years, their buried remains decompose into petroleum deposits.

Today there is great interest in using solar power to help meet human energy needs. But unicellular

Fireball on the Gulf A “blowout”—an uncontrolled release of petroleum—ignited a fireball above the drilling rig *Deepwater Horizon*. Fueled by gushing oil and natural gas, the fire could not be extinguished, and crews were forced to sink the rig without containing the blowout. Oil continued to flow from the deep-sea well for 3 months.

eukaryotes first incorporated tiny solar energy converters into their cells about 1.5 billion years ago, when they formed partnerships with photosynthetic cyanobacteria. These endosymbionts—which over time would become the chloroplasts of modern plants—allowed many eukaryotes to use solar energy to drive the reactions that convert carbon dioxide into organic carbon compounds. Over many millions of years, the carbon compounds produced in the cells of marine algae accumulated in ocean sediments. Today humans are tapping that trapped solar energy in the form of petroleum and other fossil fuels.

Given that petroleum is produced naturally from green algae, can humans use green algae to produce oil commercially?

See answer on p. 585.

28.1 The Evolution of Plants In its broadest definition, the term "plant" includes the glaucophytes, red algae, and green plants—all the groups descended from a common ancestor that had chloroplasts. Some biologists restrict the term "plant" to the green plants (those with chlorophyll *b*) or, even more narrowly, to the land plants. Three key characteristics that emerged during the evolution of land plants—protected embryos, vascular tissues, and seeds—led to their success in the terrestrial environment.

28.1

How Did Photosynthesis Arise in Plants?

More than a billion years ago, when a cyanobacterium was first engulfed by an early eukaryote, the history of life was altered radically. The chloroplasts that resulted from primary endosymbiosis of this cyanobacterium were obviously important for the evolution of plants and other photosynthetic eukaryotes,

but they were also critical to the evolution of all life on land. Until photosynthetic plants were able to move onto land, there was very little there to support multicellular animals or fungi, and almost all life was restricted to the oceans and fresh waters.

Primary endosymbiosis is a shared derived trait—a synapomorphy—of the group known as **Plantae** (Figure 28.1). Although *Plantae* is Latin for "plants," in everyday language—and throughout this book—the unmodified common name "plants"

WORKING WITH DATA:

The Phylogeny of Land Plants

Original Paper

Qiu, Y.-L. et al. 2006. *Proceedings of the National Academy of Sciences USA* 103: 15511–15516.

Analyze the Data

In addition to the morphological characters of land plants shown on the phylogeny in Figure 28.1, DNA sequences are widely used to study and reconstruct the evolutionary history of plants. These sequences are many tens of thousands of nucleotides long and have been collected from a large number of species. The full data set used by Yin-Long Qiu and his colleagues (available at treebase.org) includes DNA sequences from 67 genes. The table below provides sample sequences from a chloroplast gene that has been used to reconstruct the relationships of representative plant species; the table shows 27 nucleotide positions for 10 species.

QUESTION 1

Construct a phylogenetic tree of these 10 species using the parsimony method (see Section 22.2 and the examples in Table 22.1 and Figure 22.5 for instructions). Use the outgroup to root your tree. Assume that all changes among nucleotides are equally likely.

QUESTION 2

How many changes (from one nucleotide to another) occur along each branch on your tree?

QUESTION 3

Which nucleotide positions (i.e., which character states) exhibit homoplasy (convergence or reversal of the character state)?

QUESTION 4

Which group on your tree represents the streptophytes? The land plants? The vascular plants? The euphyllophytes?

	Nucleotide position (character state)																										
Species	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	27

Go to BioPortal for all WORKING WITH DATA exercises

is usually used to refer only to the land plants. However, the first several clades that branch off the tree of life after primary endosymbiosis are all aquatic. Most aquatic photosynthetic eukaryotes (other than those secondarily derived from land plants) are known by the common name **algae**. This name, however, is just a convenient way to refer to these groups, which are not all closely related. Many of the photosynthetic groups discussed in Chapter 27 (which acquired chloroplasts through secondary endosymbiosis) are also commonly called algae.

Several distinct clades of algae were among the first photosynthetic eukaryotes

The ancestor of Plantae was unicellular and may have been similar in general form to the modern **glaucoephytes** (Figure 28.2). These microscopic freshwater algae are thought to be the sister group of the rest of Plantae (see Figure 28.1A). The chloroplast of glaucoephytes is unique in containing a small

amount of peptidoglycan between its inner and outer membranes—the same arrangement found in cyanobacteria. Peptidoglycan has been lost from the remaining photosynthetic eukaryotes.

In contrast to the glaucoephytes, almost all **red algae** are multicellular (Figure 28.3). Their characteristic color is a result of the accessory photosynthetic pigment **phycoerythrin**, which is found in relatively large amounts in the chloroplasts of many red algae. In addition to phycoerythrin, red algal chloroplasts contain chlorophyll *a* and the accessory pigments phycocyanin and carotenoids.

The red algae include species that grow in the shallowest tide pools as well as the photosynthesizers found deepest in the ocean (as deep as 260 meters if nutrient conditions are right and the water is clear enough to permit light to penetrate). A few red algae inhabit fresh water. Most grow attached to a substrate by a holdfast.

Glaucocystis

28.2 Glaucophytes May Resemble Some of the Earliest Plantae

The large chloroplasts of unicellular glaucophytes differ from chloroplasts of other Plantae in retaining a layer of peptidoglycan. This feature is thought to have been retained from the endosymbiotic cyanobacteria that gave rise to the chloroplasts of Plantae. The photograph shows a colony of two individuals, each with two chloroplasts.

Despite their name, red algae don't always appear red in color. The ratio of two pigments—phycoerythrin (red) and chlorophyll *a* (green)—depends largely on the intensity of light that reaches the alga. In deep water, where light is dim, algae accumulate large amounts of phycoerythrin and have red coloration. But many species growing near the surface contain a higher concentration of chlorophyll *a* and are bright green.

The remaining algal groups in Plantae are the various "green algae." Like land plants, the green algae contain both chlorophylls *a* and *b* and store their reserve of photosynthetic products as starch in chloroplasts. All the groups that share these features are commonly called **green plants** because both of their photosynthetic pigments are green.

The largest clade of "green algae" is the **chlorophytes**. There are more than 17,000 species of chlorophytes, most of which are aquatic (some are marine, though more are freshwater forms), although there are a few terrestrial forms that live in moist environments. Chlorophytes range in size from microscopic unicellular forms to multicellular forms many centimeters long and display an incredible variety of shapes and body forms. Surprisingly large and well-formed colonies of cells are found in some unicellular freshwater groups, such as the genus *Volvox* (Figure 28.4A). Certain cells in these colonies are specialized for reproduction. The cells in these colonies are not differentiated into specialized tissues and organs, as in land plants and animals, but they show vividly how the preliminary step of this great evolutionary innovation might have been taken.

Volvox is a colonial unicellular chlorophyte, but there are also many true multicellular species of chlorophytes. Some of these are filamentous. Others, like species in the genus *Ulva* (Figure 28.4B), grow into thin, membranous sheets up to 30 centimeters in width.

Two groups of green algae are the closest relatives of land plants

All green algae other than the chlorophytes form a group together with the land plants known as **streptophytes** (see Figure 28.1A). Several microscopic structural features, backed by clear evidence from molecular studies, indicate that the closest relatives of the land plants are two groups of aquatic green algae, the **coleochaetophytes** (Figure 28.5A) and the **stoneworts** (Figure 28.5B). Both of these multicellular algal groups retain their eggs in the parental organism, as land plants do. As in land plants, the cytoplasm of adjacent cells in these algal groups is connected through structures called plasmodesmata; they also share similarities in the details of mitosis and cytokinesis. Of these two groups, stoneworts are thought to be the sister group of land plants (see Figure 28.1A). The growth form of stoneworts is branching and apical (new growth occurs at the tips of branches), as in most land plants. Phylogenetic

analysis of gene sequences has confirmed the close relationships of coleochaetophytes and stoneworts to the land plants.

There are ten major groups of land plants

One of the key synapomorphies of the **land plants** is development from an embryo that is protected by tissues of the parent plant. For this reason, land plants are sometimes called **embryophytes** (*phyton*, “plant”). The green plants, the streptophytes, and the land plants have each been called “the plant kingdom” by different authorities; others take an even broader view and include red algae and glaucophytes as “plants.” To avoid confusion in this chapter, we will use modifying terms (“land plants” or “green plants,” for example) to refer to the various clades of Plantae shown in Figure 28.1.

The land plants that exist today fall naturally into ten major clades (listed by their common names in the center column of **Table 28.1**). Members of seven of those clades possess well-developed vascular systems that transport materials throughout the plant body. We call these seven groups, collectively, the **vascular plants**, or **tracheophytes**, because they all possess fluid-conducting cells called **tracheids**. The remaining three clades (liverworts, mosses, and hornworts) lack tracheids and are referred to collectively as **nonvascular land plants**. Note,

however, that (unlike the vascular plants, which are a clade) the three groups of nonvascular land plants do not form a clade.

RECAP 28.1

Primary endosymbiosis is a synapomorphy of the Plantae. The glaucophytes, the sister clade of the other Plantae, are unicellular algae that are similar to some of the earliest photosynthetic eukaryotes. The green plants contain chlorophyll *b* in addition to the chlorophyll *a* found in all Plantae.

- Explain the different possible uses of the term “plant.”
See pp. 570–571 and Figure 28.1
- Why doesn’t the name “algae” designate a formal taxonomic group? **See pp. 571–572**
- What are some of the key differences between glaucophytes, red algae, and the various clades of green algae?
See pp. 571–572
- What evidence supports the phylogenetic relationship between land plants and the various groups of green algae?
See pp. 572–573

The green algal ancestors of the land plants lived at the margins of ponds or marshes, ringing them with a mat of dense green. It was from such a marginal habitat, which was sometimes wet and sometimes dry, that early plants made the transition onto land.

TABLE 28.1 Classification of Land Plants

Group	Common Name	Characteristics
Nonvascular land plants		
Hepatophyta	Liverworts	No stomata; gametophyte flat or leafy
Bryophyta	Mosses	Filamentous stage; gametophyte leafy; sporophyte grows apically (at the tip)
Anthocerophyta	Hornworts	Embedded archegonia; sporophyte grows basally (i.e., from the ground)
Vascular plants		
Lycopodiophyta	Lycophytes: Club mosses and allies	Microphylls in spirals; sporangia in leaf axils
Monilophyta	Horsetails, ferns	Simple leaves in whorls or frondlike compound leaves
SEED PLANTS		
Gymnosperms		
Cycadophyta	Cycads	Compound leaves; swimming sperm; seeds on modified leaves
Ginkgophyta	Ginkgo	Deciduous; fan-shaped leaves; swimming sperm
Gnetophyta	Gnetophytes	Vessels in vascular tissue; opposite, simple leaves
Coniferophyta	Conifers	Seeds in cones; needlelike or scalelike leaves
Angiosperms	Flowering plants	Endosperm; carpels; gametophytes much reduced; seeds contained within fruits

28.2 When and How Did Plants Colonize Land?

How did the land plants arise? To address this question, we can compare land plants with their closest relatives among the green algae. The features that differ between the two groups include the adaptations that allowed the first land plants to survive in the terrestrial environment.

Adaptations to life on land distinguish land plants from green algae

Land plants first appeared in the terrestrial environment between 450 and 500 million years ago. How did they survive in an environment that differed so dramatically from the aquatic environment of their ancestors? While the water essential for life is everywhere in the aquatic environment, water is difficult to obtain and retain in the terrestrial environment.

No longer bathed in fluid, organisms on land faced potentially lethal desiccation (drying). Large terrestrial organisms had to develop ways to transport water to body parts distant from the source of the water. And whereas water provides aquatic organisms with support against gravity, a plant living on land must either have some other support system or sprawl unsupported on the ground. A land plant must also use different mechanisms for dispersing its gametes and progeny than its aquatic relatives, which can simply release them into the water.

Survival on land was facilitated by the evolution among plants of numerous adaptations, including:

- The *cuticle*, a membrane covered in waxes to retard water loss
- *Stomata*, small openings in leaves and stems that open and close to regulate gas exchange and water loss

- *Gametangia*, multicellular organs that enclose plant gametes and prevent them from drying out
- *Embryos*, young plants contained within a protective structure
- Certain *pigments* that afford protection against the mutagenic ultraviolet radiation that bathes the terrestrial environment
- Thick *spore walls* containing a polymer that protects the spores from desiccation and resists decay
- A *mutually beneficial association with fungi* (mycorrhizae) that promotes nutrient uptake from the soil

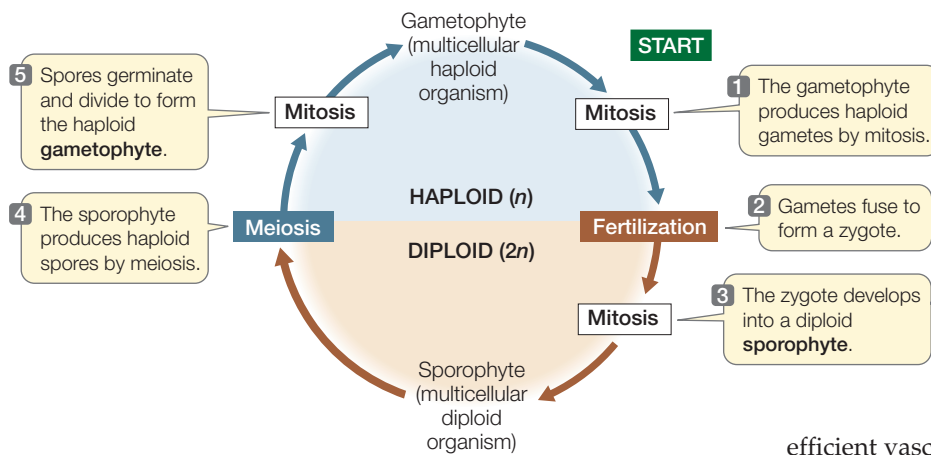

The cuticle may be the most important—and the earliest—of these features. Composed of several unique waxy lipids that coat the leaves and stems of land plants, the cuticle has several functions, the most obvious and important of which is to keep water from evaporating from the plant body.

As ancient plants colonized the land, they not only adapted to the terrestrial environment, they also modified it by contributing to the formation of soil. Acids secreted by plants helped break down rock, and the organic compounds produced by the breakdown of dead plants contributed nutrients to the soil. Such effects are repeated today wherever plants colonize and grow in new areas.

Life cycles of land plants feature alternation of generations

A universal feature of the life cycles of land plants is alternation of generations. Recall from Section 27.3 the two hallmarks of alternation of generations:

- The life cycle includes both a multicellular diploid stage and a multicellular haploid stage.

28.6 Alternation of Generations in Land Plants

A multicellular diploid sporophyte generation that produces spores by meiosis alternates with a multicellular haploid gametophyte generation that produces gametes by mitosis.

- Gametes are produced by mitosis, not by meiosis. Meiosis produces **spores** that develop into multicellular haploid organisms.

If we begin looking at the land plant life cycle at the single-cell stage—the diploid zygote—then the first phase of the cycle is the formation, by mitosis and cytokinesis, of a multicellular **embryo**, which eventually grows into a mature diploid plant. This multicellular diploid plant is called the **sporophyte** (“spore plant”).

Cells contained within specialized reproductive organs of the sporophyte, called **sporangia** (singular *sporangium*), undergo meiosis to produce haploid, unicellular spores. By mitosis and cytokinesis, a spore develops into a haploid plant. This multicellular haploid plant, called the **gametophyte** (“gamete plant”), produces haploid gametes by mitosis. The fusion of two gametes (fertilization) forms a single diploid cell—the zygote—and the cycle is repeated (Figure 28.6).

The sporophyte generation extends from the zygote through the adult multicellular diploid plant and sporangium formation; the gametophyte generation extends from the spore through the adult multicellular haploid plant to the gametes. The transitions between the generations are accomplished by fertilization and by meiosis. In all land plants, the sporophyte and the gametophyte differ genetically: the sporophyte has diploid cells, and the gametophyte has haploid cells.

There is a trend toward reduction of the gametophyte generation in plant evolution. In the nonvascular land plants, the gametophyte is larger, longer-lived, and more self-sufficient than the sporophyte. In those groups that appeared later in plant evolution, however, the sporophyte is the larger, more conspicuous, longer-lived, and more self-sufficient generation.

Nonvascular land plants live where water is readily available

The living species of nonvascular land plants are the liverworts, mosses, and hornworts. These three groups are thought to be similar in many ways to the earliest land plants. Most of these plants grow in dense mats, usually in moist habitats. Even the largest of these species are only about half a meter tall, and most are only a few centimeters tall or long. Why have they not evolved to be taller? The probable answer is that they lack an

efficient vascular system for transporting water and minerals from the soil to distant parts of the plant body.

The nonvascular land plants lack the true leaves, stems, and roots that characterize the vascular plants, although they have structures analogous to each. Their growth form allows water to move through the mats of plants by capillary action. They have leaflike structures that readily catch and hold any water that splashes onto them. They are small enough that minerals can be distributed throughout their bodies by diffusion. As in all land plants, layers of maternal tissue protect their embryos from desiccation. Many nonvascular land plants also have a cuticle, although it is often very thin (even absent in some species) and thus is not highly effective in retarding water loss.

Most nonvascular land plants live on the soil or on vascular plants, but some grow on bare rock, on dead and fallen tree trunks, and even on buildings. Their ability to grow on such marginal surfaces results from a mutualistic association with fungi. The earliest association of land plants with fungi dates back at least 460 million years. This mutualism probably facilitated the absorption of water and minerals, especially phosphorus, from the first soils.

Nonvascular land plants are widely distributed over six continents and even exist (albeit very locally) on the coast of the seventh, Antarctica. Most are terrestrial. Although a few species live in fresh water, these aquatic species are descended from terrestrial ones. None live in the oceans.

The sporophytes of nonvascular land plants are dependent on the gametophytes

In the nonvascular land plants, the conspicuous green structure visible to the naked eye is the gametophyte. The gametophyte is photosynthetic and is therefore nutritionally independent; the sporophyte may or may not be photosynthetic, but it is always nutritionally dependent on the gametophyte and remains permanently attached to it.

Figure 28.7 illustrates the life cycle of a moss, which is typical of the life cycles of nonvascular land plants. A sporophyte produces unicellular haploid spores as products of meiosis within a sporangium. When a spore germinates, it gives rise to a multicellular haploid gametophyte whose cells contain chloroplasts and are thus photosynthetic. Eventually gametes form within specialized sex organs, called the **gametangia**. The **archegonium** is a multicellular, flask-shaped female sex organ with a long neck

28.7 A Life Cycle Dependent on Water The life cycles of nonvascular land plants, exemplified here by that of a moss, are dependent on an external source of liquid water. The visible green structure of such plants is the gametophyte, which contains haploid archegonia and antheridia. Water carries sperm from the antheridia into an archegonium, inside which an egg is fertilized and grows into a multicellular, diploid sporangium.

Go to Media Clip 28.2
Bryophyte Reproduction
Life10e.com/mc28.2

and a swollen base; it produces a single egg. The **antheridium** is a male sex organ in which sperm, each bearing two flagella, are produced in large numbers. Archegonia and antheridia are produced on the same individual in many species, so each individual has both male and female reproductive structures. Adjacent individuals often fertilize one another's gametes, however, which helps maintain genetic diversity in the population.

Once released from the antheridium, the sperm must swim or be splashed by raindrops to a nearby archegonium on the same or a neighboring plant—a constraint that reflects the aquatic origins of the nonvascular land plants' ancestors. The sperm are aided on their journey by chemical attractants

released by the egg or the archegonium. Before sperm can enter the archegonium, however, certain cells in the neck of the archegonium must break down, leaving a water-filled canal through which the sperm can swim to complete their journey. Notice that *all of these events require liquid water*.

Once sperm arrive at an egg, the nucleus of a sperm fuses with the egg nucleus to form a diploid zygote. Mitotic divisions of the zygote produce a multicellular, diploid sporophyte embryo. After the sporophyte grows out of the

archegonium it produces a single sporangium, within which meiotic divisions produce spores and thus the next gametophyte generation.

Liverworts are the sister clade of the remaining land plants

There are about 9,000 species of **liverworts**. Most liverworts have leafy gametophytes (Figure 28.8A). Some have thalloid gametophytes: green, leaflike layers that lie flat on the ground (Figure 28.8B,C). The simplest liverwort gametophytes are flat plates of cells, a centimeter or so long, that produce antheridia or archegonia on their upper surfaces and rhizoids (rootlike filaments) on their lower surfaces.

Liverwort sporophytes are shorter than those of mosses and hornworts, rarely exceeding a few millimeters. The liverwort sporophyte has a stalk that raises the sporangium above the gametophyte. In most species, the stalk elongates by expansion of cells throughout its length. This elongation raises the sporangium above ground level, allowing the spores to be dispersed more widely. The sporangia of liverworts are simple: a globular sporangium wall surrounds a mass of spores. In some species of liverworts, spores are not released by the sporophyte until the surrounding sporangium wall rots. In other liverworts, however, the spores are thrown from the sporangium by structures that shorten and compress as they dry out. When the stress becomes sufficient, the compressed structure snaps back to its resting position, throwing spores in all directions.

Among the most familiar thalloid liverworts are species of the genus *Marchantia*. *Marchantia* is easily recognized by the characteristic structures on which its male and female gametophytes bear their antheridia (Figure 28.8B) and archegonia (Figure 28.8C). Like most liverworts, *Marchantia* also reproduces asexually by simple fragmentation of the gametophyte.

In addition, *Marchantia* and some other liverworts and mosses reproduce asexually by means of gemmae (singular gemma), which are lens-shaped clumps of cells. In a few liverworts, the gemmae are held in structures called gemmae cups, which promote dispersal of the gemmae by raindrops.

Liverwort Life Cycle
Life10e.com/mc28.3

Water and sugar transport mechanisms emerged in the mosses

The most familiar of the nonvascular land plants are the **mosses**. These hardy little plants, of which there are about 15,000 species, are found in almost every terrestrial environment. They are often found on damp, cool ground, where they form thick mats (Figure 28.9). The mosses are the sister clade of the vascular plants plus the hornworts (see Figure 28.1).

The mosses, along with the hornworts and vascular plants, share an advance over the liverworts in their adaptation to life on land: they have openings called **stomata**, which allow CO₂ to enter the plant body and allow water and O₂ to leave it. Stomata are a synapomorphy of mosses and all other land plants except liverworts.

In mosses, the gametophyte begins its development following spore germination as a branched, filamentous structure called a protonema (see Figure 28.7). Although the protonema looks a bit like a filamentous green alga, this structure is unique to the mosses. Some of the filaments contain chloroplasts and are photosynthetic; others, called rhizoids, are nonphotosynthetic and anchor the protonema to the substratum. After a period of linear growth, cells close to the tips of the photosynthetic filaments divide rapidly in three dimensions to form buds. The buds eventually develop a distinct tip, or apex, and produce the familiar leafy moss shoot with leaflike structures arranged spirally. These leafy shoots produce antheridia or archegonia (see Figure 28.7).

(A)

(B) *Polytrichum* sp.

28.9 Mosses Often Cover the Ground in Dense Mats (A) Dense layers of moss carpet a field of solidified volcanic lava in Iceland. (B) A close-up view of moss growing on a forest floor in Michigan.

Some moss gametophytes are too large to transport enough water through their bodies solely by diffusion. Gametophytes and sporophytes of many mosses contain a type of cell called a hydroid, which dies and leaves a tiny channel through which water can travel. The hydroid is functionally similar to the tracheid, the characteristic water-conducting cell of the vascular plants, but it lacks lignin and the cell wall structure found in tracheids. The possession of hydroids and of a limited system for transport of sugar in some mosses shows that the term “non-vascular plant” is somewhat misleading when applied to these plants. Despite their simple system of internal transport, however, the mosses are not considered vascular plants because they lack tracheids or other components of xylem and phloem.

Mosses of the genus *Sphagnum* (Figure 28.10A) often grow in cool, swampy places, where the plants begin to decompose in water after they die. Rapidly growing upper layers of moss compress the deeper-lying, decomposing layers. Partially decomposed plant matter is called **peat**. In some parts of the world, people derive the majority of their fuel from peat bogs (Figure 28.B). *Sphagnum*-dominated peatlands cover a total area approximately half the size of the United States—more

(A)

*Sphagnum* sp.

(B)

28.10 Sphagnum Moss (A) *Sphagnum* bogs are extremely dense growths of the moss shown here in a close-up view. (B) A farmer mines a bog for peat, a fossil fuel formed from decomposing *Sphagnum* mosses.

than 1 percent of Earth’s surface. Millions of years ago, continued compression of peat composed primarily of other seedless plants gave rise to coal.

Hornworts have distinctive chloroplasts and stalkless sporophytes

The approximately 100 species of **hornworts** are so named because their sporophytes look like little horns (Figure 28.11). Hornworts appear at first glance to be liverworts with very simple gametophytes. Their gametophytes are flat plates of cells a few cells thick.

Hornworts have several characteristics that distinguish them from liverworts and mosses. First, the cells of hornworts each contain a single large, platelike chloroplast, whereas the cells of the other two groups contain numerous small, lens-shaped

Anthoceros sp.

28.11 Hornworts Get Their Name from Their Hornlike Sporophytes

Unlike liverworts or mosses, the sporophytes of hornworts are persistently green. They share this trait with the vascular plants.

chloroplasts. Second, of the sporophytes in all three groups, those of the hornworts come closest to being capable of growth without a set limit. Liverwort and moss sporophytes have a stalk that stops growing as the sporangium matures, so elongation of the sporophyte is strictly limited. The hornwort sporophyte, however, has no stalk, and it is persistently green (a trait shared with vascular plants). A basal region of the sporangium remains capable of indefinite cell division, continuously producing new spore-bearing tissue above. The sporophytes of some hornworts growing in mild and continuously moist conditions can become as tall as 20 centimeters. Eventually, however, the sporophyte's growth is limited by the lack of a transport system.

Hornworts have a symbiotic relationship that promotes their growth by providing them with access to nitrogen, which is often a limiting resource. Hornworts have internal cavities filled with mucilage; these cavities are often populated by cyanobacteria that convert atmospheric nitrogen gas into a form usable by their host plant.

RECAP 28.2

The transition of plants to land required numerous adaptations, including the cuticle, stomata, gametangia, protected embryos, and mutually beneficial associations with fungi. Nonvascular land plants rely on liquid water for reproduction.

- Explain what is meant by alternation of generations.
See pp. 574–576 and Figure 28.6
- Describe several adaptations of plants to the terrestrial environment, and describe the distribution of those adaptations among the liverworts, mosses, and hornworts.

New features appeared in plants as they continued to adapt to the terrestrial environment. One of the most important of these was vascular tissues, the characteristic that defines the vascular plants.

28.3 What Features Allowed Land Plants to Diversify in Form?

The first plants possessing vascular tissues did not arise until tens of millions of years after the earliest nonvascular plants had colonized the land. But once vascular tissues arose, their ability to transport water and food throughout the plant body allowed the vascular plants to spread to new terrestrial environments and to diversify rapidly.

Vascular tissues transport water and dissolved materials

The key synapomorphy of the vascular plants is a well-developed vascular system containing two types of tissues that are specialized for the transport of materials from one part of the plant to another. One type of vascular tissue, the **xylem**, conducts water and minerals from the soil to aerial parts of the plant. Because some of its cell walls contain a stiffening substance called lignin, xylem also provides support against gravity in the terrestrial environment. The other type of vascular tissue, the **phloem**, conducts the products of photosynthesis from sites where they are produced or released to sites where they are used or stored. (Xylem and phloem will be discussed in detail in Chapters 34 and 35.)

Although the vascular plants are an extraordinarily large and diverse group, one particular event was critical to their evolution. Sometime during the Paleozoic era, probably in the mid-Silurian (430 mya), a new cell type—the tracheid—evolved in sporophytes of the earliest vascular plants. The tracheid is the principal water-conducting element of the xylem in all vascular plants except the angiosperms (flowering plants) and gnetophytes—and tracheids persist even in these groups, along with a more specialized and efficient system derived from them.

The evolution of tracheids set the stage for the complete and permanent invasion of land by plants. First, these cells provided a pathway for the transport of water and mineral nutrients from a source of supply to regions of need in the plant body. Second, the cell walls of tracheids, stiffened by lignin, provided rigid structural support. This support is a crucial factor in a terrestrial environment because it allows plants to grow upward and thus compete for sunlight. A taller plant can intercept more direct sunlight (and thus conduct photosynthesis more readily) than a shorter plant, which may be shaded by the taller one. Increased height also improves the dispersal of spores.

The vascular plants featured another evolutionary novelty: a branching, independent sporophyte. A branching sporophyte body can produce more spores than an unbranched body, and it can develop in complex ways. The sporophyte of a vascular plant is nutritionally independent of the gametophyte at maturity. Among the vascular plants, the sporophyte is the large and obvious plant one normally notices in nature, in contrast to the relatively small, dependent sporophytes typical of most nonvascular land plants.

28.12 Artist's Reconstruction of an Ancient Forest Forests of the Carboniferous period were characterized by abundant vascular plants such as club mosses, ferns, and horsetails, some of which reached heights of 40 meters. Huge flying insects (see the opening of Chapter 25) thrived in these forests, which are the source of modern coal deposits.

Vascular plants allowed herbivores to colonize the land

The initial absence of herbivores (plant-eating animals) on land helped make the first vascular plants successful. By the late Silurian period (about 425 mya), vascular plants were being preserved as fossils that we can study today. The proliferation of these plants made the terrestrial environment more hospitable to animals. Arthropods, vertebrates, and other animals moved onto land only after vascular plants became established there.

Trees of various kinds appeared in the Devonian period and dominated the landscape of the Carboniferous period (359–299 mya). Forests of lycophytes (club mosses) up to 40 meters tall, along with horsetails and tree ferns, flourished in the tropical swamps of what would become North America and Europe (Figure 28.12). Plant material from those forests sank into the swamps and was gradually covered by layers of sediment. Over millions of years, as the buried plant material was subjected to intense pressure and elevated temperatures, it was transformed into coal. Today that coal provides over half of our electricity. The world's coal deposits, although huge, are not infinite, and humans are burning coal deposits at a far faster rate than they were produced.

28.13 An Ancient Relative of the Vascular Plants The extinct rhyniophyte *Aglaophyton major* lacked roots and leaves. It had a central column of xylem running through its stems but no true tracheids. A horizontal underground stem called a rhizome anchored the plant. The dichotomously branching aerial stems were less than 50 centimeters tall. Some stems were topped by sporangia.

In the subsequent Permian period, when the continents came together to form Pangaea, the continental interior became warmer and drier. The 200-million-year reign of the lycophyte–fern forests came to an end as they were replaced by forests of early gymnosperms.

The closest relatives of vascular plants lacked roots

The closest relatives of living vascular plants belonged to several extinct groups called **rhyniophytes** (Figure 28.13). The rhyniophytes were one of a very few types of land plants in the Silurian period. The landscape at that time probably consisted mostly of bare ground, with mats of nonvascular plants and stands of rhyniophytes in low-lying moist areas. Early versions of the structural features of the vascular plant groups appeared in the rhyniophytes of that time. These shared features strengthen the case for the origin of all vascular plants from a common nonvascular land plant ancestor.

Rhyniophytes did not have roots. They were apparently anchored in the soil by horizontal portions of stem called **rhizomes**, which bore water-absorbing unicellular filaments called **rhizoids**. These plants also bore aerial branches, and sporangia—homologous to the sporangia of mosses—were found at the tips of those branches. Their branching pattern was **dichotomous**; that is, the apex (tip) of the shoot divided to produce two equivalent new branches, with each pair of branches diverging at approximately the same angle from the original stem.

The lycophytes are sister to the other vascular plants

The club mosses and their relatives, the spike mosses and quillworts, are collectively called **lycophytes**. The lycophytes are the sister clade to the remaining vascular plants (see Figure 28.1B). There are relatively few (just over 1,200) surviving species of lycophytes.

The lycophytes have true roots that branch dichotomously. The arrangement of vascular tissue in their stems is simpler than that in other vascular plants. They bear simple leaflike structures called **microphylls**, which are arranged spirally on the stem. Growth in lycophytes comes entirely from apical cell division. Branching in the stems, which is also dichotomous, occurs by division of an apical cluster of dividing cells.

The sporangia of many club mosses are aggregated in cone-like structures called **strobili** (singular *strobilus*; Figure 28.14A), which are clusters of spore-bearing microphylls attached to the end of the stem. Other club mosses lack strobili and bear their sporangia on (or adjacent to) the upper surfaces of specialized microphylls.

Horsetails and ferns constitute a clade

The horsetails and ferns were once thought to be only distantly related. From analysis of gene sequences we now know that they form a clade, the **monilophytes**. In the monilophytes—as in the seed plants, to which they are the sister clade (see Figure 28.1)—there is differentiation between a main stem and side branches (including the leaves derived from these branches). This pattern contrasts with the dichotomous branching characteristic of the lycophytes and rhyniophytes, in which each split gives rise to two branches of similar size.

Today there are only about 15 species of **horsetails**, all in the genus *Equisetum*. The horsetails have reduced true leaves that form in distinct whorls (circles) around the stem (Figure 28.14B). Horsetails are sometimes called “scouring rushes” because rough silica deposits found in their cell walls once made them useful for cleaning. They have true roots that branch irregularly. Horsetails have a large sporophyte and a small gametophyte, both independent of each other.

(D) *Dicksonia antarctica*

28.14 Lycophytes and Monilophytes

(A) Club mosses have microphylls arranged spirally on their stems. Strobili are visible at the tips of these stems. (B) Horsetails have a distinctive growth pattern in which the stem grows in segments above each whorl of leaves. These are fertile shoots with sporangia-bearing structures at the apex. (C) The leaves of two species of water ferns. (D) Tree ferns dominate this forest on the island of Tasmania, Australia.

28.15 Life Cycle of a Fern The most conspicuous stage in the fern life cycle is the mature diploid sporophyte, shown at the bottom of this diagram. The inset shows sori on the underside of a fern leaf. Each sorus contains many spore-producing sporangia.

Go to Activity 28.1 The Fern Life Cycle
Life10e.com/ac28.1

The first ferns appeared during the Devonian period; today this group comprises more than 12,000 species. Analyses of gene sequences indicate that a few species traditionally allied with ferns may in fact be more closely related to horsetails than to ferns. Nonetheless, the majority of ferns form a monophyletic group.

Although most ferns are terrestrial, a few species live in shallow fresh water (Figure 28.14C). Terrestrial ferns are characterized by large leaves with branching vascular strands (Figure 28.14D). Some fern leaves become climbing organs and may grow to be as long as 30 meters.

In the alternating generations of a fern, the gametophyte is small, delicate, and short-lived, but the sporophyte can be

very large and can sometimes survive for hundreds of years (Figure 28.15). Ferns require liquid water for the transport of the male gametes to the female gametes, so most ferns inhabit shaded, moist woodlands and swamps. The sporangia of ferns are typically borne on a stalk in clusters called **sori** (singular *sorus*). The sori are found on the undersides of the leaves, sometimes covering the entire undersurface and sometimes located at the edges.

The vascular plants branched out

Several features that were new to the vascular plants evolved in lycophytes and monilophytes. Roots probably had their evolutionary origins as branches, either of a rhizome or of the

(A) Microphylls

*Lycopodium* (club moss)

28.16 Evolution of Leaves (A) Microphylls are thought to have evolved from sterile sporangia. (B) The megaphylls of monilophytes and seed plants may have arisen as photosynthetic tissue developed between branch pairs that were “left behind” as dominant branches overtopped them.

(B) Megaphylls

*Adiantum* (fern)

aboveground portion of a stem. These branches presumably penetrated the soil and branched further. The underground portions could anchor the plant firmly, and even in this primitive condition, they could absorb water and minerals.

The microphylls of lycophytes were probably the first leaflike structures to evolve among the vascular plants. Microphylls are usually small and only rarely have more than a single vascular strand, at least in existing species. Some biologists believe that microphylls had their evolutionary origins as sterile sporangia (Figure 28.16A). A typical feature of this type of leaf is a vascular strand that departs from the vascular system of the stem in such a way that the structure of the stem's vascular system is scarcely disturbed. This pattern was evident even in the lycophyte trees of the Carboniferous period, many of which had microphylls many centimeters long.

The monilophytes and seed plants constitute a clade called the **euphyllphytes** (*eu*, “true”; *phyllon*, “leaf”). An important synapomorphy of the euphyllphytes is **overtopping**, a growth pattern in which one branch differentiates from and grows beyond the others (Figure 28.16B). Overtopping would have given these plants an advantage in the competition for light, enabling them to shade their dichotomously branching competitors. The overtopping growth of the euphyllphytes also allowed a new type of leaflike structure to evolve. This larger, more complex leaf is called a **megaphyll**. The megaphyll

is thought to have arisen from the flattening of a portion of a branching stem system that exhibited overtopping growth. This change was followed by the development of photosynthetic tissue between the members of overtopped groups of branches, which had the advantage of increasing the photosynthetic surface area of those branches.

The first megaphylls, which were very small, appeared in the Devonian period. We might expect that evolution should have led swiftly to the appearance of more and larger megaphylls because of their greater photosynthetic capacity. However, it took some 50 million years, until the Carboniferous period, for large megaphylls to become common. Why should this have been so, especially given that other advances in plant structure were taking place during that time?

According to one theory, the high concentration of CO₂ in the atmosphere during the Devonian period reduced selection for the stomata that allow a leaf to take up CO₂ for use in photosynthesis. With more CO₂ available, fewer stomata were needed. In the Devonian, larger leaves with a limited number of stomata would have absorbed heat from sunlight, but they would have been unable to lose heat fast enough by evaporation of water through their stomata. The resulting overheating would have been lethal. Recent research has supported this hypothesis, indicating that larger megaphylls evolved only as CO₂ concentrations dropped over millions of years (Figure 28.17).

INVESTIGATINGLIFE

28.17 Atmospheric CO₂ Concentrations and the Evolution of Megaphylls

High concentrations of atmospheric CO₂ during the first part of the Devonian may have limited the evolution of leaf size. C. P. Osborne and colleagues compared the leaf sizes of fossil plants against estimates of CO₂ concentrations in the atmosphere at the time the plants were alive.^a

HYPOTHESIS High atmospheric CO₂ concentrations during the early Devonian, and the resulting lack of selection for more stomata, kept leaf sizes small.

Method

1. Analyze 300 plant fossils from the Devonian and Carboniferous periods and measure the sizes of their leaves.
2. Compare the pattern of change in leaf size with that of the estimated change in atmospheric CO₂ concentrations over the same time span.

Results

CONCLUSION Leaf size increased as levels of CO₂ in the atmosphere decreased.

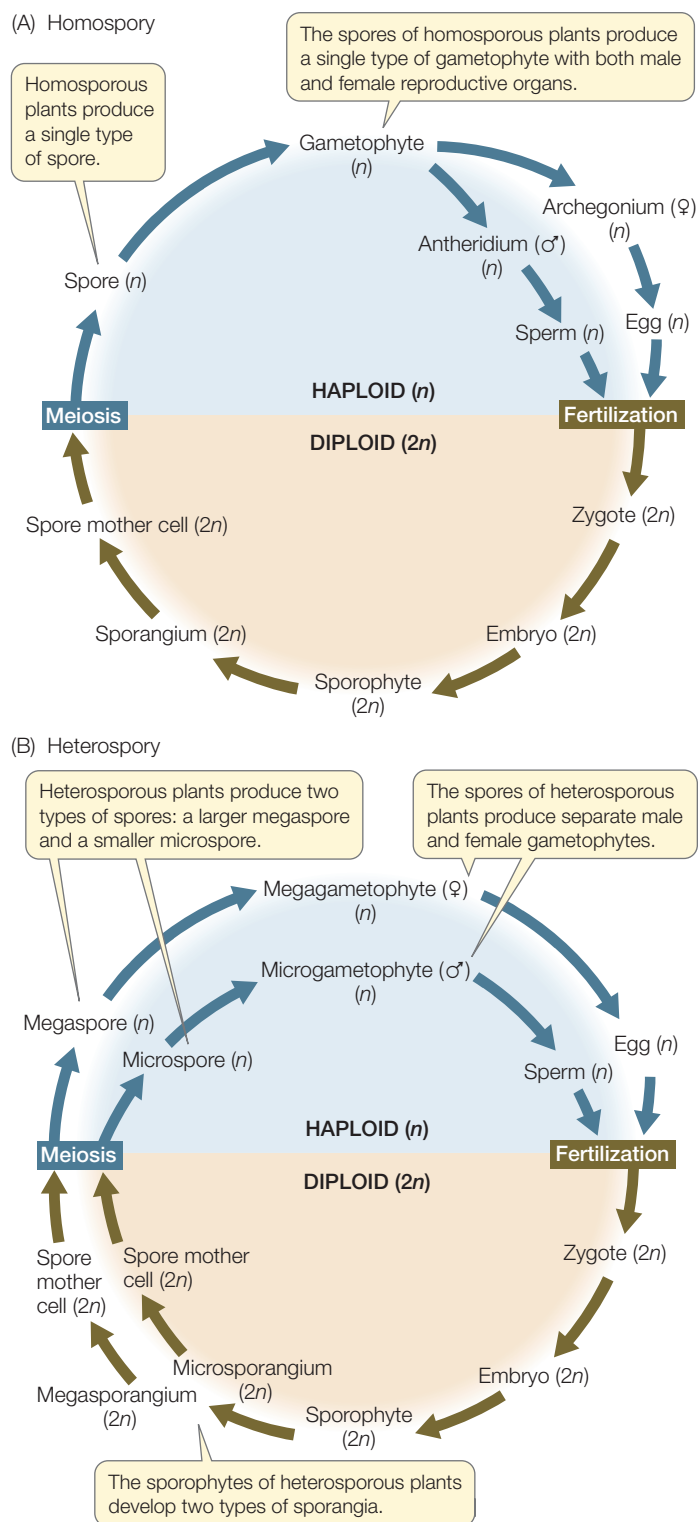

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

Heterospory appeared among the vascular plants

In the lineages of present-day, seedless vascular plants that are most similar to their ancestors, the gametophyte and the sporophyte are independent, and both are usually photosynthetic. The spores produced by the sporophyte are of a single type and develop into a single type of gametophyte that bears both female and male reproductive organs (see Figure 28.15). Such plants, which bear a single type of spore, are said to be **homosporous** (Figure 28.18A).

A system with two distinct types of spores evolved somewhat later. Plants of this type are said to be **heterosporous**

28.18 Homospory and Heterospory (A) Homosporous plants bear a single type of spore. Each gametophyte has two types of sex organs, antheridia (male) and archegonia (female). (B) Heterosporous plants bear two types of spores that develop into distinctly male and female gametophytes.

Go to **Activities 28.2 Heterospory and 28.3 Homospory**

Life10e.com/ac28.2

Life10e.com/ac28.3

(Figure 28.18B). In heterospory, one type of spore—the **megaspore**—develops into a specifically female gametophyte (a **megagametophyte**) that produces only eggs. The other type, the **microspore**, is smaller and develops into a male gametophyte (a **microgametophyte**) that produces only sperm. The sporophyte produces megaspores in small numbers in **megasporangia** and microspores in large numbers in **microsporangia**. Heterospory affects not only the spores and the gametophytes but also the sporophyte plant itself, which must develop two types of sporangia.

The earliest vascular plants were all homosporous, but heterospory evidently evolved several times independently among later groups of vascular plants. The fact that heterospory evolved repeatedly suggests that it affords selective advantages. Subsequent evolution in the land plants featured ever greater specialization of the heterosporous condition.

RECAP 28.3

Vascular plants are characterized by a vascular system specialized for the transport of materials from one part of the plant to another. A new type of cell, the tracheid, marked the origin of this group. Later evolutionary events included the appearance of roots, leaves, and heterospory.

- How do xylem and phloem serve the vascular plants?
See p. 579
- Describe the evolution and distribution of different kinds of leaves and roots among the vascular plants. See pp. 581–583 and Figure 28.16

All of the vascular plant groups we have discussed thus far disperse by means of spores. The embryos of these seedless vascular plants develop directly into sporophytes, which either survive or die, depending on environmental conditions. The spores of some seedless plants may remain dormant and viable for long periods, but the embryos of seedless plants are relatively unprotected. Greater protection of the embryo evolved in the seed plants, which we will consider in the next chapter.

28.19 Biodiesel from Algae In this vertical-growth algal cultivation system for biofuel production, algae are grown in sheets of clear plastic, exposed to sunlight on all sides.

Given that petroleum is produced naturally from green algae, can humans use green algae to produce oil commercially?

ANSWER

Scientists are developing new methods for growing green algae for the production of biofuels (fuels produced directly from living organisms, such as biodiesel). Some species of green algae can produce up to 60 percent of their dry weight in oil. So biofuels can certainly be produced from green algae, although the process is not yet commercially viable. Like conventional fossil fuels, biofuels release carbon dioxide into the atmosphere when burned. In the production of biofuels, however, algae remove carbon dioxide from the atmosphere, so the use of these fuels is more sustainable, and results in less accumulation of CO₂ in the atmosphere over time, than the use of fossil fuels.

The primary commercial limitations to growing algae for biofuels include the need to establish efficient growing facilities, water needs, costs of fertilizers, costs and difficulties associated with harvest and refining, and labor expenses. Many new methods for growing and harvesting algae are being developed (Figure 28.19), and algae production in brackish water as well as in wastewater is being explored. Once some of the technical difficulties have been overcome, it is possible that commercial production of biofuels from algae will provide a significant source of energy for humans.

28.1 How Did Photosynthesis Arise in Plants?

- Primary endosymbiosis gave rise to chloroplasts and the subsequent diversification of the **Plantae**. The descendants of the first photosynthetic eukaryote include **glaucophytes**, **red algae**, several groups of green algae, and **land plants**, all of which contain chlorophyll *a*. **Review Figure 28.1**
- **Green plants**, which include the green algae and the land plants, are characterized by the presence of chlorophyll *b* (in addition to chlorophyll *a*). **Review Figure 28.1**
- Land plants, also known as **embryophytes**, arose from an aquatic green algal ancestor related to today's **stoneworts**. Land plants develop from embryos that are protected by parental tissue. **Review Figure 28.1**

28.2 When and How Did Plants Colonize Land?

- The acquisition of a **cuticle**, **stomata**, **gametangia**, a protected **embryo**, protective pigments, thick spore walls with a protective polymer, and mutualistic associations with fungi were all adaptations of land plants to terrestrial life.
- All land plant life cycles feature alternation of generations, in which a multicellular diploid **sporophyte** alternates with a multicellular haploid **gametophyte**. **Review Figure 28.6**
- The **nonvascular land plants** comprise the **liverworts**, **mosses**, and **hornworts**. These groups lack specialized vascular tissues for the conduction of water or nutrients through the plant body.
- The life cycles of nonvascular land plants depend on liquid water. The sporophyte is usually smaller than the gametophyte and depends on it for water and nutrition. **Review Figure 28.7, ANIMATED TUTORIAL 28.1**
- Liverworts lack stomata, but they are present in mosses, hornworts, and vascular plants. Hornworts have a persistently green sporophyte, a characteristic shared with vascular plants.

28.3 What Features Allowed Land Plants to Diversify in Form?

- The **vascular plants** have a **vascular system** consisting of **xylem** and **phloem** that conducts water, minerals, and products of photosynthesis through the plant body. The vascular system includes cells called **tracheids**.
- The **rhyniophytes**, the earliest known vascular plants, are known to us only in fossil form. They lacked true roots and leaves but possessed **rhizomes** and **rhizoids**. **Review Figure 28.13**
- The **lycophytes** (club mosses and relatives) have only small, simple leaflike structures (**microphylls**). **Monilophytes** (which include **horsetails** and **ferns**) have true leaves, and so together with seed plants are known as **euphyllophytes**.
- Unlike nonvascular land plants, the diploid sporophyte is the more conspicuous life stage of lycophytes and monilophytes. **Review Figure 28.15, ACTIVITY 28.1**
- Microphylls probably evolved from sterile sporangia. **Megaphylls** (true leaves) may have resulted from the flattening and reduction of a portion of a stem system with **overtopping** growth. **Review Figure 28.16**
- The earliest-diverging groups of vascular plants are **homosporous**, but **heterospory**—the production of distinct **megaspores** and **microspores**—has evolved several times. Megaspores develop into female **megagametophytes**; microspores develop into male **microgametophytes**. **Review Figure 28.18, ACTIVITIES 28.2 and 28.3**

CHAPTER REVIEW

REMEMBERING

1. Which statement about alternation of generations in land plants is *not* true?
 - a. The gametophyte and sporophyte differ in appearance.
 - b. Meiosis occurs in sporangia.
 - c. Gametes are always produced by meiosis.
 - d. The zygote is the first cell of the sporophyte generation.
 - e. The gametophyte and sporophyte differ in chromosome number.
2. Which of the following provide evidence for the close relationship between land plants and stoneworts?
 - a. Phylogenetic analysis of DNA sequences
 - b. Similar mechanics of mitosis and cytokinesis
 - c. Similarities in chloroplast structure
 - d. Similarities of their biochemistry
 - e. All of the above
3. Liverworts, mosses, and hornworts
 - a. lack a sporophyte generation.
 - b. grow in dense masses, allowing capillary movement of water.
 - c. possess xylem and phloem.
 - d. possess true leaves.
 - e. possess true roots.
4. Which statement about ferns is *not* true?
 - a. The sporophyte is larger than the gametophyte.
 - b. Most are heterosporous.
 - c. The young sporophyte can grow independently of the gametophyte.
 - d. The leaf is a megaphyll.
 - e. The gametophytes produce archegonia and antheridia.

5. The ferns
 - a. lack a gametophyte generation.
 - b. have a large and prominent gametophyte but a much smaller sporophyte.
 - c. are more closely related to club mosses than to horsetails.
 - d. are monilophytes.
 - e. produce seeds.

UNDERSTANDING & APPLYING

6. Contrast microphylls with megaphylls in terms of structure, evolutionary origin, and occurrence among plants.

Go to BioPortal at yourBioPortal.com for Animated Tutorials, Activities, LearningCurve Quizzes, Flashcards, and many other study and review resources.

7. Heterospory is thought to have evolved multiple times within plants, suggesting an advantage to the heterosporous condition. Why might heterospory provide an evolutionary advantage over homospory?
8. Contrast the life cycles of mosses (see Figure 28.7) and ferns (see Figure 28.15). How are these life cycles similar, and how do they differ?

ANALYZING & EVALUATING

9. Are the morphological characters plotted on the phylogeny in Figure 28.1 consistent with your analysis of DNA sequences from the Working with Data exercise on p. 571? What characteristics of plants that we have discussed in this chapter appear to have evolved more than once in the history of land plants?
10. The findings of Osborne and co-workers on the evolution of megaphylls (see Figure 28.17) support the idea that large megaphylls became common only after the atmospheric CO_2 level had dropped, so that more stomata were favored, allowing evaporation from the stomata to cool larger leaves. How might you extend that work to confirm the involvement of temperature as a factor limiting leaf size?

CHAPTER OUTLINE

- 29.1** How Did Seed Plants Become Today's Dominant Vegetation?
- 29.2** What Are the Major Groups of Gymnosperms?
- 29.3** How Do Flowers and Fruits Increase the Reproductive Success of Angiosperms?
- 29.4** How Do Plants Benefit Human Society?

IN THE EARLY 1860s, much of middle- and upper-class England was caught up in an “orchid frenzy.” Amateur gardeners and professional botanists alike were enchanted with these beautiful flowers and devoted considerable effort and money to collecting and raising them. Following the publication of *On The Origin of Species* in 1859, Charles Darwin wrote his next book on this group of plants. *On the Various Contrivances by which British and Foreign Orchids are Fertilised by Insects*, which he referred to proudly as “my little book on the fertilisation of orchids,” appeared in 1862.

There are more than 25,000 species of orchids, which makes them one of the most diverse plant groups. Darwin wanted to know why orchids had experienced such rapid diversification and was particularly impressed with the role that insect pollinators might have played in this process. Seeking examples to demonstrate the power of natural selection, Darwin found such examples in abundance among the orchids.

Orchids show an impressive variety of specialized pollination mechanisms, many of which demonstrate that they have coevolved with their pollinators. For example, Darwin observed a South American orchid of the genus *Catasetum* shooting a packet of pollen at an insect that landed on its flower. When he was shown *Angraecum sesquipedale*, an orchid from Madagascar with a nectar tube more than a foot long, Darwin hypothesized that there must be a moth with a proboscis of unprecedented length that fed from and pollinated that flower. Many people scoffed at his

Darwin's Ever-Fascinating Orchids On examining a specimen of the orchid *Angraecum sesquipedale*, Charles Darwin noted its exceptionally long nectar tube and predicted the existence of a pollinator with a correspondingly long proboscis. This pollinator, the sphinx moth *Xanthopan morgani*, was not discovered until after Darwin's death.

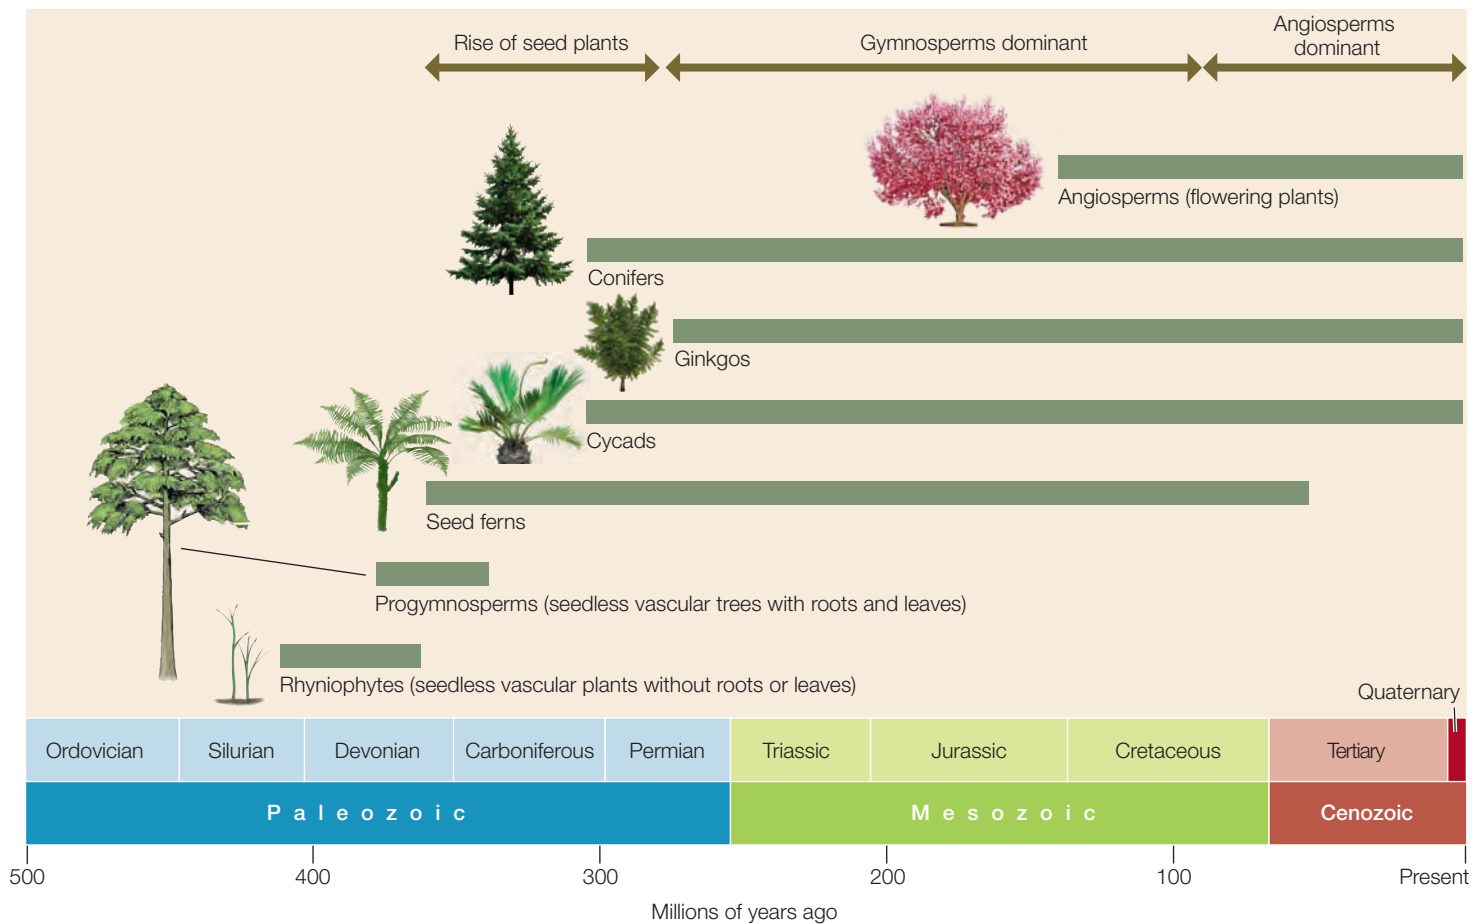

vision, but the moth he described was eventually discovered—21 years after his death.

In 1836 the explorer Robert Schomburgk shook the botanical world with a report that he had seen flowers described as belonging to three different genera of orchids—*Catasetum*, *Monachanthus*, and *Myanthus*—growing together on a single plant. The English botanist John Lindley remarked that this observation would “shake to the foundation all our ideas of the stability of genera and species.” Orchid enthusiasts were befuddled by their efforts to grow specimens of *Myanthus*, only to have them flower with the more common blooms of *Catasetum*. Darwin knew that he needed to find the explanation for these odd observations, for otherwise he would have to conclude that individual plants were able to change their specific identity, something that did not fit with his explanations of the evolution of diversity.

What was Darwin's explanation for the three distinct flowers growing on a single orchid plant?

See answer on p. 605.

29.1 The Fossil Record of Seed Plant Evolution Woody growth evolved in the seedless progymnosperms. The now-extinct seed ferns had woody growth, fernlike foliage, and seeds attached to their leaves. New lineages of seed plants arose during the Carboniferous, but the earliest known fossils of flowering plants are from near the Jurassic–Cretaceous boundary.

29.1

How Did Seed Plants Become Today's Dominant Vegetation?

By the late Devonian period, more than 360 million years ago, Earth was home to a great variety of land plants, many of which we discussed in Chapter 28. The land plants shared the hot, humid terrestrial environment with insects, spiders, centipedes, and fishlike amphibians (early tetrapods). These plants and animals evolved together, each acting as agents of natural selection on the other. In the Devonian, a new innovation appeared when some plants developed extensively thickened woody stems. Among the first plants with this adaptation were seedless vascular plants called **progymnosperms**, all species of which are now extinct. The progymnosperms included many large trees.

Another innovation, the **seed**, arose in the seed plants. Seeds provide a secure and lasting dormant stage for the embryo. A plant embryo may safely wait within its seed (in some cases for many years, or even centuries) until conditions are right for germination.

The earliest fossil evidence of seed plants is found in late Devonian rocks. Like the progymnosperms, these now-extinct

seed ferns were woody. They possessed fernlike foliage but had seeds attached to their leaves. By the end of the Permian, other groups of seed plants had become dominant (**Figure 29.1**). Today's living seed plants fall into two major groups, the **gymnosperms** (such as pines and cycads) and the hugely diverse group known as the **angiosperms** (flowering plants).

Features of the seed plant life cycle protect gametes and embryos

In Section 28.2 we described a major trend in land plant evolution: the sporophyte became less dependent on the gametophyte, which became smaller in relation to the sporophyte. This trend continued with the seed plants, whose gametophyte generation is reduced even further than that of the ferns (**Figure 29.2**). The haploid seed plant gametophyte develops partly or entirely while attached to and nutritionally dependent on the diploid sporophyte.

Among the seed plants, only a few groups of gymnosperms (including modern cycads and ginkgos) have swimming sperm. Even in these groups, sperm is transferred via pollen grains, so fertilization does not require liquid water outside the plant body. This adaptation, along with the advent of the seed, gave seed plants the opportunity to colonize drier areas and spread over the terrestrial environment.

Seed plants are heterosporous (see Figure 28.18B)—that is, they produce two types of spores, one that becomes a

29.2 The Relationship between Sporophyte and Gametophyte

In the course of plant evolution, the gametophyte (brown) has been reduced and the sporophyte (blue) has become more prominent.

microgametophyte (male gametophyte) and one that becomes a megagametophyte (female gametophyte). These plants form separate microsporangia and megasporangia on structures that are grouped on short stems.

Within the microsporangium, the meiotic products are microspores. Within its spore wall, a microspore divides mitotically one or a few times to form a multicellular male gametophyte called a **pollen grain**. Pollen grains are released from the microsporangium to be distributed by wind or by an animal pollinator (Figure 29.3). As in seedless land plants, the spore wall surrounding the pollen grain contains sporopollenin, the most chemically resistant biological compound known, which protects the pollen grain against dehydration and chemical damage—another advantage in terms of survival in the terrestrial environment.

In contrast to the microspores, the megaspores of seed plants are not shed. Instead, they develop into female gametophytes within the megasporangia. These megagametophytes are dependent on the sporophyte for food and water.

In most seed plant species, only one of the meiotic products in a megasporangium survives. The surviving haploid nucleus divides mitotically, and the resulting cells divide again to produce a multicellular female gametophyte. The megasporangium is surrounded by an **integument**: a layer of sporophytic tissue that protects the megasporangium and its contents. Together, the megasporangium and integument constitute the **ovule**, which will develop into a seed after fertilization.

The arrival of a pollen grain at an appropriate landing point, close to a female gametophyte on a sporophyte of the same species, is called **pollination**. A pollen grain that reaches this point produces a slender **pollen tube** that elongates and usually digests

its way toward the megagametophyte (Figure 29.4). When the tip of the pollen tube reaches the megagametophyte, sperm are released from the tube and fertilization occurs. The resulting diploid zygote divides repeatedly, forming an embryonic sporophyte. After a period of embryonic development, growth is temporarily suspended (the embryo enters a dormant stage). The end product at this stage is the multicellular seed.

29.3 Blown on the Wind Pollen grains are the male gametophytes of seed plants. The male flowers of this hazel tree release pollen-containing spores that are dispersed by the wind and may land near female gametophytes of the same or other hazel plants.

Go to Media Clip 29.1
Pollen Transfer by Wind
Life10e.com/mc29.1

29.4 Pollination is a Hallmark of the Seed Plants In most seed plants, a pollen tube grows from the pollen grain to the female gametophyte, where sperm are released and fertilize the egg within the ovule. Once fertilization takes place, the ovule can develop into a seed (see Figure 29.5). (A) Scanning electron micrograph of a pollen tube growing in the flower of an angiosperm, the prairie gentian. (B) The process of pollination is diagrammed for a generalized angiosperm flower.

Go to Activity 29.1 Flower Morphology

Life10e.com/ac29.1

The seed is a complex, well-protected package

A seed contains tissues from three generations (**Figure 29.5**). A seed coat develops from the integument—the tissues of the diploid sporophyte parent that surround the megasporangium. Within the megasporangium is haploid tissue from the female gametophyte, which contains a supply of nutrients for the developing embryo. (This tissue is fairly extensive in most gymnosperm seeds. In angiosperm seeds it is greatly reduced, and nutrition for the embryo is supplied instead by a tissue called endosperm.) In the center of the seed is the third generation, the embryo of the new diploid sporophyte.

The seed is a well-protected resting stage. The seeds of some species may remain dormant but stay viable (capable of growth and development) for many years, germinating only when conditions are favorable for the growth of the sporophyte. During the dormant stage, the seed coat protects the embryo from excessive drying and may also protect it against potential predators that would otherwise consume the embryo and its nutrient reserves. Many seeds have structural adaptations that promote their dispersal by wind or, more often, by animals. When the

young sporophyte resumes growth, it draws on the food reserves in the seed. The possession of seeds is a major reason for the enormous evolutionary success of the seed plants, which are the dominant life forms of most modern terrestrial floras.

A change in stem anatomy enabled seed plants to grow to great heights

Fossils of the closest relatives of seed plants (progymnosperms) and the earliest seed plants (seed ferns) are found in late Devonian rocks (see Figure 29.1). These plants had thickened woody stems, developed through the proliferation of xylem. This type of growth, which increases the diameter of stems and roots in many modern seed plants, is called **secondary growth**. Its product is secondary xylem, or wood.

The younger portion of the wood produced by secondary growth is well adapted for water transport, but older wood becomes clogged with resins or other materials. Although no longer functional in transport, the older wood continues to provide support for the plant. This support allows woody plants to grow taller than other plants around them and thus capture more light for photosynthesis.

29.5 A Seed Develops These cross sections diagram the development of the ovule into a seed in a gymnosperm (*Pinus* sp.). Angiosperm seed development has differences (e.g., angiosperm integuments have two layers rather than one, and the angiosperm embryo is nourished by specialized tissue called endosperm) but follows the same principle (compare Figures 29.8 and 29.16). (A) The haploid megaspore is nourished by tissues of the parental sporophyte (the diploid megasporangium). (B) The mature megaspore is fertilized by a pollen grain that penetrates the integument, germinates (grows a pollen tube; see Figure 29.4A), and releases a sperm nucleus. (C) Fertilization initiates production of a seed. A mature seed contains three generations: a diploid embryo (the new sporophyte), which is surrounded by haploid female gametophyte tissue that supplies nutrition, which is in turn surrounded by the seed coat (diploid parental sporophyte tissue).

Not all seed plants are woody. In the course of seed plant evolution, many groups lost the woody growth habit; however, other advantageous attributes helped them become established in an astonishing variety of places.

RECAP 29.1

Pollen grains, seeds, and wood are major evolutionary innovations of the seed plants. Protection of gametes and embryos is a hallmark of seed plants.

- Distinguish between the roles of the megagametophyte and the pollen grain. **See p. 590 and Figure 29.4**
- Explain the importance of pollen in freeing seed plants from dependence on liquid water. **See p. 590 and Figure 29.4**
- What are some of the advantages afforded by seeds? By wood? **See pp. 591–592 and Figure 29.5**

The seed ferns have long been extinct, but the surviving seed plants have been remarkable successes. After the seed ferns, the gymnosperms were the next group of plants to dominate terrestrial environments.

29.2 What Are the Major Groups of Gymnosperms?

The gymnosperms are seed plants that do not form flowers or fruits. Gymnosperms (which means “naked-seeded”) are so named because their ovules and seeds, unlike those of angiosperms, are not protected by ovary or fruit tissue. Although there are probably fewer than 1,200 living species of gymnosperms, these plants are second only to the angiosperms in their dominance of the terrestrial environment.

There are four major groups of living gymnosperms

The living gymnosperms can be divided into four major groups (see Figure 28.1B):

- **Cycads** are palmlike plants of the tropics and subtropics (**Figure 29.6A**). Of the present-day gymnosperms, the cycads are probably the earliest-diverging clade. There are about 300 species, some of which grow as tall as 20 meters. The tissues of many species are highly toxic to humans if ingested.
- **Ginkgos**, common during the Mesozoic era, are represented today by a single species, *Ginkgo biloba*, the maidenhair tree (**Figure 29.6B**). There are both male (microsporangiate) and female (megasporangiate) maidenhair trees. The difference is determined by X and Y sex chromosomes, as in humans; few other plants have distinct sex chromosomes.

(A) *Encephalartos* sp.(B) *Ginkgo biloba*(C) *Welwitschia mirabilis*(D) *Pinus longaeva*

29.6 Diversity among the Gymnosperms

(A) Many cycads have growth forms that resemble both ferns and palms, although cycads are not closely related to either group. (B) The characteristic broad leaves of the maidenhair tree. (C) The straplike leaves of *Welwitschia*, a gnetophyte, grow throughout the life of the plant, breaking and splitting as they grow. (D) Conifers dominate many types of landscapes in the Northern Hemisphere. Bristlecone pines such as these are the longest-lived individual trees known.

- **Gnetophytes** number about 90 species in three very different genera, which share certain characteristics analogous to ones found in the angiosperms. One of the gnetophytes is *Welwitschia* (Figure 29.6C), a long-lived desert plant with straplike leaves that sprawl on the sand and can grow as long as 3 meters.
- **Conifers** are by far the most abundant of the gymnosperms. There are about 700 species of these cone-bearing plants, including the pines and redwoods (Figure 29.6D).

With the exception of the gnetophytes, the living gymnosperm groups have only tracheids as water-conducting and support cells within the xylem; they lack the vessel elements and fibers (cells specialized for water conduction and support, respectively) that are found in angiosperms. While the gymnosperm water-transport and support system may seem somewhat less efficient than that of the angiosperms, it serves some of the largest trees known. The coastal redwoods of California are the tallest gymnosperms; the largest are well over 100 meters tall.

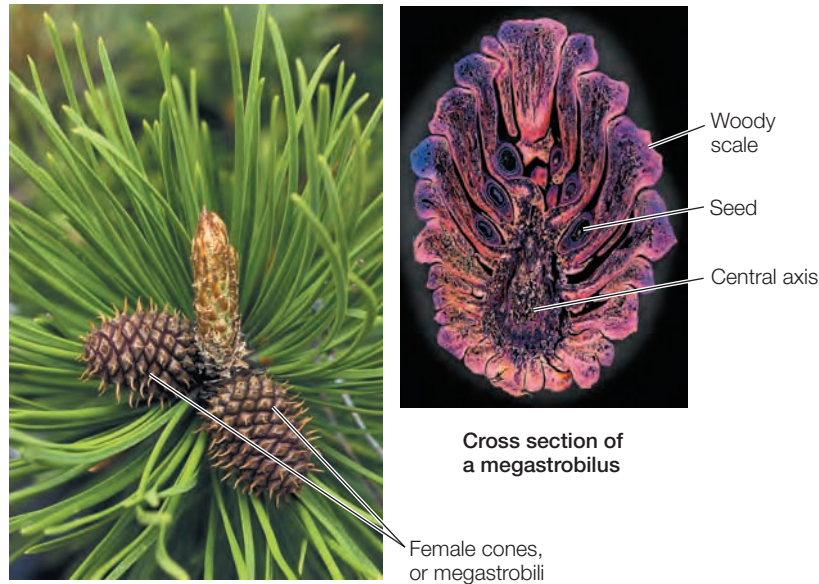

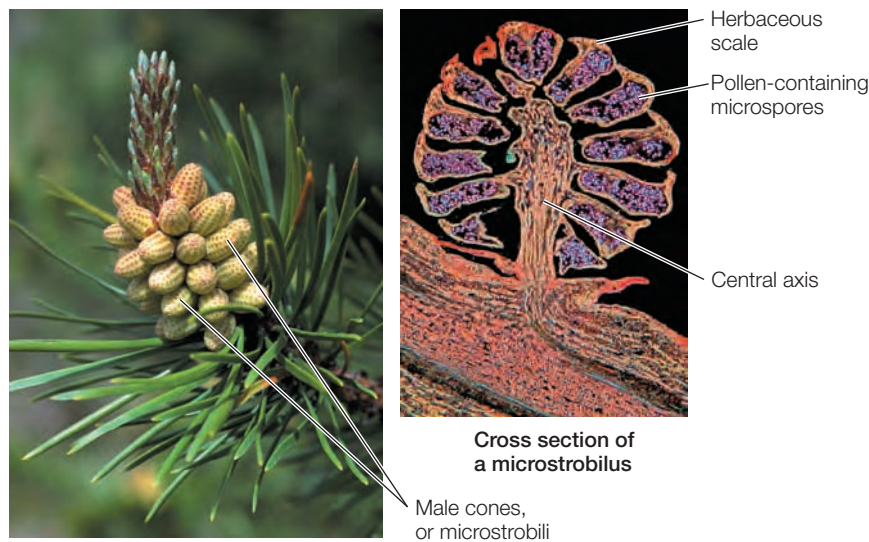

During the Permian, as environments became warmer and dryer, the conifers and cycads flourished. Gymnosperm forests

changed over time as the gymnosperm groups evolved. Gymnosperms dominated most of the Mesozoic era, during which the continents drifted apart and large dinosaurs lived. Gymnosperms were the principal trees in all forests until about 90 million years ago, and even today conifers are the dominant trees in many forests. The oldest living single organism on Earth today is a gymnosperm in California—a bristlecone pine that germinated some 4,800 years ago, at about the time the ancient Egyptians were starting to develop writing.

Conifers have cones and no swimming sperm

The great Douglas fir and cedar forests found in northwestern North America, the massive boreal forests of pine, fir, and spruce of the northern regions of the Northern Hemisphere, and the alpine forests on the upper slopes of mountain ranges everywhere rank among the great forests of the world. All these forests are dominated by trees belong to one group of gymnosperms: the conifers, or cone-bearers.

Male and female **cones** contain the reproductive structures of conifers. The female (seed-bearing) cone is known as a

(A) *Pinus contorta*(B) *Pinus contorta*

29.7 Female and Male Cones (A) The woody scales of female cones (megastrobili) are modified branches. (B) The herbaceous scales of male cones (microstrobili) are modified leaves.

megastrobilus (plural *megastrobili*); an example is the familiar woody pine cone. The seeds in a megastrobilus are protected by a tight cluster of woody scales, which are modifications of branches extending from a central axis (**Figure 29.7A**). The typically much smaller male (pollen-bearing) cone is known as a **microstrobilus**. The microstrobilus is typically herbaceous rather than woody, as its scales are composed of modified leaves, beneath which are the pollen-bearing microsporangia (**Figure 29.7B**).

The life cycle of a pine illustrates reproduction in gymnosperms (**Figure 29.8**). The production of male gametophytes in

the form of pollen grains frees the plant completely from dependence on liquid water for fertilization. Wind assists conifer pollen grains in their travel from the microstrobilus to near the female gametophyte inside a megastrobilus. A pollen tube provides the sperm with the means for the last stage of travel by growing through maternal sporophytic tissue. When the pollen tube reaches the female gametophyte, it releases two sperm, one of which degenerates after the other unites with an egg. Union of sperm and egg results in a zygote; mitotic divisions and further development of the zygote result in an embryo.

The megasporangium, in which the female gametophyte will form, is enclosed in a layer of sporophytic tissue—the integument—that will eventually develop into the seed coat that protects the embryo (see **Figure 29.5**). The integument, the megasporangium inside it, and the tissue attaching it to the maternal sporophyte constitute the ovule. The pollen grain enters the ovule through a small opening in the integument at the tip of the ovule, the **micropyle**.

Most conifer ovules, which will develop into seeds after fertilization, are borne exposed on the upper surfaces of the scales of the megastrobilus. The only protection of the ovules comes from the scales, which are tightly pressed against one another within the cone. Some pines, such as the lodgepole pine, have such tightly closed cones that only fire suffices to split them open and release the seeds. These species are said to be fire-adapted, and fire is essential to their reproduction. A fire devastated lodgepole pine forests in Yellowstone National Park in 1988, but also released large numbers of seeds from cones. As a result, large numbers of lodgepole pine seedlings are now emerging in the burn area (**Figure 29.9**).

About half of all conifer species have soft, fleshy tissues that envelop their seeds.

Some of these are fleshy, fruitlike cones, as in junipers. Others are fruitlike extensions of the seeds, called arils, as in yews. These tissues, although often mistaken for “berries,” are not true fruits. As we will see in the next section, true fruits are the plant’s ripened ovaries, which are absent in gymnosperms. Nonetheless, the fleshy tissues that surround many conifers serve a similar purpose to that of the fruits of flowering plants, acting as an enticement for seed-dispersing animals. Animals eat these fleshy tissues and disperse the seeds in their feces, often depositing the seeds considerable distances away from the parent plant.

29.9 From Devastation, New Life A stand of lodgepole pines in Yellowstone National Park. The mature trees were destroyed by a forest fire in 1988. However, the fire released large numbers of seeds from cones, and now many young lodgepole pine trees are growing in the burn area.

RECAP 29.2

Living gymnosperms can be divided into four major groups: cycads, ginkgos, gnetophytes, and conifers. All of these plants are woody and have seeds that are not protected by ovaries.

- Explain the differences in structure and function between a megastrobilus and a microstrobilus. **See p. 594 and Figures 29.7 and 29.8**
- What is the role of the integument in a gymnosperm seed? **See p. 594 and Figure 29.8**
- Explain how fire can be necessary for the survival of some plant species. **See p. 594**

29.3 How Do Flowers and Fruits Increase the Reproductive Success of Angiosperms?

The most obvious feature defining the angiosperms is the **flower**, which is their sexual structure. Production of **fruits** is also a synapomorphy (shared derived trait) of angiosperms. After fertilization, the ovary of a flower (together with the seeds it contains) develops into a fruit that protects the seeds and can promote seed dispersal. As we will see, both flowers and fruits give angiosperms major reproductive advantages.

Angiosperms have many shared derived traits

The name *angiosperm* (“enclosed seed”) is drawn from another distinctive synapomorphy of these plants that is related to

the formation of fruits: the ovules and seeds are enclosed in a modified leaf called a **carpel**. Besides protecting the ovules and seeds, the carpel often interacts with incoming pollen to prevent self-pollination, thus favoring cross-pollination and increasing genetic diversity.

The female gametophyte of the angiosperms is even more reduced than that of the gymnosperms, usually consisting of only seven cells (see Figure 29.16). Thus the angiosperms represent the current extreme of the trend we have traced throughout the evolution of the vascular plants: the sporophyte generation becomes larger and more independent of the gametophyte, while the gametophyte generation becomes smaller and more dependent on the sporophyte.

The xylem of most angiosperms is distinguished by the presence of specialized water-transporting cells called **vessel elements**. These cells are larger in diameter than tracheids and connect with one another without obstruction, allowing easy water movement. A second distinctive cell type in angiosperm xylem is the **fiber**, which plays an important role in supporting the plant body. The phloem of angiosperms possesses its own unique cell type, called a companion cell. Like the gymnosperms, woody angiosperms exhibit secondary growth, increasing in diameter by producing secondary xylem and secondary phloem.

A more comprehensive list of angiosperm synapomorphies, then, includes the following:

- Flowers
- Fruits
- Highly reduced female gametophytes
- Ovules and seeds enclosed in a carpel
- Germination of pollen on a stigma
- Double fertilization
- Endosperm (nutritive tissue for the embryo)
- Phloem with companion cells

The majority of these traits bear directly on angiosperm reproduction, which is a large factor in the success of this dominant plant group.

The sexual structures of angiosperms are flowers

Flowers come in an astonishing variety of forms—just think of a few of the flowers you recognize. Flowers may be single, or they may be grouped together to form an **inflorescence**. Different families of flowering plants have characteristic types of inflorescences, such as the compound umbels of the carrot family (**Figure 29.10A**), the heads of the aster family (**Figure 29.10B**), and the spikes of many grasses (**Figure 29.10C**).

If you examine any familiar flower, you will notice that the outer parts look somewhat like leaves. In fact, all the parts of a flower *are* modified leaves. The diagram in Figure 29.4B represents a generalized flower, for which there is no exact counterpart in nature. The structures bearing microsporangia are called **stamens**. Each stamen is composed of a **filament** bearing an **anther** that contains the pollen-producing microsporangia. The structures bearing megasporangia are called carpels. A structure

29.10 Inflorescences (A) The inflorescence of bishop's goutweed, a member of the carrot family, is a compound umbel. Each umbel bears flowers on stalks that arise from a common center. (B) Zinnias are members of the aster family; their inflorescence is a head. Within the head, each of the long, petal-like structures is a ray flower; the central portion of the head consists of dozens to hundreds of disc flowers. (C) Some grasses, such as quack grass, have inflorescences called spikes, which are composed of many smaller groups of flowers, or spikelets.

composed of one carpel or two or more fused carpels is called a **pistil**. The swollen base of the pistil, containing one or more ovules (each containing a megasporangium surrounded by two protective integuments), is called the **ovary**. The apical stalk of the pistil is the **style**, and the terminal surface that receives pollen grains is the **stigma**.

In addition, many flowers contain specialized sterile (non-spore-bearing) leaves. The inner ones are called **petals** (collectively, the corolla) and the outer ones **sepals** (collectively, the calyx). The corolla and calyx (collectively, the perianth) can be quite showy and often play roles in attracting animal pollinators to the flower. The calyx more commonly protects the immature flower in bud. From base to apex, these floral organs—sepals, petals, stamens, and carpels—are usually positioned in circular arrangements or whorls and attached to a central stalk.

The generalized flower in Figure 29.4B has both functional megasporangia and functional microsporangia; such flowers are referred to as **perfect** (or hermaphroditic). Many angiosperms produce two types of flowers, one with only megasporangia and the other with only microsporangia. Consequently, either the stamens or the carpels are nonfunctional or absent in a given flower, and the flower is referred to as **imperfect** (see Figure 38.1).

Species such as corn or birch, in which both megasporangiate (female) and microsporangiate (male) flowers occur on the same plant, are said to be **monoecious** (“one-housed”—but, it must be added, one house with

separate rooms). Complete separation of imperfect flowers occurs in some other angiosperm species, such as willows and date palms; in these species, an individual plant produces either flowers with stamens or flowers with carpels, but never both. Such species are said to be **dioecious** (“two-housed”).

Flower structure has evolved over time

The flowers of the earliest-diverging clades of angiosperms have a large and variable number of tepals (undifferentiated sepals and petals), carpels, and stamens (Figure 29.11A). Evolutionary change within the angiosperms has included some striking modifications of this early condition: reductions in the number of each type of floral organ to a fixed number, differentiation of petals from sepals, and changes in symmetry from radial (as in a lily or magnolia) to bilateral (as in the orchid shown at the opening of this chapter), often accompanied by an extensive fusion of parts (Figure 29.11B).

(A) *Nymphaea* sp.

(B) *Viola tricolor*

29.11 Flower Form and Evolution (A) A water lily shows the major features of early flowers: it is radially symmetrical, and the individual tepals, stamens, and carpels are separate, numerous, and attached at their bases. (B) Violets such as this “Johnny jump-up” have a bilaterally symmetrical structure that evolved much later than radial flower symmetry.

(A) Carpel evolution

(B) Stamen evolution

**29.12 Carpels and Stamens Evolved from Leaflike Structures**

(A) Possible stages in the evolution of a carpel from a more leaflike structure. (B) The stamens of three modern plants show three possible stages in the evolution of that organ. (It is *not* implied that these species evolved from one another; their structures simply illustrate the possible stages.)

According to one hypothesis, the first carpels to evolve were leaves with marginal ovules, folded but incompletely closed. Early in angiosperm evolution, carpels fused with one another, forming a single, multichambered ovary (**Figure 29.12A**). In some flowers, the other floral organs are attached at the top of the ovary rather than at the bottom as in **Figure 29.4B**. The stamens of the most ancient flowers may have been leaflike (**Figure 29.12B**), with little resemblance to the stamens of the generalized flower seen in **Figure 29.4B**.

Why do so many flowers have pistils with long styles and anthers with long filaments? Natural selection has favored length in both of these floral organs, probably because length increases the likelihood of successful pollination. Long filaments may bring the anthers into contact with insect bodies, or they may place the anthers in a better position to catch the wind. Similar arguments apply to long styles.

A perfect flower represents a compromise of sorts. On the one hand, by attracting a pollinating bird or insect, the plant is attending to both its female and male functions with a single flower type, whereas plants with imperfect flowers must create that attraction twice—once for each type of flower. On the other hand, the perfect flower can favor self-pollination, which is usually disadvantageous. Another potential problem is that the female and male functions might interfere with each other—for example, the stigma might be placed so as to make it difficult for pollinators to reach the anthers, thus reducing the export of pollen to other flowers.

Might there be a way around these problems? One solution is seen in the bush monkeyflower (*Mimulus aurantiacus*), which is pollinated by hummingbirds. Its flower has a stigma that initially serves as a screen, hiding the anthers (**Figure 29.13**). Once a hummingbird touches the stigma, however, one of the stigma's two lobes is retracted, so that subsequent hummingbird visitors pick up pollen from the previously screened anthers. Thus the first bird to visit the flower transfers pollen from another plant to the stigma. Later visitors pick up pollen from the now-accessible anthers, fulfilling the flower's male function. **Figure 29.14** describes the experiment that revealed the function of this mechanism.

Angiosperms have coevolved with animals

Whereas most gymnosperms are pollinated by wind, most angiosperms are pollinated by animals. The many different

29.13 An Unusual Way to Prevent Selfing Both long stamens and long styles facilitate cross-pollination, but if these male and female structures are too close to each other, the likelihood of (disadvantageous) self-pollination increases. In *Mimulus aurantiacus*, the stigma is initially open, blocking access to the anthers. A hummingbird's touch as it deposits pollen on the stigma causes one lobe of the stigma to retract, creating a path to the anthers and allowing pollen dispersal by subsequent hummingbird visitors.

29.14 The Effect of Stigma Retraction in Monkeyflowers

Elizabeth Fetscher's experiments showed that the unusual stigma retraction response to pollination in monkeyflowers (illustrated in Figure 29.13) enhances the dispersal of pollen to other flowers.^a

HYPOTHESIS The stigma-retraction response in *M. aurantiacus* increases the likelihood that an individual flower's pollen will be exported to another flower once pollen from another flower has been deposited on its stigma.

Method

1. Set up three groups of monkeyflower arrays. Each array consists of one pollen-donor flower and multiple pollen-recipient flowers (with the anthers removed to prevent pollen donation).
2. In control arrays, the stigma of the pollen donor is allowed to function normally.
3. In one group of experimental arrays, the stigma of the pollen donor is permanently propped open (blocking access to the anthers).
4. In a second group of experimental arrays, the stigma of the pollen donor is artificially sealed closed (allowing access to anthers).
5. Allow hummingbirds to visit the arrays, then count the pollen grains transferred from each donor flower to the recipient flowers in the same array.

Results

CONCLUSION The stigma-retraction response enhances the male function of the flower (dispersal of pollen) once the female function (receipt of pollen) has been performed.

^aFetscher, A. E. 2001. *Proceedings of the Royal Society B* 268: 525–529.

mutualistic pollination relationships between plants and animals are vital to both parties. We mentioned coevolution between insects and orchids at the opening of this chapter, and we'll revisit plant–pollinator coevolution in more detail when we discuss mutualisms in Chapter 56, but we'll consider a few important aspects of the plant–pollinator relationship here.

Many flowers entice animals to visit them by providing food rewards. Pollen grains themselves sometimes serve as food for animals. In addition, some flowers produce a sugary fluid called nectar, and some of these flowers have specialized structures to store and distribute it, as we saw at the opening of this chapter. In the process of visiting flowers to obtain nectar or pollen, animals often carry pollen from one flower to another or from one plant to another. Thus, in their quest for food, the animals contribute

Rubeckia fulgida

29.15 See Like a Bee To normal human vision (above), the petals of a black-eyed Susan appear solid yellow. Ultraviolet photography reveals patterns that attract bees to the central region, where pollen and nectar are located.

to the genetic diversity of the plant population. Insects, especially bees, are among the most important pollinators; birds and some species of bats are also major pollinators.

Pollen Transfer by a Bat
Life10e.com/mc29.2

For more than 150 million years, angiosperms and their animal pollinators have coevolved in the terrestrial environment. Animals have affected the evolution of the plants, and plants have affected the evolution of the animals. Flower structure has become incredibly diverse under these selection pressures. Some of the products of coevolution are highly specific; for example, the flowers of some yucca species are pollinated by only one species of yucca moth, and that moth may exclusively pollinate just one species of yucca (see Figure 56.12). Such specific relationships provide plants with a reliable mechanism for transferring pollen only to members of their own species.

Most plant–pollinator interactions are much less specific; that is, many different animal species pollinate the same plant species, and the same animal species pollinates many different plant species. However, even these less specific interactions have developed some specialization (see Table 56.1). For example, many bird-pollinated flowers are red and odorless, whereas many insect-pollinated flowers have characteristic odors. Some bee-pollinated flowers have markings, called nectar guides, that are conspicuous only to animals, such as bees, that can see colors in the ultraviolet region of the spectrum (**Figure 29.15**).

29.16 The Life Cycle of an Angiosperm Double fertilization results in triploid endosperm in most species of angiosperms. One sperm nucleus fertilizes the egg to form the zygote, while the other combines with the two polar nuclei to form the endosperm.

Go to Animated Tutorial 29.2
Life Cycle of an Angiosperm
Life10e.com/at29.2

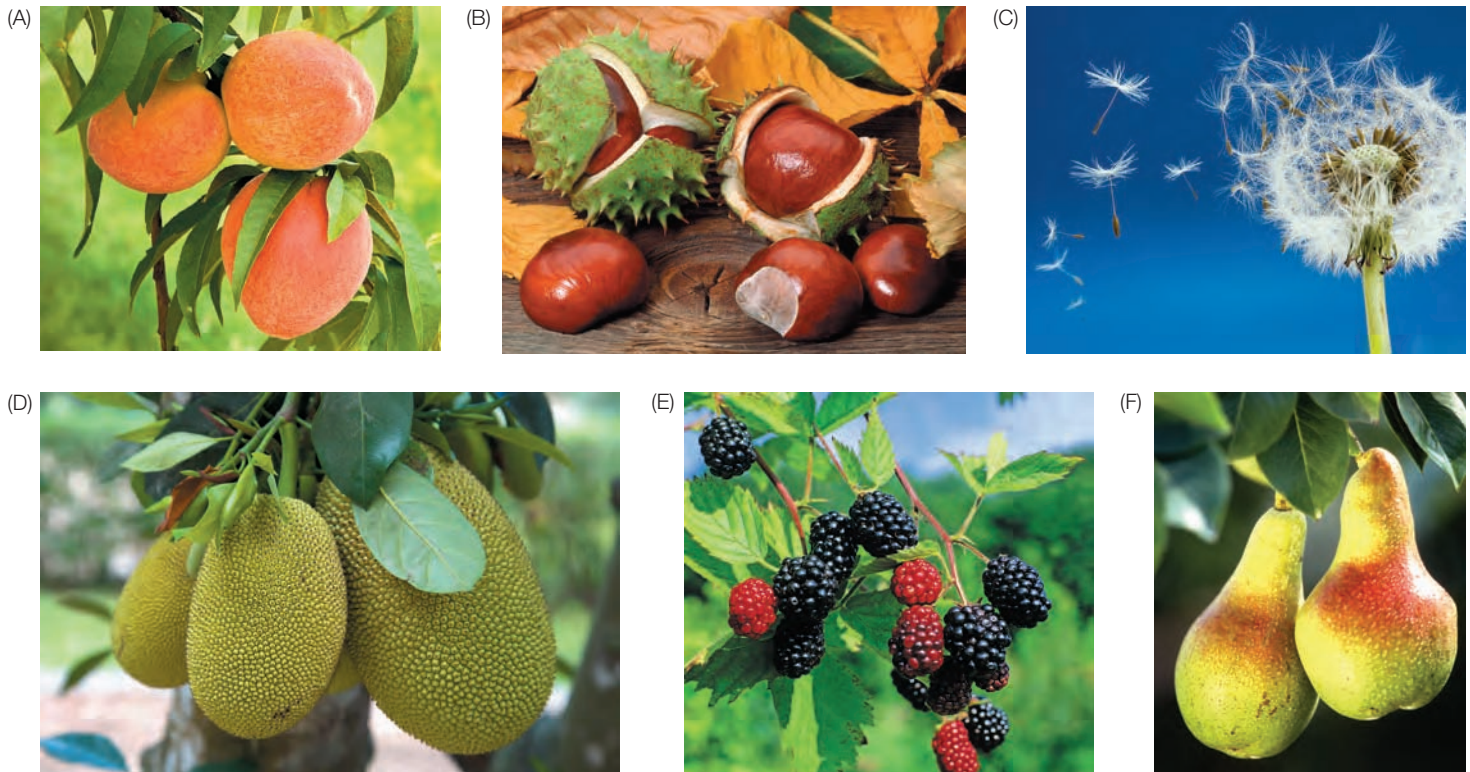

The angiosperm life cycle produces diploid zygotes nourished by triploid endosperms

Like all seed plants, angiosperms are heterosporous. As we have seen, their ovules are contained within carpels rather than being exposed on the surfaces of scales, as in most gymnosperms. The male gametophytes, as in the gymnosperms, are pollen grains.

Pollination in the angiosperms consists of the arrival of a microgametophyte—a pollen grain—on the receptive surface

of a flower (the stigma). As in the gymnosperms, pollination is the first in a series of events that results in the formation of a seed. The next event is the growth of a pollen tube extending to the megagametophyte. The third event is a fertilization process that, in detail, is unique to the angiosperms (**Figure 29.16**).

In angiosperms, *two* male gametes, contained in a single microgametophyte, participate in fertilization. The nucleus of one sperm combines with that of the egg to produce a diploid zygote—the first cell of the sporophyte generation. In

29.17 Fruits Come in Many Forms (A) The single seeds inside the simple fruits of peaches are dispersed by animals. (B) Each seed of the horse chestnut is covered by a hard, woody fruit that allows it to survive drought. Although such fruits are commonly called “nuts,” this is a culinary rather than a biological term. (C) The highly reduced simple fruits of dandelions are dispersed by wind. (D) A multiple fruit, the jackfruit (*Artocarpus heterophyllus*) of tropical Asia, is the largest tree-borne fruit in the world. (E) An aggregate fruit (blackberry). (F) An accessory fruit (pear).

most angiosperms, the other sperm nucleus combines with two other haploid nuclei of the female gametophyte to form a cell with a *triploid* ($3n$) nucleus. That cell in turn gives rise to a triploid tissue called the **endosperm**, which nourishes the embryonic sporophyte during its early development. This process, in which two fertilization events take place, is known as **double fertilization**. In some angiosperms, additional haploid nuclei are incorporated to form even higher ploidy levels in the endosperm, or the second sperm fuses with only one haploid nucleus, resulting in diploid endosperm.

The angiosperm zygote develops into an embryo, which consists of an embryonic axis that will become a stem and a root and one or two **cotyledons**, or “seed leaves.” The cotyledons have different fates in different plants. In many, they serve as absorptive organs that take up and digest the endosperm. In others, they enlarge and become photosynthetic when the seed germinates. Often they play both roles.

The ovule develops into a seed containing the products of the double fertilization that characterizes angiosperms: the diploid zygote and a triploid endosperm (see Figure 29.16).

Fruits aid angiosperm seed dispersal

As mentioned at the start of this section, the production of seed-protecting fruits is an important synapomorphy. Fruits may attach to or be eaten by an animal. Fruits are not necessarily fleshy; they can be hard and woody, or small with modified structures that allow them to be dispersed by wind or water (**Figure 29.17**).

A fruit may consist of only the mature ovary and its seeds, or it may include other parts of the flower or structures associated with it. A **simple fruit** is one that develops from a single carpel or several fused carpels, such as a plum or peach. A raspberry is an example of an **aggregate fruit**—one that develops from several separate carpels of a single flower. Pineapples and figs are examples of **multiple fruits**, formed from a cluster of flowers (an inflorescence). Fruits derived from parts in addition to the carpel and seeds are called **accessory fruits**; examples are apples, pears, and strawberries.

Flower and Fruit Formation
Life10e.com/mc29.3

Recent analyses have revealed the phylogenetic relationships of angiosperms

Figure 29.18 shows the relationships among the major angiosperm clades. The two largest clades—the **monocots** and the **eudicots**—include the great majority of angiosperm species. The monocots are so called because they have a single

29.18 Evolutionary Relationships among the Angiosperms Recent analyses of many angiosperm genes have clarified the relationships among the major groups.

embryonic cotyledon; the eudicots have two. Some familiar angiosperms belong to other clades, among them the water lilies, star anise and its relatives, and the magnoliids (**Figure 29.19**). The **magnoliids** are the likely sister group to the monocots and eudicots. Although less numerous than the latter two clades, the magnoliids include many familiar and useful plants, such as avocados, cinnamon, black pepper, and magnolias.

The root of the evolutionary tree of flowering plants was once a matter of great controversy. A fundamental challenge was identifying the group that is sister to the remaining angiosperms, and members of the magnoliid clade were leading candidates for the position. At the close of the twentieth century,

however, an impressive convergence of molecular and morphological evidence led to the conclusion that the sister group to the remaining flowering plants is the single species of the genus *Amborella* (see Figure 29.19A). This woody shrub, with cream-colored flowers, lives only on New Caledonia, an island in the South Pacific. Its 5 to 8 carpels have a spiral arrangement,

(A) *Amborella trichopoda*

Sterile stamens

(B) *Victoria amazonica*

(C) *Illicium floridanum*

(D) *Magnolia* sp.

(E) *Aristolochia littoralis*

29.19 Monocots and Eudicots Are Not the Only Surviving Angiosperms (A) *Amborella*, a shrub, is sister to the remaining extant angiosperms. Notice the sterile stamens on this female flower, which may serve to lure insects that are searching for pollen. (B) The water lily clade was the next to diverge after *Amborella*. (C) Star

anise and its relatives belong to another early-diverging angiosperm clade. (D, E) The largest clade other than the monocots and eudicots is the magnoliid complex, which includes magnolias and the group known as "Dutchman's pipe."

(A)

(B) *Saccharum* sp.(C) *Posidonia oceanica*(D) *Phoenix dactylifera*

29.20 Monocots (A) Monocots include many popular garden flowers such as these hyacinths (*Muscari armeniacum*; blue), tulips (*Tulipa* sp.; red) and daffodils (*Narcissus* sp.; yellow). (B) Monocot grasses such as this sugarcane feed the world; wheat, rice, and maize (corn) are also grasses. (C) Seagrasses such as this Neptune's grass form "meadows" in the shallow, sunlit waters of the world's oceans. (D) Palms are among the few monocot trees. Date palms like these are a major food source in some areas of the world.

and it has 30 to 100 stamens. The xylem of *Amborella* lacks vessel elements, which evolved after this deepest split in the angiosperm evolutionary tree.

Representatives of the two largest angiosperm clades are everywhere. The monocots (**Figure 29.20**) include grasses,

cattails, lilies, orchids, and palms. The eudicots (**Figure 29.21**) include the vast majority of familiar seed plants, including most herbs (i.e., nonwoody plants), vines, trees, and shrubs. Among the eudicots are such diverse plants as oaks, willows, beans, snapdragons, roses, and sunflowers.

(A) *Delonix regia*(B) *Passiflora caerulea*(C) *Echinocereus reichenbachii*(D) *Rafflesia arnoldii*

Filaments of corona

29.21 Eudicots (A) The royal poinciana, or "flame tree," is native to Madagascar. Humans have introduced this ornamental flowering tree throughout the world's tropical regions. (B) Passionflower vines are found throughout the tropics and subtropics. Their flowers are distinguished by elaborate coronas (the purple filaments on this flower). (C) Cacti comprise a large group of eudicots, with about 1,500 species

in the Americas. Many, such as this black lace cactus, bear large flowers for a brief period of each year. (D) *Rafflesia arnoldii*, found in the rainforests of Indonesia, bears the largest flower in the world. The flower lives as a parasite on tropical vines and has lost its leaf, stem, and even root structures. It smells like decaying meat, which attracts its fly pollinators.

RECAP
29.3

- The synapomorphies of angiosperms include flowers, fruit, carpels, double fertilization, and endosperm. Most angiosperms also possess distinctive cells in the xylem and phloem. The largest angiosperm clades are the monocots and the eudicots.
- Explain the difference between pollination and fertilization. See pp. 598–601
 - What are the respective roles of the two sperm in double fertilization in angiosperms? See pp. 600–601 and Figure 29.16
 - What are the different functions of flowers, fruits, and seeds?

The remarkable diversity of the seed plants has been shaped by both biotic and abiotic components of the environments to which they have adapted. In turn, land plants—and seed plants in particular—shape their environments.

29.4
How Do Plants Benefit Human Society?

Plants make profound contributions to ecosystem services—processes by which the environment maintains resources that benefit human society. Plants produce oxygen and remove carbon dioxide from the atmosphere, and they play important roles in forming soils and renewing soil fertility. Plant roots help hold soil in place, providing a defense against erosion by wind and water (Figure 29.22). They also moderate local climate in various ways, such as by increasing humidity, providing shade, and blocking wind.

Seed plants have been sources of medicine since ancient times

One of the oldest human professions is that of medicine man (shaman) or “wise woman”—a person who cures others with medicines, most of which are derived from plants. It is said that in 2700 BCE, a legendary Chinese emperor understood the use of some 365 medicinal plants. Although we also use medicines derived from fungi, lichens, and actinobacteria, seed plants are the source of many of our medications; a few examples are shown in Table 29.1. Even in synthetic pharmaceuticals, the chemical structures of the active ingredients are often based on the biochemistry of substances isolated from plants.

How are plant-based medicines discovered? These days, many are found by systematic testing of tremendous numbers of plants from all over the world, a process that began in the 1960s. One

29.22 Plants Prevent Erosion When forest vegetation was cleared on these hillsides in Malaysia, landslides and extensive soil erosion quickly followed. Adjacent forested areas did not have landslides.

TABLE 29.1
Some Medicinal Plants and Their Products

Product	Plant Source	Medical Application
Atropine	Belladonna	Dilate pupils for eye examination
Bromelain	Pineapple stem	Control tissue inflammation
Digitalin	Foxglove	Strengthen heart muscle contraction
Ephedrine	<i>Ephedra</i>	Ease nasal congestion
Menthol	Japanese mint	Relieve coughing
Morphine	Opium poppy	Relieve pain
Quinine	<i>Cinchona</i> bark	Treat malaria
Taxol	Pacific yew	Treat ovarian and breast cancers
Tubocurarine	Curare plant	Muscle relaxant (used in surgery)
Vincristine	Periwinkle	Treat leukemia and lymphoma

example of a medicine discovered in this way is taxol, an important anticancer drug. Among the myriad plant samples that had been tested by 1962, extracts of the bark of the Pacific yew (*Taxus brevifolia*) showed anti-tumor activity in tests against rodent tumors. The active ingredient, taxol, was isolated in 1971 and tested against human cancers in 1977. After another 16 years, the U.S. Food and Drug Administration approved it for human use, and taxol is now widely used in treating breast and ovarian cancers as well as several other types of cancers.

Widespread screening of plant samples was eventually deemphasized in favor of a purely chemical approach. Using automation and miniaturization, pharmaceutical laboratories generate vast numbers of compounds, which are then screened just as plant materials had been screened in the search for taxol. Today,

however, the screening of plant materials is getting renewed interest. Both screening approaches are based on trial and error.

The other leading source of plant-based medicines is work by ethnobotanists, who study how people use and view plants in their local environments. This work proceeds all over the globe today. An older example of this approach is the discovery of quinine as a treatment for malaria. In the sixteenth century, Spanish priests in Peru became aware that the native population used the bark of local *Cinchona* trees to treat fevers. The priests successfully used the bark to treat malaria. Word of the medicine spread to Europe, where it is said to have been in use in Rome by 1631. The active ingredient of *Cinchona* bark—quinine—was identified in 1820, and quinine remained the standard malarial remedy well into the twentieth century.

Seed plants are our primary food source

Plants are primary producers; that is, they trap energy and carbon by means of photosynthesis, making those resources available not only for their own needs, but also for the herbivores and omnivores that consume them, for the carnivores and omnivores that eat the herbivores, and for the prokaryotes and fungi that complete food webs. The earliest steps in human civilization involved cultivating angiosperms to provide a reliable food supply.

Today, twelve species of seed plants stand between the human race and starvation: rice, coconut, wheat, corn (maize), potato, sweet potato, cassava (also called tapioca or manioc), sugarcane, sugar beet, soybean, common bean (*Phaseolus vulgaris*), and banana. Hundreds of other seed plants are cultivated for food,

29.23 Rice Feeds Much of the World's Human Population

These rice fields, or “paddies,” are on the island of Luzon in the Philippines. Rice has been cultivated in this manner for thousands of years.

but none rank with these twelve in importance. Indeed, more than half of the world’s human population derives the bulk of its food energy from the seeds of a single plant, *Oryza sativa*, better known as rice. Rice is particularly important in eastern Asia, where it has been cultivated for more than 8,000 years (**Figure 29.23**). People also use rice straw in many ways, such as thatching for roofs, food and bedding for livestock, and clothing. Even rice hulls have many uses, ranging from fertilizer to fuel.

What was Darwin’s explanation for the three distinct flowers growing on a single orchid plant?

ANSWER

After obtaining specimens of the plant in question and dissecting the flowers, Darwin was able to demonstrate that the orchid was a single species (*Catasetum macrocarpum*) that bore three distinct types of flowers: megasporangiate (female), microsporangiate (male), and perfect (hermaphroditic). The three types of flowers were remarkable in their morphological differences, which were great enough to have misled botanists into describing the different flower types as species in different genera. Most individual plants were either male (specimens identified as *Catasetum*) or female (specimens identified as *Monachanthus*), but some individuals that bore predominately male or female flowers also produced perfect flowers (specimens identified as *Myanthus*).

The case of *C. macrocarpum* demonstrates that some plants blur the lines between the categories we have discussed in this chapter. Most flowers on a *C. macrocarpum* individual are either male or female, but some plants can bear some perfect flowers as well.

Why do the male and female flowers of *C. macrocarpum* look so different? Part of the explanation is their different roles in pollination. Recall Darwin’s observation of a *Catasetum* flower shooting a packet of pollen at an insect that landed on its flower. The pollinia (pollen packets) and associated structures in male flowers of *Catasetum* are coiled like springs and are

released suddenly when disturbed by an insect. This release forcefully propels the pollinia precisely into position on the back of the insect. The insect pollinator of *C. macrocarpum* is a specific bee species, the males of which are attracted to the odor of the flowers. The flowers produce no nectar reward, but the male bee does gather the chemical that produces the scent. The bee then moves on to another flower. When the bee visits a female flower on a different *C. macrocarpum* individual (again attracted by the same scent), no such “loaded spring” awaits. Instead, the morphology of the female flower enhances the removal of the pollinia from the insect’s body. In this way, floral morphology makes cross-fertilization more likely and reduces the chances of self-pollination.

Orchids were important in forming Darwin’s ideas about the mechanisms of evolution, for they showed that even aspects of the coloration and form of flowers evolved in response to natural selection. This conclusion ran counter to the thinking of the day. For example, Thomas Huxley, one of Darwin’s earliest and strongest supporters, doubted that the beauty of color in plants and animals could be explained on the basis of their importance to function. Darwin showed that the beauty of flowers is indeed connected to their reproductive success and is a key element in explaining the great diversity of plants.

29.1 How Did Seed Plants Become Today's Dominant Vegetation?

- Fossils of woody **seed ferns** are the earliest evidence of seed plants. The surviving groups of seed plants are the **gymnosperms** and **angiosperms**. **Review Figure 29.1**
- All seed plants are heterosporous, and their gametophytes are much smaller than (and dependent on) their sporophytes. **Review Figure 29.2**
- Seed plants do not require liquid water for fertilization. **Pollen grains**, the microgametophytes of seed plants, are carried to a megagametophyte by wind or by animals.
- An **ovule** consists of the seed plant megagametophyte and the **integument** of sporophytic tissue that protects it.
- Following **pollination**, a **pollen tube** emerges from the pollen grain, elongates, and usually delivers gametes to the megagametophyte. **Review Figure 29.4, ACTIVITY 29.1**
- The ovule develops into a **seed** that contains an embryo (the new sporophyte generation). Seeds are well protected and are often capable of long periods of dormancy, germinating only when conditions are favorable. **Review Figure 29.5**

29.2 What Are the Major Groups of Gymnosperms?

- The gymnosperms produce ovules and seeds that are not protected by ovary or fruit tissues.
- The major gymnosperm groups are the **cycads**, **ginkgos**, **gnetophytes**, and **conifers**. **Review Figure 29.6**
- The megaspores of conifers are produced in woody **cones** called **megastrobili**; the microspores are produced in herbaceous cones called **microstrobili**. **Review Figures 29.7 and 29.8, ACTIVITY 29.2, ANIMATED TUTORIAL 29.1**

29.3 How Do Flowers and Fruits Increase the Reproductive Success of Angiosperms?

- **Flowers** and **fruits** are unique to the angiosperms, distinguishing them from the gymnosperms.
- The xylem of most angiosperms is more complex than that of the gymnosperms. It contains two specialized cell types: **vessel elements**, which function in water transport, and **fibers**, which play an important role in structural support.

- The ovules and seeds of angiosperms are enclosed in and protected by **carpels**.
- The floral organs, from the base to the apex of the flower, are the **sepals**, **petals**, **stamens**, and **pistil**. Stamens bear microsporangia in **anthers**. The pistil (consisting of one or more carpels) includes an **ovary** containing ovules. The **stigma** is the receptive surface of the pistil.
- A flower with both megasporangia and microsporangia is referred to as **perfect**; a flower with only one or the other is **imperfect**.
- A **monoecious** species has megasporangiate and microsporangiate flowers on the same plant. A **dioecious** species is one in which megasporangiate and microsporangiate flowers occur on different plants.
- The carpels and stamens of flowers probably evolved from leaflike structures. **Review Figure 29.12**
- Some plants with perfect flowers have adaptations to prevent self-fertilization. **Review Figure 29.13**
- Many angiosperms have coevolved with their animal pollinators.
- Angiosperms exhibit **double fertilization**, usually resulting in the production of a diploid zygote and triploid **endosperm**. **Review Figure 29.16, ANIMATED TUTORIAL 29.2**
- The oldest evolutionary split among the angiosperms is between the clade represented by the single species in the genus *Amborella* and all the remaining flowering plants. **Review Figure 29.18**
- The most species-rich angiosperm clades are the **monocots** and the **eudicots**. The **magnoliids** are likely the sister group to the monocots and eudicots.

29.4 How Do Plants Benefit Human Society?

- Plants provide ecosystem services that affect soil, water, air quality, and climate.
- Plants are primary producers and as such are the foundation of terrestrial food webs.
- Plants provide humans with many important medicinal products.

CHAPTERREVIEW

REMEMBERING

- Which of the following statements about seed plants is *true*?
 - Seeds are produced only by flowering plants (angiosperms).
 - The sporophyte generation is more reduced in seed plants than in the ferns.
 - The gametophytes of seed plants are independent of the sporophytes.
 - All seed plant species are heterosporous.
 - The zygote of seed plants divides repeatedly to form the gametophyte.
- Most angiosperms
 - have seeds enclosed in a carpel.
 - have haploid endosperm that nourishes the developing embryo.
 - lack secondary growth.
 - bear two kinds of cones.
 - lack flowers.

3. Which statement about flowers is *not* true?
 - a. Pollen is produced in the anthers.
 - b. Pollen is received on the stigma.
 - c. An inflorescence is a cluster of flowers.
 - d. A species having female and male flowers on the same plant is dioecious.
 - e. A flower with both megasporangia and microsporangia is said to be perfect.
4. Which statement about the angiosperm pollen grain is *not* true?
 - a. It is the male gamete.
 - b. It is haploid.
 - c. It produces a long tube.
 - d. It is multicellular.
 - e. It is produced in microsporangia.
5. The eudicots
 - a. include many herbs, vines, shrubs, and trees.
 - b. along with the monocots are the only extant angiosperm clades.
 - c. are not a clade.
 - d. include the magnolias.
 - e. include orchids and palm trees.

UNDERSTANDING & APPLYING

6. Not all flowers possess all of the following floral organs: sepals, petals, stamens, and carpels. Which floral organ or organs do you think might be found in the flowers that have the smallest number of floral organ types? Discuss the possibilities, both for a single flower and for a species.

7. The origin of the angiosperms has long been “an abominable mystery,” as Charles Darwin once put it. The earliest known angiosperm fossils are from the late Jurassic or early Cretaceous, but fossils of their sister group, the gymnosperms, are known from as early as the late Carboniferous (about 150 million years earlier; see Figure 29.1). Given that these two sister groups are thought to have arisen from a single split in the seed plant lineage, what might explain the lack of earlier angiosperm fossils?

ANALYZING & EVALUATING

In 1879, W. J. Beal began an experiment that he could not hope to finish in his lifetime. He prepared 20 lots of seeds for long-term storage. Each lot consisted of 50 seeds from each of 23 species. He mixed each lot of seeds with sand and placed the mixture in an uncapped bottle, then buried all the bottles on a sandy knoll. At 10-year intervals over the next century, biologists have excavated a bottle and checked the viability of its contents. The table below shows the number of germinating seeds (of the original 50) from three of the species in years 50–100 of this ongoing experiment. Use these data to answer Questions 8–10.

Species	Years after burial					
	50	60	70	80	90	100
<i>Oenothera biennis</i> (Evening primrose)	19	12	7	5	0	0
<i>Rumex crispus</i> (Curly dock)	26	2	7	1	0	0
<i>Verbascum blattaria</i> (Moth mullein)	31	34	37	35	10	21

8. Calculate the percent of viable seeds for these three species in years 50–100 and graph seed survivorship as a function of time buried.
9. No seeds of the first two species were viable after 90 years of the experiment. Assume 100 percent seed viability at the start of the experiment (year 0), and predict from your graph the approximate year when you think the last of the *Verbascum blattaria* seeds will germinate.
10. What factors do you think might influence the differences among the species in long-term seed viability?

The Evolution and Diversity of Fungi

CHAPTER OUTLINE

- 30.1** What Is a Fungus?
- 30.2** How Do Fungi Interact with Other Organisms?
- 30.3** How Do Major Groups of Fungi Differ in Structure and Life History?
- 30.4** What Are Some Applications of Fungal Biology?

ALEXANDER FLEMING WAS ALREADY A famous scientist in 1928, but his laboratory was often a mess. That year he was studying the properties of *Staphylococcus* bacteria, the agents of dangerous staph infections. In August he took a long vacation with his family. When he returned in early September, he found that some of his petri dishes of *Staphylococcus* had become infested with a fungus that killed many of the bacteria.

Many scientists would have sighed at the loss, thrown out the petri dishes, and started new cultures of bacteria. But when Fleming looked at the dishes, he saw something exciting. Around each colony of fungi was a ring within which all the bacteria were dead.

Fleming hypothesized that the bacteria-free rings around the fungal colonies were produced by a substance excreted from the fungi, which he initially called "mould juice." He identified the fungi as members of the genus *Penicillium* and eventually named the antibacterial substance they produced "penicillin." Fleming published his discovery in 1929, but initially it received very little attention.

Over the next decade, Fleming produced small quantities of penicillin for testing as an antibacterial agent. Some of the tests showed promise, but many were inconclusive, and eventually Fleming gave up on the research. But his tests had shown enough promise to attract the attention of several chemists, who worked out the practical problems of producing a stable form of the substance. Clinical trials of this stable form of

Source of a "Miracle Drug" All species of the fungus *Penicillium* are recognizable by their dense, spore-bearing structures. The derivation of the antibiotic agent penicillin from these fungi was one of the most important achievements in medical history.

penicillin were extremely successful, and by 1945 it was being produced and distributed as an antibiotic on a large scale. That same year, Fleming and two of the chemists, Howard Florey and Ernst Chain, received the Nobel Prize in Medicine for their work on penicillin.

The development of penicillin was one of the most important achievements in modern medicine. Until the introduction of modern antibiotics, the most widespread agents of human death included bacterial infections such as gangrene, tuberculosis, and syphilis. Penicillin proved to be highly effective in curing such infections, and its success led to the creation of the modern pharmaceutical industry. Soon many additional antibiotic compounds were isolated from other fungi or synthesized in the laboratory, leading to a "golden age" of human health.

Have antibiotics derived from fungi eliminated the danger of bacterial diseases in human populations?

See answer on p. 627.

30.1 What Is a Fungus?

Fungi are organisms that digest their food outside their bodies. They secrete digestive enzymes to break down large food molecules in the environment, then absorb the breakdown products through the plasma membranes of their cells in a process known as **absorptive heterotrophy**. This mode of nutrition allows them to be successful in a wide variety of environments. Many fungi are **saprobies**, which means that they absorb nutrients from dead organic matter. Others are parasites, absorbing nutrients from living hosts. Still others are mutualists, living in intimate associations with other organisms that benefit both partners.

Modern fungi are believed to have evolved from a unicellular protist ancestor that had a flagellum. The probable common ancestor of the animals was also a flagellated protist much like the living choanoflagellates (see Figure 31.2). Current evidence, including the sequences of many genes, suggests that the fungi, choanoflagellates, and animals share a common ancestor not shared by other eukaryotes. These three lineages form a group known as the **opisthokonts** (Figure 30.1). A synapomorphy of the opisthokonts is a flagellum that, if present, is posterior, as in animal sperm. The flagella of all other eukaryotes are anterior.

Synapomorphies that distinguish the fungi as a group among the opisthokonts include absorptive heterotrophy and the presence of **chitin**, a nitrogen-containing structural polysaccharide, in their cell walls. The fungi represent one of the four independent evolutionary origins of large multicellular organisms (plants, brown algae, and animals are the other three).

Unicellular yeasts absorb nutrients directly

Most fungi are multicellular, but single-celled species are found in most fungal groups. Unicellular, free-living fungi are referred to as **yeasts** (Figure 30.2). Some fungi have both a yeast life stage and a multicellular life stage. Thus the term “yeast” does not refer to a single taxonomic group, but rather to a lifestyle that has evolved multiple times. Yeasts live in liquid or moist environments and absorb nutrients directly across their cell surfaces.

The ease with which many yeasts can be cultured, combined with their rapid growth rates, has made them ideal model organisms for study in the laboratory. They present many of the

30.1 Fungi in Evolutionary Context Absorptive heterotrophy and the presence of chitin in their cell walls distinguish the fungi from other opisthokonts.

Saccharomyces cerevisiae

30.2 Yeasts Unicellular, free-living fungi are known as yeasts. Many yeasts reproduce by budding—mitosis followed by asymmetrical cell division—as illustrated here.

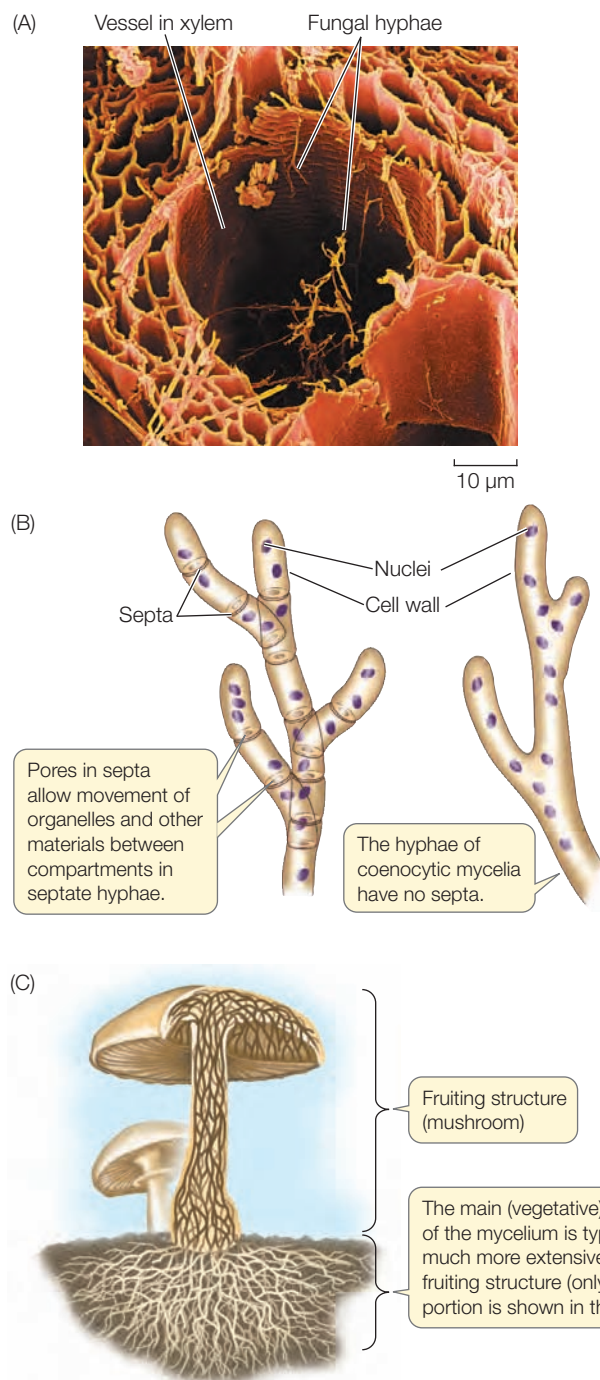

same advantages to laboratory investigators as do many bacteria, but because they are eukaryotes, their genome structures and cells are much more like those of humans and other eukaryotes than are those of bacteria.

Multicellular fungi use hyphae to absorb nutrients

The body of a multicellular fungus is called a **mycelium** (plural *mycelia*). A mycelium is composed of a mass of individual tubular filaments called **hyphae** (singular *hypha*; Figure 30.3A), in which absorption of nutrients takes place. The cell walls of the hyphae are greatly strengthened by microscopic fibrils of chitin. In some species of fungi, the hyphae are subdivided into cell-like compartments by incomplete cross-walls called **septa** (singular *septum*); these hyphae are referred to as **septate**. Septa do not completely close off compartments in the hyphae. Pores at the centers of the septa allow organelles—sometimes even nuclei—to move in a controlled way between compartments (Figure 30.3B). In other species of fungi, the hyphae lack septa but may contain hundreds of nuclei; these hyphae are referred to as **coenocytic**. The coenocytic condition results from repeated nuclear divisions without cytokinesis.

Certain modified hyphae, called **rhizoids**, anchor some fungi to their substrate (i.e., the dead organism or other matter on which they are feeding). These rhizoids are not homologous to the rhizoids of plants, and they are not specialized to absorb nutrients and water.

Fungi can grow very rapidly. In some species, the total hyphal growth of a fungal mycelium (not the growth of an individual hypha) may exceed 1 kilometer a day! The hyphae may be widely dispersed to forage for nutrients over a large area, or they may clump together in a cottony mass to exploit a rich nutrient source. The familiar mushrooms you may notice in the environment are spore-producing fruiting structures (Figure 30.3C). In the fungal species that produce these structures, the

30.3 Mycelia Are Made Up of Hyphae (A) The minute individual hyphae of fungal mycelia can penetrate small spaces. In this artificially colored micrograph, hyphae (yellow structures) of a dry-rot fungus are penetrating the xylem tissues of a log. (B) The hyphae of septate fungal species are divided into organelle-containing compartments by porous septa. The hyphae of coenocytic fungal species have no septa. (C) The fruiting structure of a club fungus is short-lived, but the filamentous, nutrient-absorbing mycelium can be long-lived and cover large areas.

mycelial mass is often far larger than the visible mushroom. The mycelium of one individual fungus discovered in Oregon covers almost 900 hectares underground and weighs considerably more than a blue whale (the largest animal). Aboveground, this individual is evident only as isolated clumps of mushrooms.

Lycoperdon perlatum

30.4 Spores Galore Puffballs (a type of club fungus) disperse trillions of spores in great bursts. Few of the spores travel very far, however; some 99 percent of them fall within 100 meters of the parent puffball.

What happens when a fungus faces a dwindling food supply? A common strategy is to reproduce rapidly and abundantly. When conditions are good, fungi produce great quantities of spores, but the rate of spore production is commonly even higher when nutrient supplies go down. The spores may then remain dormant until conditions improve, or they may be dispersed to areas where nutrient supplies are higher.

Not only are fungal spores abundant in number, but they are extremely tiny and easily spread by wind or water (Figure 30.4). These attributes virtually ensure that they will be scattered over great distances and that at least some of them will find conditions suitable for growth. The air we breathe contains as many as 10,000 fungal spores per cubic meter. No wonder we find fungi just about everywhere.

Fungi are in intimate contact with their environment

The filamentous hyphae of a fungus give it a unique relationship with its physical environment. The fungal mycelium has an enormous surface area-to-volume ratio compared with that of most large multicellular organisms. This large ratio is a marvelous adaptation for absorptive heterotrophy. Throughout the mycelium (except in fruiting structures), all of the hyphae are very close to their food source.

The downside of the large surface area-to-volume ratio of the mycelium is its tendency to lose water rapidly in a dry environment. Thus fungi are most common in moist environments. You have probably observed the tendency of molds, toadstools, and other fungi to appear in damp places.

Another characteristic of some fungi is a tolerance for highly hypertonic environments (those with a solute concentration higher than their own; see Section 6.3). Many fungi

are more resilient than bacteria in hypertonic surroundings. Jelly in the refrigerator, for example, will not become a growth medium for bacteria because it is too hypertonic to those organisms, but it may eventually harbor mold colonies. Mold in the refrigerator illustrates yet another trait of many fungi: tolerance of temperature extremes. Many fungi grow in temperatures as low as -6°C , and some can tolerate temperatures higher than 50°C .

RECAP 30.1

Fungi, like animals, are opisthokonts. Fungi are distinguished from other opisthokonts by absorptive heterotrophy and by the presence of chitin in their cell walls. Unicellular fungi called yeasts absorb nutrients directly across their cell surfaces. The body form of multicellular fungi—a mycelium made up of rapidly growing hyphae—allows them to practice absorptive heterotrophy efficiently in a variety of moist environments.

- Describe the relationship between fungal structure and absorptive heterotrophy. **See pp. 609–610 and Figure 30.3**
- What are the advantages and disadvantages to multicellular fungi of the large surface area-to-volume ratio of the mycelium? **See p. 610**

Fungi are important components of healthy ecosystems. They interact with other organisms in many ways, some of which are harmful and some beneficial to those other organisms.

30.2 How Do Fungi Interact with Other Organisms?

Without the fungi, our planet would be very different. Picture Earth with only a few stunted plants and watery environments choked with the remains of dead organisms. Fungi do much of Earth's garbage disposal. Fungi not only help clean up the landscape and form soil, but also play key roles in the recycling of mineral nutrients. Furthermore, the colonization of the terrestrial environment was made possible in large part by associations fungi formed with land plants and other organisms.

Saprobic fungi are critical to the planetary carbon cycle

Saprobic fungi, along with bacteria, are the major decomposers on Earth. These organisms contribute to the decay of nonliving organic matter and thus to the recycling of the elements required by living things. In forests, for example, fungi digest and absorb nutrients from fallen trees, thus decomposing their wood. Fungi are the principal decomposers of cellulose and lignin, the main components of plant cell walls (which most bacteria cannot break down). Other fungi produce enzymes that decompose keratin and thus break down animal structures such as hair and nails.

Were it not for the fungal decomposers, Earth's carbon cycle would fail: great quantities of carbon atoms would remain trapped forever on forest floors and elsewhere. Instead, those carbon atoms are returned to the atmosphere in the form of

CO_2 by fungal respiration, where they are again available for photosynthesis by plants.

There was a time in Earth's history when populations of saprobic fungi declined dramatically. Vast tropical swamps existed during the Carboniferous period, as we saw in Chapter 25. When plants in these swamps died, they began to form peat. Peat formation led to acidification of the swamps; that acidity, in turn, drastically reduced the fungal population. The result? With the decomposers largely absent, large quantities of peat remained on the swamp floor and over time were converted into coal.

In contrast to their decline during the Carboniferous, fungi did very well at the end of the Permian, about 250 million years ago, when the aggregation of the continents produced volcanic eruptions that triggered a global mass extinction. The fossil record shows that even as 96 percent of all multicellular species became extinct, fungi flourished—demonstrating both their hardiness and their role in recycling the elements in dead plants and animals.

Simple sugars and the breakdown products of complex polysaccharides are the favored source of carbon for saprobic fungi. Most fungi obtain nitrogen from proteins or the products of protein breakdown. Many fungi can use nitrate (NO_3^-) or ammonium (NH_4^+) ions as their sole source of nitrogen. No known fungus can get its nitrogen directly from inorganic nitrogen gas, however, as can some bacteria and plant–bacteria associations (that is, fungi cannot fix nitrogen; see Section 26.3).

Fungal Decomposers
Life10e.com/mc30.1

Some fungi engage in parasitic or predatory interactions

Whereas saprobic fungi obtain their energy, carbon, and nitrogen directly from dead organic matter, other species of fungi obtain their nutrition from parasitic—and even predatory—interactions.

PARASITIC FUNGI **Mycologists** (biologists who study fungi) distinguish between two classes of parasitic fungi based on their degree of dependence on their host. **Facultative parasites** can grow on living organisms but can also grow independently (including on artificial media). **Obligate parasites** can grow only on a specific, living host. The fact that their growth depends on a living host shows that obligate parasites have specialized nutritional requirements.

Plants and insects are the most common hosts of parasitic fungi. The filamentous structure of fungal hyphae is especially well suited to a life of absorbing nutrients from living plants. The slender hyphae of a parasitic fungus can invade a plant through stomata, through wounds, or in some cases, by direct penetration of epidermal cell walls (**Figure 30.5A**). Once inside the plant, the hyphae branch out to expand the mycelium. Some hyphae produce **haustoria**, branching projections that push through cell walls into living plant cells, absorbing the nutrients within those cells. The haustoria do not break

30.5 Invading a Leaf (A) Hyphae of the mildew *Phyllactinia guttata* growing on the surface of a hazel leaf. (B) Haustoria are fungal hyphae that push into the living cells of plants, from which they absorb nutrients.

through the plasma membranes inside the cell walls; they simply invaginate into the membranes, so that the plasma membrane fits them like a glove (Figure 30.5B). Fruiting structures may form, either within the plant body or on its surface.

Some parasitic fungi live in a close physical (symbiotic) relationship with a plant host that is usually not lethal to the plant. Others are *pathogenic*, sickening or even killing the host from which they derive nutrition.

Go to Media Clip 30.2

Mind-Control Killer Fungi

Life10e.com/mc30.2

PATHOGENIC FUNGI Although most human diseases are caused by bacteria or viruses, fungal pathogens are a major cause of death among people with compromised immune systems. Most people with AIDS die of fungal diseases, including the pneumonia caused by *Pneumocystis jirovecii*. Even *Candida albicans* and certain other yeasts that are normally part of a healthy microbiome can cause severe diseases, such as esophagitis (which impairs swallowing), in individuals with AIDS and in individuals taking immunosuppressive drugs. Various fungi cause other, less threatening human diseases, such as ringworm and athlete's foot. Our limited understanding of the basic biology of these fungi hampers our ability to treat the diseases they cause. As a result, fungal diseases are a growing international health problem.

The worldwide decline of amphibian species has been linked to the spread of a chytrid fungus, *Batrachochytrium dendrobatidis*. Genetic analyses indicate that the populations of this fungus that are attacking amphibian populations around the world are genetically almost identical, which suggests a recent introduction of the fungus across the globe. This chytrid appears to be native to southern Africa, and its spread around the world may have been initiated in the 1930s with exports of the African clawed frog (*Xenopus laevis*), which was once widely used in human pregnancy tests.

Fungi are by far the most important plant pathogens, much more so than bacteria and viruses. Pathogenic fungi cause crop losses amounting to billions of dollars each year. Major fungal diseases of crop plants include black stem rust of wheat and other diseases of wheat, corn, and oats. The agent of black stem rust is *Puccinia graminis*, which has a complicated life cycle that involves two plant hosts (wheat and barberry). In an epidemic in 1935, *P. graminis* was responsible for the loss of about one-fourth of the wheat crop in Canada and the United States.

PREDATORY FUNGI Some fungi have adaptations that enable them to function as active predators, trapping nearby microscopic protists or animals. The most common predatory strategy seen in fungi is to secrete sticky substances from the hyphae so that passing organisms stick to them. The hyphae then quickly invade the trapped prey, growing and branching within it, spreading through its body, absorbing nutrients, and eventually killing it.

A more dramatic adaptation for predation is the constricting ring formed by some species of soil fungi (Figure 30.6). When nematodes (tiny roundworms) are present in the soil, these fungi form three-celled rings with a diameter that just fits a nematode. A nematode crawling through one of these rings stimulates the fungus, causing the cells of the ring to swell and trap the worm. Fungal hyphae quickly invade and digest the unlucky victim.

Mutualistic fungi engage in relationships that benefit both partners

Certain relationships between fungi and other organisms have nutritional consequences for both partners. Two relationships of this type are **symbiotic** (the partners live in close, permanent contact with each other) as well as **mutualistic** (the relationship benefits both partners; see Section 56.3).

30.6 Fungus as Predator A nematode is trapped by hyphal rings of the soil-dwelling fungus *Arthrobotrys dactyloides*.

LICHENS A **lichen** is not a single organism, but rather a meshwork of two radically different species: a fungus and a photosynthetic microorganism. Together, the organisms that constitute a lichen can survive some of the harshest environments on Earth. The biota of Antarctica, for example, features more than a hundred times as many species of lichens as of plants. Relatively little experimental work has focused on lichens, perhaps because they grow so slowly—typically less than 1 centimeter in a year.

There are nearly 30,000 described “species” of lichens, each of which is assigned the name of its fungal component. These fungal components may constitute as many as 20 percent of all fungal species. Most of them are sac fungi (Ascomycota). Some of them are able to grow independently without a photosynthetic partner, but most have never been observed in nature other than in a lichen association. The photosynthetic component of a lichen is most often a unicellular green alga, but it can be a cyanobacterium, or may even include both.

Lichens are found in all sorts of exposed habitats: on tree bark, on open soil, and on bare rock. Reindeer moss (not a moss at all, but the lichen *Cladonia subtenuis*) covers vast areas in Arctic, sub-Arctic, and boreal regions, where it is an important part of the diets of reindeer and other large mammals.

The body forms of lichens fall into three principal categories. **Crustose** (crustlike) lichens adhere tightly to their substrate (Figure 30.7A). **Foliose** (leafy) lichens are loosely attached and grow parallel to their substrate (Figure 30.7B). **Fruticose** lichens are highly branched and can grow upward like shrubs or hang in long strands from tree branches or rocks (Figure 30.7C).

A cross section of a typical foliose lichen reveals a tight upper region of fungal hyphae; a layer of photosynthetic cyanobacteria or algae; a loose hyphal layer; and finally hyphal rhizoids that attach the structure to its substrate (Figure 30.8). The meshwork of fungal hyphae takes up mineral nutrients needed by the photosynthetic cells and also holds water tenaciously, providing a suitably moist environment. The fungus obtains fixed carbon from the photosynthetic products of the algal or cyanobacterial cells.

Within the lichen, fungal hyphae are tightly pressed against the photosynthetic cells and sometimes invade them without breaching the plasma membrane (similar to the haustoria in parasitic fungi; see Figure 30.5). The photosynthetic cells not only survive these intrusions but continue to grow. Algal cells in a lichen “leak” photosynthetic products at a greater rate than do similar cells growing on their own, and photosynthetic cells taken from lichens grow more rapidly on their own than when associated with a fungus. On the basis of these observations, we could consider lichen fungi to be parasitic on their photosynthetic partners. In many places where lichens grow, however, the photosynthetic cells could not grow at all on their own.

Lichens can reproduce simply by fragmentation of the vegetative body (the **thallus**) or by means of specialized structures called **soredia** (singular *soredium*). Soredia consist of one or a few photosynthetic cells bound by fungal hyphae. They become detached from the lichen, are dispersed by air currents, and upon arriving at a favorable location, develop into a new

30.7 Lichen Body Forms The body forms of lichens fall into three principal categories. (A) Two crustose lichen species are growing together on this exposed rock surface. (B) Foliose lichens have a leafy appearance. (C) The brown and orange growth is a “shrubby” fruticose lichen.

30.8 Lichen Anatomy Cross section showing the layers of a foliose lichen and the release of soredia.

lichen thallus. Alternatively, the fungal partner may go through its sexual reproductive cycle, producing haploid spores. When these spores are discharged, however, they disperse alone, unaccompanied by the photosynthetic partner.

Lichens are often the first colonists on new areas of bare rock. They get most of the mineral nutrients they need from the air and rainwater, augmented by minerals absorbed from dust. A lichen begins to grow shortly after a rain, as it begins to dry. As it grows, the lichen acidifies its environment slightly, and this acidity contributes to the slow breakdown of rocks, an early step in soil formation. With further drying, the lichen's photosynthesis ceases. The water content of the lichen may drop to less than 10 percent of its dry weight, at which point it becomes highly insensitive to extremes of temperature.

MYCORRHIZAE Many vascular plants depend on a symbiotic association with fungi. This ancient association between plants and fungi was critical to the successful exploitation of the terrestrial environment by plants. Unassisted, the root hairs of many plants often do not take up enough water or minerals to sustain their growth. However, the roots of such plants usually become infected with fungi, forming an association called a **mycorrhiza**. (We'll describe the infection process in detail in Section 36.4.) There

(A)

30.9 Mycorrhizal Associations (A) Ectomycorrhizal fungi wrap themselves around a plant root, increasing the area available for absorption of water and minerals. (B) Hyphae of arbuscular mycorrhizal fungi infect the root internally and penetrate the root cell walls, branching within the cells and forming a treelike structure, the arbuscule. (The cell cytoplasm has been removed to better visualize the arbuscule.)

are two types of mycorrhizae, distinguished by whether or not the fungal hyphae penetrate the plant cell walls.

In **ectomycorrhizae**, the fungus wraps around the root, and its mass is often as great as that of the root itself (**Figure 30.9A**). The fungal hyphae wrap around individual cells in the root but do not penetrate the cell walls. An extensive web of hyphae penetrates the soil in the area around the root, so that up to 25 percent of the soil volume near the root may be fungal hyphae. The hyphae attached to the root increase its surface area for the absorption of water and minerals, and the mass of hyphae in the soil acts like a sponge to hold water in the neighborhood of the root. Infected roots are short, swollen, and club-shaped, and they lack root hairs.

The fungal hyphae of **arbuscular mycorrhizae** enter the root and penetrate the cell walls of the root cells, forming arbuscular (treelike) structures inside the cell wall but outside the plasma membrane. These structures, like the haustoria of parasitic fungi and the contact regions of fungal hyphae and photosynthetic cells in lichens, become the primary site of exchange between plant and fungus (**Figure 30.9B**). As in the ectomycorrhizae, the fungus forms a vast web of hyphae leading from the root surface into the surrounding soil.

The mycorrhizal association is important to both partners. The fungus obtains needed organic compounds, such as sugars and amino acids, from the plant. In return, the fungus, because of its high surface area-to-volume ratio and its ability to penetrate the fine structure of the soil, greatly increases the plant's ability to absorb water and minerals (especially phosphorus). The fungus may also provide the plant with certain growth hormones and may protect it against attack by disease-causing microorganisms.

Plants that have active arbuscular mycorrhizae typically are a deeper green, exhibit higher growth rates, and may resist drought and temperature extremes better than plants of the same species that have little mycorrhizal development. Attempts to introduce some plant species to new areas have failed

(B) Arbuscule of *Glomus mosseae*

Hyphae of the fungus *Pisolithus tinctorius* cover a eucalyptus root.

until a bit of soil from the native area (presumably containing the fungus necessary to establish mycorrhizae) was provided. Trees without ectomycorrhizae do not grow well in the absence of abundant nutrients and water, so the health of our forests depends on the presence of ectomycorrhizal fungi. Many agricultural crops require inoculation of seeds with appropriate mycorrhizal fungi prior to planting. Without these fungi, the plants are unlikely to grow well, or in some cases at all. Certain plants that live in nitrogen-poor habitats, such as cranberry bushes and orchids, invariably have mycorrhizae. Orchid seeds will not germinate in nature unless they are already infected by the fungus that will form their mycorrhizae. Plants that lack chlorophyll always have mycorrhizae, which they often share with the roots of green, photosynthetic plants. In effect, these plants without chlorophyll are feeding on nearby green plants, using the fungus as a bridge.

Endophytic fungi protect some plants from pathogens, herbivores, and stress

In a tropical rainforest, 10,000 or more fungal spores may land on a single leaf each day. Some are plant pathogens, some do not affect the plant at all, and some invade the plant in a beneficial way. Fungi that live within aboveground parts of plants without causing obvious deleterious symptoms are called **endophytic fungi**. Recent research has shown that endophytic fungi are abundant in plants in all terrestrial environments.

Among the grasses, individual plants with endophytic fungi are more resistant to pathogens and to insect and mammalian herbivores than are plants lacking endophytes. The fungi produce alkaloids (nitrogen-containing compounds) that are toxic to animals. The alkaloids do not harm the host plant; in fact, some plants produce alkaloids (such as nicotine) themselves. The fungal alkaloids also increase the ability of grasses to resist stresses of various types, including drought (water shortage) and salty soils. Such resistance is useful in agriculture.

The role, if any, of endophytic fungi in most broad-leaved plants is unclear. They may convey protection against pathogens, or they may simply occupy space within leaves without conferring any benefit, but also without doing harm. The benefit, in fact, might be all for the fungus.

RECAP 30.2

Fungi interact with other organisms in many ways, both harmful and beneficial. Saprobic fungi play critical roles in the recycling of elements required by living organisms. Lichens are mutualistic associations of a fungus with algae or cyanobacteria. Mycorrhizae are associations of fungi and the roots of plants; they are essential for the survival of most plant species.

- What is the role of fungi in Earth's carbon cycle? [See p. 611](#)
- Describe the nature and benefits of the lichen association. [See pp. 613–614 and Figure 30.8](#)
- Why do plants grow better in the presence of mycorrhizal fungi? [See pp. 614–615 and Figure 30.9](#)

Before molecular techniques clarified their phylogenetic relationships, one criterion used for assigning fungi to taxonomic groups was the nature of their life cycles—including the types of fruiting structures they produced. The next section will take a closer look at life cycles in the six major groups of fungi.

30.3 How Do Major Groups of Fungi Differ in Structure and Life History?

Major fungal groups were originally distinguished by their structures and processes for sexual reproduction and, to a lesser extent, by other morphological differences. Although fungal life cycles are even more diverse than was once realized, specific types of life cycles generally characterize the six major groups of fungi: microsporidia, chytrids, zygospor fungi (Zygomycota), arbuscular mycorrhizal fungi (Glomeromycota), sac fungi (Ascomycota), and club fungi (Basidiomycota). **Figure 30.10** diagrams the evolutionary relationships of these groups as they are understood today.

The chytrids and the zygospor fungi may not represent monophyletic groups, as they each consist of several distantly related lineages that retain some ancestral features. The clades

30.10 A Phylogeny of the Fungi Microsporidia are reduced, parasitic fungi whose relationships among the fungi are uncertain. They may be the sister group of most other fungi, or they may be more closely related to particular groups of chytrids or zygospor fungi. The dashed lines indicate that chytrids and zygospor fungi are thought to be paraphyletic; the relationships of the lineages within these two informal groups (see Table 30.1) are not yet well resolved. The sac fungi and club fungi together form the clade Dikarya.

TABLE 30.1

Classification of the Fungi

Group	Common Name	Features
Microsporidia	Microsporidia	Intracellular parasites of animals; greatly reduced, among smallest eukaryotes known; polar tube used to infect hosts
Chytrids (paraphyletic) ^a Chytridiomycota Neocallimastigomycota Blastocladiomycota	Chytrids	Mostly aquatic and microscopic; zoospores and gametes have flagella
Zygomycota (paraphyletic) ^a Entomophthoromycotina Kickxellomycotina Mucoromycotina Zoopagomycotina	Zygosporangia	Reproductive structure is a unicellular zygosporangium with many diploid nuclei; hyphae coenocytic; no fleshy fruiting body
Glomeromycota	Arbuscular mycorrhizal fungi	Form arbuscular mycorrhizae in plant roots; only asexual reproduction is known
Ascomycota	Sac fungi	Sexual reproductive saclike structure known as an ascus, which contains haploid ascospores; hyphae septate; dikaryon
Basidiomycota	Club fungi	Sexual reproductive structure is a basidium, a swollen cell at the tip of a specialized hypha that supports haploid basidiospores; hyphae septate; dikaryon

^aThe formally named groups within the chytrids and Zygomycota are each thought to be monophyletic, but their relationships to one another (and to microsporidia) are not yet well resolved.

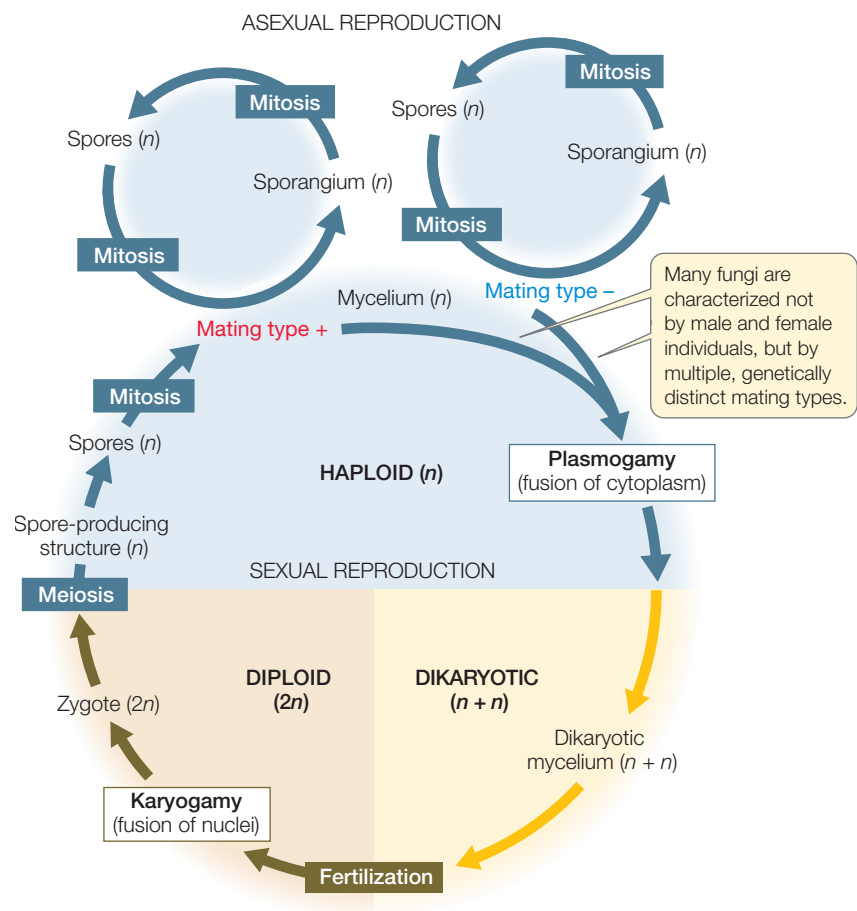

that are thought to be monophyletic within these two informal groupings are listed in **Table 30.1**. Recent evidence from DNA analyses has established the placement of the microsporidia among the fungi, the likely paraphyly of the chytrids and the zygosporangia fungi, the independence of arbuscular mycorrhizal fungi from the other fungal groups, and the monophyly of sac fungi and club fungi.

Fungi reproduce both sexually and asexually

Both asexual and sexual reproduction occur among the fungi (**Figure 30.11**). Asexual reproduction takes several forms:

- The production of (usually) haploid spores within sporangia
- The production of haploid spores (not enclosed in sporangia) at the tips of hyphae; such spores are called **conidia** (Greek *konis*, “dust”)
- Cell division by unicellular fungi—either a relatively equal division of one cell into two (*fission*) or an asymmetrical division in which a smaller daughter cell is produced (*budding*)
- Simple breakage of the mycelium

Sexual reproduction is rare (or even unknown) in some groups of fungi but is common in others. Sexual reproduction may not occur in some species, or it may occur so rarely that mycologists have never observed it. Species in which no sexual stage has been observed were once placed in a separate taxonomic group because knowledge of the sexual life cycle was considered necessary for classifying fungi. Now, however, these species can be related to other species of fungi through analysis of their DNA sequences.

30.11 A Generalized Fungal Life Cycle Environmental conditions may determine which mode of reproduction—sexual or asexual—takes place at a given time.

Sexual reproduction in most fungi features an interesting twist: There is no morphological distinction between female and male structures, or between female and male individuals, in most groups of fungi. Rather, there is a genetically determined distinction between two or more **mating types**. Individuals of the same mating type cannot mate with each other, but they can mate with individuals of another mating type within the same species, thus avoiding self-fertilization. Individuals of different mating types differ genetically but are often visually and physiologically indistinguishable.

Microsporidia are highly reduced, parasitic fungi

Microsporidia are unicellular parasitic fungi. They are among the smallest eukaryotes known, with infective spores that are only 1 to 40 micrometers (μm) in diameter. About 1,500 species have been described, but many more species are thought to exist. Their relationships among the eukaryotes have puzzled biologists for many decades.

Microsporidia lack true mitochondria, although they have reduced structures, known as **mitosomes**, that are derived from mitochondria. Unlike mitochondria, however, mitosomes contain no DNA; the mitochondrial genome has been completely transferred to the nucleus. Because microsporidia lack mitochondria, biologists initially suspected that they represented an early lineage of eukaryotes that diverged before the endosymbiotic event from which mitochondria evolved. The presence of mitosomes, however, indicates that this hypothesis is incorrect. DNA sequence analysis, along with the fact that their cell walls contain chitin, has confirmed that the microsporidia are in fact highly reduced, parasitic fungi, although their exact placement among the fungal lineages is still being investigated.

Microsporidia are obligate intracellular parasites of animals, especially of insects, crustaceans, and fishes. Some species are known to infect mammals, including humans. Most infections by microsporidia cause chronic disease in the host, with effects that include weight loss, reduced fertility, and a shortened life span. The host cell is penetrated by a polar tube that grows from the microsporidian spore. The function of the polar tube is to inject the contents of the spore, the sporoplasm, into the host (**Figure 30.12**). The sporoplasm replicates within the host cell and produces new infective spores. The life cycle of some species is complex and involves multiple hosts, whereas other species infect a single host. In some insects, parasitic microsporidia are transmitted vertically (i.e., from parent to offspring). Reproduction is thought to be strictly asexual in some microsporidians, but it includes poorly understood asexual and sexual cycles in other species.

Most chytrids are aquatic

The **chytrids** (**Figure 30.13**) include several distinct lineages of aquatic microorganisms that were once classified with the protists. However, morphological evidence (cell

30.12 Invasion of the Microsporidia The spores of microsporidia grow polar tubes that transfer the contents of the spores into the host's cells. The species shown here infects many animals, including humans.

walls that consist primarily of chitin) and molecular evidence support the classification of the chytrids as early-diverging fungi. In this book we use the term “chytrid” to refer to all three of the formally named clades listed as chytrids in Table 30.1, but some mycologists use this term to refer to only one of those clades, the Chytridiomycota. There are fewer than 1,000 described species among the three groups of chytrids.

Chytrids reproduce both sexually and asexually. Like the animals, chytrids that reproduce sexually possess flagellated gametes. The retention of this trait reflects the aquatic environment in which fungi first evolved. Chytrids are the only fungi that include species with flagella at any life cycle stage. Both the spores (called zoospores) and the gametes are flagellated (**Figure 30.14A**).

The alternation between multicellular haploid (n) and multicellular diploid ($2n$) generations that exists in plants and certain protist groups is seen in many fungi as well. For fungal groups other than the chytrids, this cycle differs from the usual system known as “alternation of generations” (see Figure 28.6) in that

30.13 A Chytrid Branched rhizoids emerge from the sporangium of a mature chytrid.

(A) Chytrids

Unlike other fungi, some chytrids produce flagellated male and female gametes from a multicellular haploid stage.

(B) Zygospor fungi (Zygomycota)

The single-celled zygospor is the only diploid cell in the life cycle of zygospor fungi.

30.14 Sexual Life Cycles of Chytrids and Zygospor Fungi

(A) Chytrids are the only fungi that possess flagella at any stage of the life cycle. (B) The unicellular zygospor, which contains multiple diploid nuclei, is a resting structure unique to the zygospor fungi.

the multicellular haploid stages do not produce specialized male and female gametes that are independent of the hyphae. Instead, in most fungi, cells of haploid hyphae from different mating types (of which there can be many more than two) fuse to form the diploid stage. But in sexually reproducing chytrids, the multicellular haploid stage produces independent male and female gametes, both of which are flagellated (see Figure 30.14A). The male gamete is distinguished from the female gamete by its smaller size; otherwise the two gametes are very similar in form.

The chytrids are diverse in form; some are unicellular, others have rhizoids, and still others have coenocytic hyphae. They may be parasitic (on organisms such as algae, mosquito larvae, nematodes, and amphibians) or saprobic. Some have complex mutualistic relationships with foregut-fermenting animals such as cattle and deer. Many chytrids live in freshwater habitats or in moist soil, but some are marine.

Some fungal life cycles feature separate fusion of cytoplasm and nuclei

Most members of the remaining four groups of fungi are terrestrial. Although the terrestrial fungi grow in moist places, they do not have motile gametes, and they do not release gametes into the environment, so liquid water is not required for fertilization. Instead, the cytoplasm of two individuals of different mating types fuse (a process called **plasmogamy**) before their nuclei fuse (a process called **karyogamy**; see Figure 30.11). Sexual species of terrestrial fungi include some zygosporer fungi, sac fungi, and club fungi.

Zygosporer fungi reproduce sexually when adjacent hyphae of two different mating types release chemical signals that cause them to grow toward each other. These hyphae produce gametangia, which are specialized cells for reproduction that are retained as part of the hyphae. In the gametangia, nuclei replicate without cell division, resulting in multiple haploid nuclei in both gametangia. The two gametangia then fuse to form a zygosporangium that contains many haploid nuclei of each mating type (Figure 30.14B). Haploid nuclei of different mating types then pair up to form multiple diploid nuclei within the zygosporangium. A thick, multilayered cell wall forms around the zygosporangium to form a well-protected resting stage that can remain dormant for months. In harsh environmental conditions, this resting stage may be the only cell that survives as the surrounding cells of the hyphae die. At this stage the single surviving cell is known as a **zygosporer**, which is the basis of the name of the zygosporer fungi. When environmental conditions improve, the nuclei within the zygosporer undergo meiosis and one or more stalked **sporangiophores** sprout, each bearing a sporangium. Each sporangium contains the products of meiosis: haploid nuclei that are incorporated into spores. These spores disperse and germinate to form a new generation of haploid hyphae.

The zygosporer fungi include four major lineages of terrestrial fungi that live on soil as saprobes, as parasites of insects and spiders, or as mutualists of other fungi and invertebrate animals. They produce no cells with flagella, and only one diploid cell—the zygosporer—appears in the entire life cycle. Their

30.15 Zygosporer Fungi Produce Sporangiophores These transparent structures are sporangiophores produced by a zygosporer fungus growing on decomposing animal dung. The sporangiophores grow toward the light and end in tiny sporangia, which the stalked sporangiophores can eject as far as 2 meters. Animals ingest sporangia and then disseminate the spores in their feces.

Go to Animated Tutorial 30.1
Life Cycle of a Zygosporer Fungus
Life10e.com/at30.1

hyphae are coenocytic. These species do not form a fleshy fruiting structure; rather, the hyphae spread in a radial pattern from the spore, with occasional stalked sporangiophores reaching up into the air (Figure 30.15).

More than 1,000 species of zygosporer fungi have been described. One species you may have seen is *Rhizopus stolonifer*, the black bread mold. *Rhizopus* produces many stalked sporangiophores, each bearing a single sporangium containing hundreds of minute spores (see Figure 30.14B).

Arbuscular mycorrhizal fungi form symbioses with plants

Arbuscular mycorrhizal fungi

(Glomeromycota) are terrestrial fungi that associate with plant roots in a symbiotic, mutualistic relationship (see Figure 30.9B). Fewer than 200 species have been described, but 80 to 90 percent of all plants have associations with them. Molecular systematic studies have suggested that arbuscular mycorrhizal fungi are the sister group of the Dikarya (sac fungi and club fungi).

The hyphae of arbuscular mycorrhizal fungi are coenocytic. These fungi use glucose from their plant partners as their

primary energy source, converting it into other, fungus-specific sugars that cannot return to the plant. Arbuscular mycorrhizal fungi reproduce asexually; there is not yet any direct evidence that they reproduce sexually.

The dikaryotic condition is a synapomorphy of sac fungi and club fungi

In the two remaining groups of fungi—the sac fungi and the club fungi—some stages have a nuclear configuration other than the familiar haploid or diploid states (see Figure 30.11). In these fungi, karyogamy (fusion of nuclei) occurs long after plasmogamy (fusion of cytoplasm), so that *two genetically different haploid nuclei coexist and divide within each cell of the mycelium* (Figure 30.16). This stage of the life cycle is called a **dikaryon** (“two nuclei”), and its ploidy is indicated as $n + n$. The dikaryon is a synapomorphy of the sac fungi and club fungi, which are placed together in a clade called **Dikarya**.

Eventually, specialized fruiting structures form, within which pairs of genetically dissimilar nuclei—one from each parent—fuse, giving rise to zygotes long after the original “mating.” The diploid zygote nucleus then undergoes meiosis, producing four haploid nuclei. The mitotic descendants of those nuclei become spores, which germinate to give rise to the next haploid generation.

A life cycle with a dikaryon stage has several unusual features. First, there are no gamete *cells*, only gamete *nuclei*. Second, the only true diploid structure is the zygote, although for a long period the genes of both parents are present in the dikaryon and can be expressed. In effect, the dikaryon is neither diploid ($2n$) nor haploid (n); rather, it is dikaryotic ($n + n$). Therefore a harmful recessive mutation in one nucleus may be compensated for by a normal allele on the same chromosome in the other nucleus, and dikaryotic hyphae often have characteristics that are different from their n or $2n$ products. The dikaryotic condition is perhaps the most distinctive of the genetic peculiarities of the fungi.

The sexual reproductive structure of sac fungi is the ascus

The **sac fungi** (Ascomycota) are found in terrestrial, marine, and freshwater habitats. There are approximately 64,000 known species, nearly half of which are the fungal partners in lichens. The hyphae of sac fungi are segmented by more or less regularly spaced septa. A large pore in each septum permits movement of nuclei and organelles from one segment to the next.

Sac fungi are distinguished by the production of sacs called **asci** (singular *ascus*), which at maturity contain sexually produced haploid **ascospores** (see Figure 30.16A). The ascus is the characteristic sexual reproductive structure of the sac fungi. In the past, the sac fungi were classified on the basis of whether or not the asci are contained within a specialized fruiting structure known as an **ascoma** (plural *ascomata*) and on differences in the morphology of that fruiting structure. DNA sequence

30.16 Sexual Life Cycles among the Dikarya (A) In sac fungi, the products of meiosis are borne in a microscopic sac called an ascus. The fleshy fruiting structure, the ascoma, consists of both dikaryotic and haploid hyphae. (B) The basidium is the characteristic sexual reproductive structure of the club fungi. The fruiting structures, called basidiomata, consist solely of dikaryotic hyphae, and the dikaryotic phase can last a long time.

Go to Activity 30.2 Life Cycle of a Dikaryotic Fungus
Life10e.com/ac30.2

analyses have resulted in a revision of these traditional groupings, however.

SAC FUNGUS YEASTS Some species of sac fungi are unicellular yeasts. The 1,000 or so species in this group are among the most important domesticated fungi. Perhaps the best known is baker’s, or brewer’s, yeast (*Saccharomyces cerevisiae*; see Figure 30.2 and Section 30.4), which metabolizes glucose obtained from its environment into ethanol and carbon dioxide by fermentation. Other sac fungus yeasts live on fruits such as figs and grapes and play an important role in the making of wine. Many others are associated with insects; in the guts of some insects, they provide enzymes that break down materials that are otherwise difficult for the insects to digest, especially cellulose.

Sac fungus yeasts reproduce asexually by budding. Sexual reproduction takes place when two adjacent haploid cells of dissimilar mating types fuse. In some species, the resulting zygote buds to form a diploid cell population. In others, the zygote nucleus undergoes meiosis immediately; when this happens, the entire cell becomes an ascus. Depending on whether the products of meiosis then undergo mitosis, a yeast ascus contains either eight or four ascospores, which germinate to become haploid cells. The sac fungus yeasts have lost the dikaryon stage.

FILAMENTOUS SAC FUNGI Most sac fungi are filamentous species, such as the cup fungi (Figure 30.17), in which the ascomata are cup-shaped and can be as large as several centimeters across (although most are much smaller). The inner surfaces of the ascomata, which are covered with a mixture of specialized hyphae and asci, produce huge numbers of spores. The edible ascomata of some species, including morels and truffles, are regarded by humans as gourmet delicacies (and can sell at prices higher than gold). The underground ascomata of truffles have a strong odor that attracts mammals such as pigs, which then eat the fungi and disperse the spores.

The sexual reproductive cycle of filamentous sac fungi includes the formation of a dikaryon, although this stage is relatively brief compared with that in club fungi. Many filamentous sac fungi form multinucleate mating structures (see Figure 30.16A). Mating structures of two different mating types fuse and produce a dikaryotic mycelium, containing nuclei from both mating types. The dikaryotic mycelium often forms a cup-shaped ascoma, which bears the asci. Only after the formation of asci do the nuclei from the two mating types finally fuse.

(A) Sac fungi (Ascomycota)

In sac fungi, the products of meiosis are borne in a microscopic sac called an ascus. The fleshy fruiting bodies consist of both dikaryotic and haploid hyphae.

(B) Club fungi (Basidiomycota)

In club fungi, the products of meiosis are borne on the surface of the gills on pedestals called basidia. Fruiting bodies consist solely of dikaryotic hyphae, and the dikaryotic phase can last a long time.

30.17 Sac Fungi (A) These brilliant red cups are the ascomata of a cup fungus. (B) Morels, which have a spongelike ascoma and a subtle flavor, are considered a culinary delicacy by humans.

(A) *Aleuria aurantia*(B) *Morchella esculenta*

Both nuclear fusion and the subsequent meiosis that produces haploid ascospores take place within individual asci. The ascospores are ultimately released (sometimes shot off forcefully) by the ascus to begin the new haploid generation.

The sac fungi also include many of the filamentous fungi known as molds. **Molds** consist of filamentous hyphae that do not form large ascomata, although they can still produce asci and ascospores. Many molds are parasites of flowering plants. Chestnut blight and Dutch elm disease are both caused by molds. The chestnut blight fungus, which was introduced to the United States in the 1890s, had destroyed the American chestnut as a commercial tree species by 1940. Before the blight, this species accounted for more than half the trees in eastern U.S. forests. Another familiar story is that of the American elm. Sometime before 1930, the Dutch elm disease fungus (first discovered in the Netherlands but native to Asia) was introduced into the United States on infected elm logs from Europe. Spreading rapidly—sometimes by way of connected root systems—the fungus destroyed great numbers of American elm trees.

Other plant pathogens among the sac fungi include the powdery mildews that infect cereal crops, lilacs, and roses, among many other plants. Mildews can be a serious problem to farmers and gardeners, and a great deal of research has focused on ways to control these agricultural pests.

The filamentous sac fungi can also reproduce asexually by means of conidia that form at the tips of specialized hyphae (Figure 30.18). Small chains of conidia are produced by the millions and can survive for weeks in nature. The conidia are what give molds their characteristic colors.

The sexual reproductive structure of club fungi is the basidium

Club fungi (Basidiomycota) produce some of the most spectacular fruiting structures found among the fungi. These fruiting structures, called **basidiomata** (singular *basidioma*), include mushrooms of all kinds, puffballs (see Figure 30.4), and the bracket fungi often encountered on trees and fallen logs in a damp forest. About 30,000 species of club fungi have been described. They include about 4,000 species of mushrooms, including both poisonous and edible species (Figure 30.19A).

Bracket fungi (Figure 30.19B) play an important role in the carbon cycle by breaking down wood; they also do great economic damage to both cut lumber and timber stands. Some of the most economically damaging plant pathogens are club fungi, including the rust fungi and smut fungi that parasitize cereal grains. In contrast, other club fungi contribute to the survival of plants as fungal partners in ectomycorrhizae.

The hyphae of club fungi characteristically have septa with small, distinctive pores. As they grow, haploid hyphae of different mating types meet and fuse, forming dikaryotic hyphae, each cell of which contains two nuclei, one from each parent hypha. The dikaryotic mycelium grows and eventually, when triggered by rain or another environmental cue, produces a basidioma. The dikaryon stage may persist for years—some club fungi live for decades or even centuries. This pattern contrasts with the life cycle of the sac fungi, in which the dikaryon is found only in the stages leading up to formation of the asci.

*Penicillium roqueforti*5 μ m

30.18 Conidia Chains of conidia (yellow) are developing at the tips of specialized hyphae arising from a *Penicillium roqueforti* mold. This species is used to produce “blue” cheese.

30.19 Club Fungus Basidiomata

(A) These edible mushrooms are the fruiting structures of a honey fungus. Mycelia of this genus form connected underground masses that cover many hectares and are among the largest and longest-lived organisms in the world. (B) A bracket fungus growing parasitically on a tree. Although this particular species is edible, many similar-appearing bracket fungi are poisonous.

(A) *Armillaria* sp.(B) *Laetiporus sulphureus*

The **basidium** (plural *basidia*), a swollen cell at the tip of a specialized hypha, is the characteristic sexual reproductive structure of the club fungi (see Figure 30.16B). In mushroom-forming club fungi, the basidia typically form on specialized structures of the basidiomata known as gills. The basidium is the site of nuclear fusion and meiosis and thus plays the same role in the club fungi as the ascus does in the sac fungi and the zygosporangium does in the zygosporangium fungi.

After nuclei fuse in the basidium, the resulting diploid nucleus undergoes meiosis, and the four resulting haploid nuclei are incorporated into haploid **basidiospores**, which form on tiny stalks on the outside of the basidium. A single basidioma of the common bracket fungus *Ganoderma applanatum* can produce as many as 4.5 trillion basidiospores in one growing season. Basidiospores typically are forcibly discharged from their basidia and then germinate, and give rise to hyphae with haploid nuclei.

RECAP 30.3

Sexual reproduction is common in some groups of fungi but has never been observed in others. Many fungal species have two or more genetically distinct mating types. The sac fungi and club fungi share a dikaryotic condition, in which two genetically different haploid nuclei coexist in the same cell.

- Explain how microsporidia infect the cells of their animal hosts. **See p. 617 and Figure 30.12**
- What is the role of the zygospore in the life cycle of zygosporangium fungi? **See p. 619 and Figure 30.14B**
- Explain the dikaryon stage in terms of plasmogamy and karyogamy. **See p. 620 and Figure 30.16**
- What distinguishes the fruiting bodies of sac fungi from those of club fungi? **See pp. 620–623 and Figure 30.16**

Fungi are of special interest to biologists because of the roles they play in interactions with other organisms. But they are also useful as tools for studying many kinds of biological problems and for finding solutions to those problems.

30.4 What Are Some Applications of Fungal Biology?

We've briefly noted the important part that fungi play in the production of human foods and beverages. We have also described the diverse roles that fungi play in natural ecosystems, from decomposers to pathogens to mutualistic partners. These diverse ecological roles have led to the use of fungi in studies of environmental change and in remediation of environmental pollution. Many fungi are also important model organisms for laboratory investigations of basic biological process. Others, as we saw at the opening of this chapter, have given us treatments for human diseases.

Fungi are important in producing food and drink

Grains from grasses provide most of the world's food supply for humans. But in most cases, we do not eat these grains directly as they are produced by the plants. Instead, we use them as a source of starch. To make the starch more pleasing and digestible for human consumption, we usually convert it to more complex and tasty forms of food and drink, often with the help of fungi.

Baker's (or brewer's) yeast (*Saccharomyces cerevisiae*) converts the starch from grain into ethanol. This process also forms carbon dioxide bubbles in bread dough, causing it to rise, which gives baked bread its light texture. The ethanol and carbon dioxide are baked away in bread making (which produces the pleasant aroma of baking bread). In contrast, the ethanol and carbon dioxide are retained when yeast is used to ferment grain into beer. The carbon dioxide gives beer its fizz, and the alcohol contributes to the taste and appeal of beer to those who enjoy it. Sugars, especially from fruit such as grapes, are also converted into alcohol and carbon dioxide by yeasts in the production of wine (although the carbon dioxide is not retained in finished wine, as it is in beer). Many different strains of *S. cerevisiae* are used in wine production, which contributes to the distinctive nature of wine from different regions and wineries. Many other species of local,

native yeasts are also used in producing distinctive local wines and beers. For example, fission yeast (*Schizosaccharomyces pombe*) was first isolated from African millet beer; it takes its specific name (*pombe*) from the Swahili word for beer.

Go to Media Clip 30.3

Time Lapse of Beer Formation

Life10e.com/mc30.3

Brown molds of the genus *Aspergillus* are important in some human diets. *Aspergillus tamarii* acts on soybeans in the production of soy sauce, and *A. oryzae* is used in brewing the Japanese alcoholic beverage sake from rice. *Aspergillus niger* is the source of most commercial citric acid production; citric acid gives food and soft drinks a tart taste and is also used as a food preservative. But some species of *Aspergillus* that grow on grains and on nuts such as peanuts and pecans produce extremely carcinogenic (cancer-inducing) compounds called aflatoxins. Aflatoxins can occur in high concentrations in foods such as peanut butter. In the United States and most other industrialized countries, moldy grain infected with *Aspergillus* is typically thrown out. In Africa, where food is scarcer, the grain gets eaten, moldy or not, and causes severe health problems, including high levels of certain cancers.

Penicillium is a genus of green molds, of which some species produce the antibiotic penicillin, as described in the beginning of this chapter. But several species of *Penicillium* are important for food production as well. For example, *P. camembertii* and *P. roqueforti* are the organisms responsible for the characteristic strong flavors of Camembert and Roquefort cheeses, respectively.

Many fungi serve directly as a human food source. Mushroom enthusiasts seek out the delicious fruiting structures of a wide variety of edible sac and club fungi. In the United States, relatively few species of mushrooms are grown commercially, and wild mushrooms are collected mostly for personal consumption. But in many parts of the world, a wide variety of wild mushrooms are collected for sale and consumption. Fungi used for food are not limited to fruiting bodies such as mushrooms, however. Various species of lichens are eaten in Arctic regions as well as in parts of North America and Asia. In southwestern China, for example, several species of lichens are used as a primary ingredient in cooking (Figure 30.20).

Fungi record and help remediate environmental pollution

Each year, biologists deposit samples of many groups of organisms in the collections of natural history museums. These museum collections serve many purposes, one of which is to document changes in the biota of our planet over time.

Collections of fungi made over many decades or centuries provide a record of the environmental pollutants that were present when the fungi were growing. Biologists can analyze these historical samples to see how different sources of pollutants were affecting our environment before anyone thought to take direct measurements. These long-term records are also useful for analyzing the effectiveness of cleanup efforts and regulatory programs for controlling environmental pollutants.

30.20 Some Lichens Are Edible In southwestern China, several species of lichens that grow on tree bark serve as a primary ingredient in the local cuisine.

We have already seen that fungi are critical to the planetary carbon cycle because of their role in breaking down dead organic matter. Fungi are also used in remediation efforts to help clean up sites that have been polluted by oil spills or contaminated with toxic petroleum-derived hydrocarbons. Many herbicides, pesticides, and other synthetic hydrocarbons are broken down primarily through the action of fungi.

Lichen diversity and abundance are indicators of air quality

Lichens can live in many harsh environments where few other species can survive, as we saw in Section 30.2. In spite of their hardiness, however, lichens are highly sensitive to air pollution because they are unable to excrete any toxic substances they absorb. This sensitivity means that lichens are good biological indicators of air pollution levels. It also explains why they are not commonly found in heavily industrialized regions or in large cities.

Sensitive biological indicators of pollution such as lichen growth allow biologists to monitor air quality without the use of specialized equipment. Monitoring the diversity and abundance of lichens growing on trees is a practical and inexpensive system for gauging air quality around cities (Figure 30.21). Maps of lichen diversity provide environmental biologists with a tool for tracking the spatial distribution of air pollutants and their effects. Lichens can also provide a long-term measure of the effects of air pollution across many seasons and years.

Fungi are used as model organisms in laboratory studies

Much of what we know about many basic aspects of cell and molecular biology comes from the study of model organisms. Among the eukaryotes, some fungi have numerous advantages over model plant and animals systems for laboratory investigations.

Of particular importance as model organisms are several species of sac fungi: *Aspergillus nidulans* (a brown mold), *Neurospora crassa* (a red bread mold), *Saccharomyces cerevisiae* (baker's, or brewer's, yeast), and *Schizosaccharomyces pombe* (fission yeast). These species can be cultured in large numbers in small spaces, and they have short generation times, so that genetic

WORKING WITH DATA:

Using Fungi to Study Environmental Contamination

Original Paper

Flegal, A. R., C. Gallon, S. Hibdon, Z. E. Kuspa, and L. F. Laporte. 2010. Declining—but persistent—atmospheric contamination in central California from the resuspension of historic leaded gasoline emissions as recorded in the lace lichen (*Ramalina menziesii* Taylor) from 1892 to 2006. *Environmental Science and Technology* 44: 5613–5618.

Analyze the Data

A. Russell Flegal and his colleagues analyzed over 100 years' worth of museum samples of lace lichens collected near San Francisco, California for evidence of lead contamination. They measured concentrations of lead (Pb) as well as the ratios of two lead isotopes, ^{206}Pb and ^{207}Pb . The isotope ratio was used to determine the source of lead contamination. Possible sources included a lead smelter that operated in the area from 1885 to 1971 (which produced emissions with a $^{206}\text{Pb}/^{207}\text{Pb}$ ratio of about 1.15–1.17); leaded gasoline in use from the 1930s to the early 1980s, peaking in 1970 (which produced automobile emissions with a $^{206}\text{Pb}/^{207}\text{Pb}$ ratio of 1.18–1.23); and resuspension of historic lead contamination as atmospheric aerosols in recent decades (with an intermediate $^{206}\text{Pb}/^{207}\text{Pb}$ ratio of about 1.16–1.19).

Before analyzing the data, use the information in the preceding paragraph to formulate hypotheses about the following two questions: What trends in atmospheric lead concentrations would you expect to see? What $^{206}\text{Pb}/^{207}\text{Pb}$ ratios would you expect to find at different times from the late 1800s to the early 2000s? After formulating your hypotheses, plot lead concentration in the lichen samples against year of sample collection. Make a second plot, this one of $^{206}\text{Pb}/^{207}\text{Pb}$ ratio against year of sample collection.

Sample	Year collected	Lead concentration (μg of Pb/g lichen)	$^{206}\text{Pb}/^{207}\text{Pb}$ ratio
1	1892	11.9	1.165
2	1894	4.0	1.155
3	1906	13.7	1.154
4	1907	22.9	1.157
5	1945	49.9	1.187
6	1957	34.2	1.185
7	1978	50.9	1.221
8	1982	10.0	1.215
9	1983	4.6	1.224
10	1987	1.0	1.198
11	1988	1.3	1.199
12	1995	1.9	1.202
13	2000	0.4	1.184
14	2006	1.8	1.184

QUESTION 1

Do your analyses support the hypotheses you formulated?

QUESTION 2

Are your hypotheses consistent with your analyses of trends in both lead concentrations and $^{206}\text{Pb}/^{207}\text{Pb}$ ratios through time? If not, how would you modify your hypotheses, and what additional tests can you design to test your ideas?

Go to **BioPortal** for all **WORKING WITH DATA** exercises

(A)

30.21 More Lichens, Better Air Lichen abundance and diversity are excellent indicators of air quality. (A) In suitable environments with few pollutants in the air, many lichen species show luxuriant growth on trees. These lichens are growing on an oak tree 150 kilometers west of Austin, Texas, in an area relatively free of human

(B)

habitation and industry. (B) As air quality declines, so do the number and diversity of lichens. These lichens are growing on an oak tree inside the city of Austin, where air quality is reduced (primarily by automobile exhaust).

30.22 A Pathogenic Fungus Attacks a Parasitic Plant The fungus *Fusarium oxysporum* is a potent pathogen of witchweed (*Striga*), a parasitic plant that attacks crops. The fungal spores are shown in blue; fungal filaments are in tan. Both colors were added to enhance this scanning electron micrograph.

investigations can be conducted in days rather than years. Furthermore, their genomes are relatively small and encode relatively few genes compared with those of most plants and animals, so it is easier to elucidate the functions of the fungal genes responsible for basic biological functions.

Reforestation may depend on mycorrhizal fungi

When a forest is cut down, it is not just the trees that are lost. A forest is an ecosystem that depends on the interactions of many species. As we have discussed, many plants depend on close relationships with mycorrhizal fungal partners. When trees are removed from a site, the populations of mycorrhizal fungi there decline rapidly. If we wish to restore the forest on the site, we cannot simply replant it with trees and other plants and expect them to survive. The mycorrhizal fungal community must be reestablished as well. For large forest restoration projects, a planned succession of plant growth and soil improvement is often necessary before forest trees can be replanted. As the community of soil fungi gradually recovers, trees that have been inoculated with appropriate mycorrhizal fungi in tree nurseries can be planted to reintroduce greater diversity to the soil fungal community.

Fungi provide important weapons against diseases and pests

We started this chapter with the story of the discovery of penicillin. The discovery of antibiotics produced by fungi revolutionized medical treatment of bacterial diseases in humans and their domestic animals. Live strains of fungi are also used to combat various pest species of plants and animals.

In Africa, the parasitic plant witchweed (*Striga*) causes crop losses of about \$7 billion every year. A group of Canadian

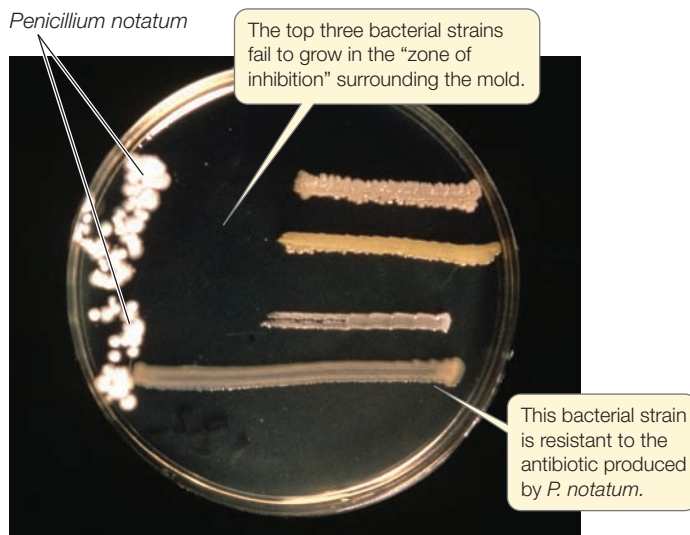

biologists discovered that a strain of the mold *Fusarium oxysporum* could be applied to crops to control witchweed without harming the crop plants (Figure 30.22). Other strains of *Fusarium* that preferentially attack coca plants, the source of cocaine, have been proposed to combat illicit drug production. Still other fungi are used to attack various animal pests, such as termites and aphids, and even malaria-carrying mosquitoes, as we'll see below.

RECAP 30.4

Fungi are important to humans in many ways. Some species are consumed directly as food, while others are important in food production. Fungi serve as important indicators of ecosystem health and are critical in reforestation and in pollution remediation efforts. Several species are important model organisms for studies of eukaryote cell and molecular biology. Fungi are widely used to combat diseases and pests.

- What are some of the ways in which fungi or fungal products contribute to the human food supply? [See pp. 623–624](#)
- What are some advantages of using surveys of lichen diversity and museum collections of lichens to measure long-term changes in air quality, compared with direct measurements of atmospheric pollutants? [See pp. 624–625 and Figure 30.21](#)
- Why are some fungi particularly appropriate as model organisms for the study of eukaryote cell and molecular biology? [See pp. 625–626](#)

Whether living on their own or in symbiotic associations, fungi have spread successfully over much of Earth since their origin from a protist ancestor. An earlier ancestor of fungi also gave rise to the choanoflagellates and the animals, which we will describe in the following three chapters.

30.23 Penicillin Resistance In a petri dish similar to those in Alexander Fleming's lab, four strains of a pathogenic bacterium have been cultured along with *Penicillium* mold. One strain is resistant to the mold's antibiotic substance, as is evidenced by its growth up to the mold.

Have antibiotics derived from fungi eliminated the danger of bacterial diseases in human populations?

ANSWER

Beginning in the 1940s, antibiotics derived from fungi ushered in a “golden age” of freedom from bacterial infections. Today, however, many of these antibiotics are losing their effectiveness as pathogenic bacteria evolve resistance to them (**Figure 30.23**)

Most medical antibiotics are chemically modified forms of substances that are found naturally in fungi and other organisms. Fungi naturally produce antibiotic compounds to defend themselves against bacterial growth and to reduce competition from bacteria for nutritional resources. These naturally occurring compounds are usually chemically modified to increase their stability, to improve their effectiveness, and to facilitate synthetic production. From the late 1950s to the late 1990s,

no new major classes of antibiotics were discovered. In recent years, however, three new classes of antibiotics have been synthesized based on information learned from naturally occurring, fungally derived antibiotics, leading to improved treatment of some formerly resistant strains of bacteria.

Fungi have also been used to combat non-bacterial diseases. One of the more unusual applications of fungi is in the war against malaria. Biologists have discovered that two species of fungi, *Beauveria bassiana* and *Metarhizium anisopliae*, can kill malaria-causing mosquitoes when applied to mosquito netting. Mosquitoes have not yet shown evidence of developing resistance to these biological pathogens.

CHAPTER SUMMARY 30

30.1 What Is a Fungus?

- Fungi are distinguished from other **opisthokonts** by **absorptive heterotrophy** and by the presence of **chitin** in their cell walls. **Review Figure 30.1**
- Some fungi are **saprobies**, others are parasites, and some are mutualists.
- Yeasts** are unicellular, free-living fungi.
- The body of a multicellular fungus is a **mycelium**—a meshwork of filaments called **hyphae**. Hyphae may be **septate** (having **septa**) or **coenocytic** (multinucleate). **Review Figure 30.3**

30.2 How Do Fungi Interact with Other Organisms?

- Saprobic fungi, which act as decomposers, make crucial contributions to the recycling of elements, especially carbon.
- Many fungi are parasites, harvesting nutrients from host cells by means of **haustoria**. **Review Figure 30.5**
- Certain fungi have relationships with other organisms that are **symbiotic** and **mutualistic**.
- Some fungi associate with unicellular green algae, cyanobacteria, or both to form **lichens**, which live on exposed surfaces of rocks, trees, and soil. **Review Figure 30.8**
- Mycorrhizae** are mutualistic associations of fungi with plant roots. They improve a plant's ability to take up nutrients and water.
- Endophytic fungi** live within plants and may provide their hosts with protection from herbivores and pathogens.

30.3 How Do Major Groups of Fungi Differ in Structure and Life History?

- The **microsporidia**, **chytrids**, and **zygospore fungi** diversified early in fungal evolution. The arbuscular mycorrhizal fungi, sac fungi, and club fungi form a monophyletic group, and the latter two groups form the clade Dikarya. **Review Figure 30.10, Table 30.1, ACTIVITY 30.1**

- Many species of fungi reproduce both sexually and asexually. In many fungi, sexual reproduction occurs between individuals of different **mating types**. **Review Figure 30.11**
- The **microsporidia** are highly reduced unicellular fungi. They are obligate intracellular parasites of animals.
- The three distinct lineages of **chytrids** all include species with flagellated gametes. **Review Figure 30.14A**
- In the sexual reproduction of terrestrial fungi, **plasmogamy** (fusion of cytoplasm) precedes **karyogamy** (fusion of nuclei).
- Zygosporic fungi** have a resting stage known as a **zygosporangium**, which contains many diploid nuclei. Their spores are dispersed from simple stalked **sporangiophores**. **Review Figure 30.14B, ANIMATED TUTORIAL 30.1**
- Arbuscular mycorrhizal fungi** form symbiotic associations with plant roots. They are only known to reproduce asexually. Their hyphae are coenocytic.
- In sac fungi and club fungi, a mycelium containing two genetically different haploid nuclei, called a **dikaryon**, is formed. The **dikaryotic** ($n + n$) condition is unique to the fungi. **Review Figure 30.16, ACTIVITY 30.2**
- Sac fungi** have septate hyphae with large pores; their sexual reproductive structures are **asci**. Some sac fungi are unicellular yeasts. Many filamentous sac fungi produce fleshy fruiting structures called **ascocata**. The dikaryon stage in the sac fungus life cycle is relatively brief. **Review Figure 30.16A**
- Club fungi** have septate hyphae with distinctive small pores. Their fruiting structures are called **basidiomata**, and their sexual reproductive structures are **basidia**. The dikaryon stage may last for years. **Review Figure 30.16B**

30.4 What Are Some Applications of Fungal Biology?

- Some fungi are consumed as food by humans; other fungi are critical in baking, fermentation, and flavoring food.
- Fungi play important roles in cleaning up environmental pollutants such as synthetic petroleum-derived hydrocarbons.

continued

- The diversity and abundance of lichen growth on trees is a sensitive indicator of air quality.
- Reforestation projects require restoration of the mycorrhizal fungal community.

- Several species of fungi are important model organisms.
- Fungi provide important weapons against diseases and pests.

Life10e.com/is30

CHAPTER REVIEW

REMEMBERING

- The absorptive heterotrophy of fungi is aided by
 - dikaryon formation.
 - spore formation.
 - the fact that they are all parasites.
 - their large surface area-to-volume ratio.
 - their possession of chloroplasts.
- Which of the following is a reason that lichens can be useful indicators of environmental change?
 - Lichens excrete the toxic substances that they absorb, and these excretions can be used to measure local contamination.
 - Because lichens retain toxins, historical collections of lichens can be used to measure past atmospheric conditions.
 - Atmospheric pollutants (such as ^{206}Pb) stimulate lichen growth, so heavy lichen growth is a sign of air pollution.
 - Atmospheric pollution stimulates mycorrhizal activity, which inhibits lichen growth.
 - None of the above
- Which statement about the dikaryon stage is *not* true?
 - The cytoplasm of two cells fuses before their nuclei fuse.
 - The two haploid nuclei are genetically different.
 - The two nuclei are of the same mating type.
 - The dikaryon stage ends when the two nuclei fuse.
 - Not all fungi have a dikaryon stage.
- Microsporidia
 - lack true mitochondria.
 - are parasites of animals.
 - contain mitosomes.
 - are among the smallest eukaryotes known.
 - All of the above
- Which statement about lichens is *not* true?
 - They can reproduce by fragmentation of the vegetative body.
 - They are often the first colonists in a new area.
 - They render their environment more basic (alkaline).
 - They contribute to soil formation.
 - They may contain less than 10 percent water by weight.

UNDERSTANDING & APPLYING

- You are shown an object that looks superficially like a pale green mushroom. Describe at least three criteria (including anatomical and chemical traits) that would enable you to tell whether the object is a piece of a plant or a piece of a fungus.
- Many fungi are dikaryotic during part of their life cycle. Why are dikaryons described as $n + n$ instead of $2n$?
- If all the fungi on Earth were suddenly to die, how would the surviving organisms be affected?

ANALYZING & EVALUATING

- Consider the following data for lichens at five survey sites:

Site number	Number of lichen species	Tree branches covered in lichens (%)
1	5	38
2	1	2
3	3	15
4	8	75
5	13	100

Predict the relative order of the sites with respect to their distance from the center of a large city. Other factors (besides distance to city center, such as prevailing wind direction) might affect your prediction. Can you think of two other major factors that might influence these results?

- When biologists isolate DNA from whole-plant samples to study plant genomes, the investigators sometimes find that some of the genes they isolate appear to be more closely related to fungal genes than they are to the genes of close relatives of the plants they are studying. What is a likely explanation of this observation? How could you test your hypothesis?

Animal Origins and the Evolution of Body Plans

CHAPTER OUTLINE

- 31.1** What Characteristics Distinguish the Animals?
- 31.2** What Are the Features of Animal Body Plans?
- 31.3** How Do Animals Get Their Food?
- 31.4** How Do Life Cycles Differ among Animals?
- 31.5** What Are the Major Groups of Animals?

IN 1883 THE ZOOLOGIST FRANZ SCHULZE

noticed something unusual in his Austrian laboratory: transparent, flattened organisms were crawling on the sides of his saltwater aquarium. These organisms, which Schulze had collected accidentally along with the sponges that were his primary interest, appeared to be animals, but they were unlike any animals previously described—especially since they continually changed shape as they moved.

Further examination revealed that the new organisms were indeed animals. Structurally, however, they were among the simplest animals that Schulze—or anyone else—had ever observed, being made up of only four types of cells. He named the new species *Trichoplax adhaerens*, which means “sticky hairy plate,” and argued that the new species had no close relationships with other major animal groups. For decades, however, most biologists dismissed Schulze’s findings, insisting that the transparent organisms must be larval forms of other, well-known, animals.

In the 1960s more detailed studies confirmed the distinctive nature of *Trichoplax*. Even then, this odd animal continued to be known almost exclusively from aquariums. Only in the past decade have biologists located natural populations of *T. adhaerens* growing on hard surfaces in tropical and subtropical coastal regions. A few additional closely related species have been discovered (although most have not yet been formally named). Collectively, these species are known as placozoans (Greek, “flat animals”).

The more biologists have studied *Trichoplax*, the odder this animal appears. It has the smallest genome of any animal studied to date. The mature stages lack body symmetry and have no mouth, gut, or nervous system. Is

Did Placozoans Diverge at the Root of the Animal Tree? Answering that question requires an understanding of animal phylogeny. Although placozoans are morphologically simple and have the smallest genome of any animal studied to date, they may have descended from ancestors with more complex body plans.

Trichoplax a relict representative of a group of animals that appeared early in animal evolution?

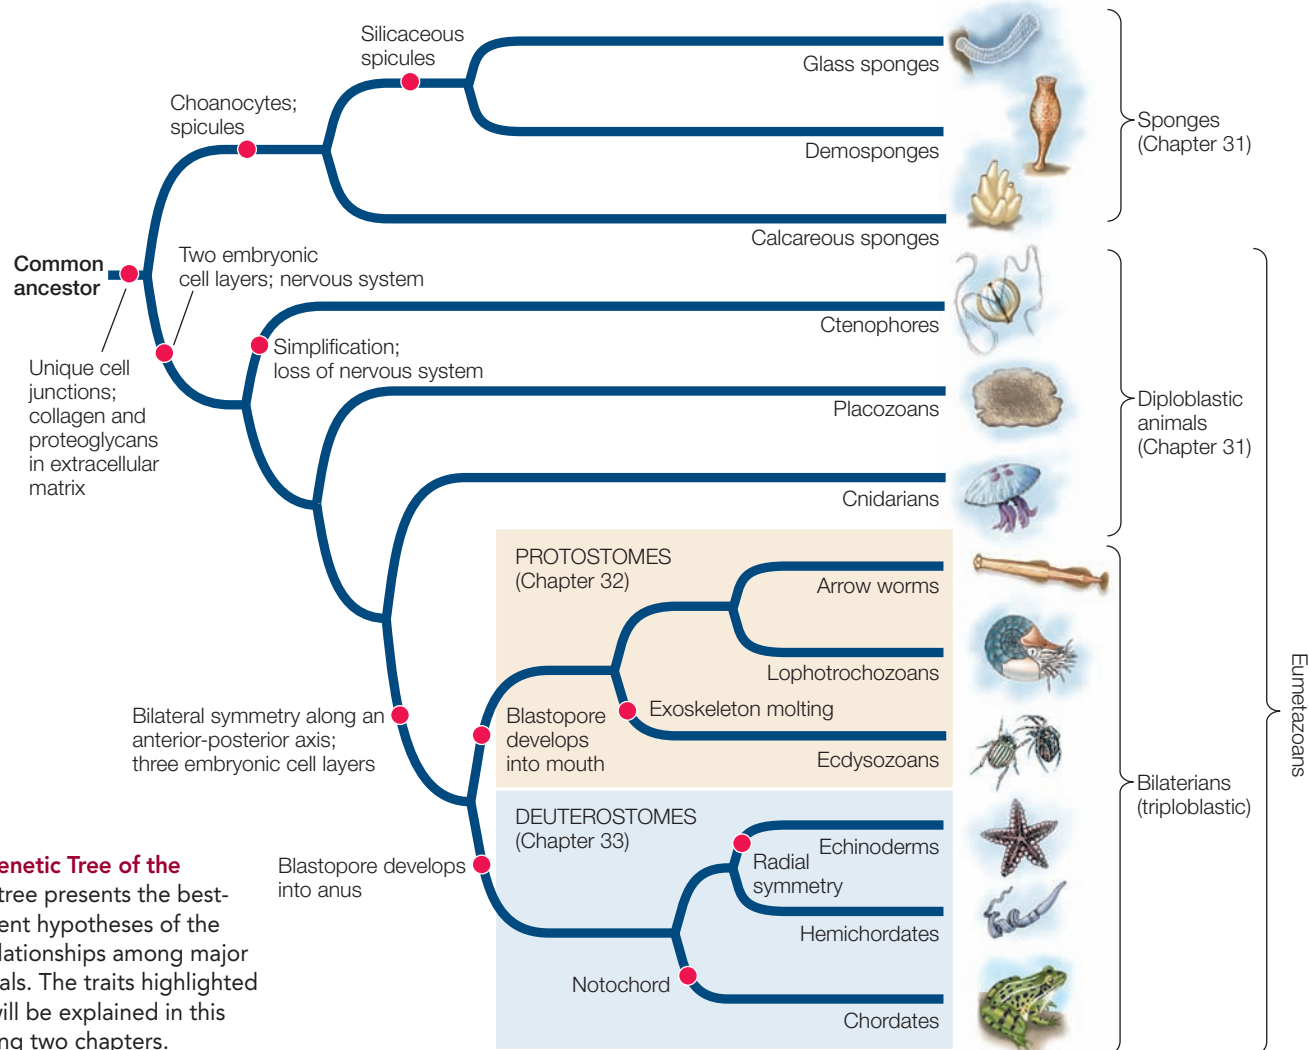

Which groups of organisms are at the root of the animal tree is currently a subject of considerable investigation and debate. Several possible hypotheses of relationships are being explored with genomic analyses. The structural simplicity of *Trichoplax* is now considered by most biologists to be an evolutionary reversal from a more complex body form. Most genomic studies point to other groups of animals as forming the earliest split with the remaining species.

This chapter explores the earliest branches on the animal tree and shows how a few fundamental “body plans” have been modified to yield the remarkable variety of animal forms described in this and the following two chapters.

Which animal groups are involved in the earliest split in the animal tree?

See answer on p. 648.

31.1 What Characteristics Distinguish the Animals?

How do we recognize an organism as an animal? That may seem obvious for many familiar animals, but less so for groups such as sponges, which were once thought to be plants. Some of the general characteristics we associate with animals include:

- **Multicellularity.** In contrast to the Bacteria, Archaea, and most protists (see Chapters 26 and 27), all animals are multicellular. Animal life cycles feature complex patterns of development from a single-celled zygote into a multicellular adult.
- **Heterotrophic metabolism.** In contrast to most plants, all animals are heterotrophs. Animals are able to synthesize very few organic molecules from inorganic chemicals, so they must obtain the necessary organic molecules from their environment.
- **Internal digestion.** Although the fungi are also heterotrophs (see Chapter 30), animals and fungi digest their food differently. While fungi digest food outside their bodies, most animals use internal processes to break down materials from their environment into the organic molecules they need. Most animals ingest food into an internal **gut** that is continuous with the outside environment and in which digestion takes place.

- **Movement and nervous systems.** In contrast to the majority of plants and fungi, most animals can move their bodies. This movement is often coordinated through a well-developed nervous system, which also typically functions as a sensory system. Animals must move to find food or bring food to them. Muscle tissue and nervous systems are unique to animals, and many animal body plans are specialized for movement and detection of prey.

Although these general features help us recognize animals, none is diagnostic for all animals. Some animals do not move, at least during certain life stages, and some plants and fungi do have limited movement. Some animals lack a centralized nervous system, and some lack a gut. Many multicellular organisms are not animals. On what basis do we group all animals together in a single clade?

Animal monophyly is supported by gene sequences and morphology

The most convincing evidence that all the organisms considered to be animals share a common ancestor comes from phylogenetic analyses of their gene sequences. Relatively few complete animal genomes are available, but more are being sequenced each year. Analyses of these genomes, as well as of many individual gene sequences, have shown that the animals are indeed monophyletic. The best-supported phylogenetic

WORKING WITHDATA:

Reconstructing Animal Phylogeny**Original Paper**

Dunn, C. W. and 17 others 2008. Broad phylogenomic sampling improves resolution of the Animal Tree of Life. *Nature* 452: 745–749.

Analyze the Data

Several breakthroughs in our understanding of animal phylogeny have occurred in recent years as the sequences of genes and proteins have been compared across species. Casey Dunn and his colleagues compared sequences from many different proteins across a wide variety of animal groups. The table below is a sample of their data that can be used to reconstruct the relationships among these representative species. In the original paper, Dunn and colleagues reported on 11,234 amino acid positions among 77 species of animals. Twenty-seven of these amino acid positions for ten of those species are shown in the table.

Species	Character state (amino acid at position)																										
	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	27

QUESTION 1

As you did in Chapter 22 (see Section 22.2), construct a phylogenetic tree of these ten species using the parsimony method. Use the outgroup (a choanoflagellate) to root your tree. Assume that all changes from one amino acid to another are equally likely.

QUESTION 2

How many character state changes (i.e., changes from one amino acid to another) occur along each branch on your tree?

QUESTION 3

Which amino acid positions (i.e., which character numbers) exhibit homoplasy (convergence or reversal of the character state)?

QUESTION 4

Which group on your tree represents the bilaterian animals? The protostomes? The deuterostomes?

Go to **BioPortal** for all **WORKING WITHDATA** exercises

tree for the major animal groups is shown in **Figure 31.1**. **Table 31.1** summarizes the living members of those groups.

Although animals were considered to belong to a single clade long before gene sequencing became possible, surprisingly few morphological features are shared across all species of animals. Two morphological synapomorphies have been identified that distinguish the animals:

- A common set of extracellular matrix molecules, including collagen and proteoglycans (see Figure 5.22)
- Unique types of junctions between cells (tight junctions, desmosomes, and gap junctions; see Figure 6.7)

Although some animals in a few groups lack one or the other of these traits, it is believed that these traits were possessed by the ancestor of all animals and subsequently lost in those groups. Similarities among animals in the organization and function of Hox and other developmental genes (see Chapter 20) provide additional evidence of developmental mechanisms shared by a common animal ancestor.

The common ancestor of animals was probably a colonial flagellated protist similar to existing colonial choanoflagellates. Choanoflagellate colonies have clear similarities to the multicellular sponges (**Figure 31.2**). The best-supported hypothesis of animal origins postulates a choanoflagellate-like lineage in which certain cells in the colony became specialized—some for movement, others for nutrition, others for reproduction, and so on. Once this functional specialization had begun, cells could have continued to differentiate. Coordination among groups of cells could have improved by means of specific regulatory and signaling molecules that guided differentiation and migration of cells in developing embryos. Such coordinated groups of cells eventually could have evolved into the larger and more complex organisms that we call animals.

Nearly 80 percent of the 1.8 million named species of living organisms are animals, and millions of additional animal species await discovery. Evidence for the evolutionary relationships among animal groups can be found in fossils, in patterns of embryonic development, in the morphology

TABLE 31.1
Summary of Living Members of the Major Animal Groups

Group	Approximate Number of Living Species Described	Major Subgroups, Other Names, and Notes	Group	Approximate Number of Living Species Described	Major Subgroups, Other Names, and Notes
Sponges	8,500	Demosponges, glass sponges, calcareous sponges	Ecdysozoans		
Ctenophores	250	Comb jellies	Kinorhynchs	180	Mud dragons
Placozoans	2	Additional species have been discovered but not yet formally named	Loriciferans	30	Brush heads
Cnidarians	12,500	Anthozoans: corals, sea anemones Hydrozoans: hydras and hydroids Scyphozoans: jellyfish Myxozoans: parasitic mucous animals; sometimes placed in group distinct from cnidarians	Priapulids	20	Penis worms
Orthonectids	45	Microscopic wormlike parasites of marine invertebrates; relationships uncertain	Nematodes	25,000	Roundworms
Rhombozoans	125	Tiny (0.5–7 mm) parasites of cephalopods; relationships uncertain	Horsehair worms	350	Gordian worms
PROTOSTOMES			Tardigrades	1,200	Water bears
Arrow worms	180	Glass worms	Onychophorans	180	Velvet worms
Lophotrochozoans			Arthropods		
Bryozoans	5,500	Moss animals	Chelicerates	114,000	Horseshoe crabs, pycnogonids, and arachnids (scorpions, harvestmen, spiders, mites, ticks)
Entoprocts	170	Sessile aquatic animals, 0.1–7 mm long, superficially similar to bryozoans	Myriapods	12,000	Millipedes, centipedes
Flatworms	30,000	Free-living flatworms; flukes and tapeworms (all parasitic); monogeneans (ectoparasites of fishes)	Crustaceans	67,000	Crabs, shrimps, lobsters and crayfishes, barnacles, copepods
Gastrotrichs	800	“Hairy backs”	Hexapods	1,020,000	Insects and their wingless relatives
Rotifers and relatives	3,000	Rotifers, spiny-headed worms, and jaw worms	DEUTEROSTOMES		
Ribbon worms	1,200	Proboscis worms	Xenoturbellids	2	Secondarily simple marine worms; relationships uncertain
Brachiopods	450	Lampshells	Acoels	400	Very small (mostly <2 mm) flattened marine worms; relationships uncertain
Phoronids	10	Sessile marine filter feeders	Echinoderms	7,500	Crinoids (sea lilies and feather stars); brittle stars; sea stars; sea daisies; sea urchins; sea cucumbers
Annelids	19,000	Polychaetes (generally marine; may not be monophyletic) Clitellates: earthworms, freshwater worms, leeches	Hemichordates	120	Acorn worms and pterobranchs
Mollusks	117,000	Monoplacophorans Chitons Bivalves: clams, oysters, mussels Gastropods: snails, slugs, limpets Cephalopods: squids, octopuses, nautiloids	Tunicates	2,800	Sea squirts (ascidians), salps, and larvaceans
			Lancelets	35	Cephalochordates
			Vertebrates	65,000	Hagfishes, lampreys, cartilaginous fishes, ray-finned fishes, coelacanths, lungfishes, amphibians, reptiles (including birds), and mammals

(B)

31.2 Choanocytes in Sponges Resemble Choanoflagellate Protists

(A) The similarity of choanoflagellate protist colonies to sponge choanocytes supports an evolutionary link between this protist lineage and the animals. (B) A sponge moves food-containing water through its body by beating the flagella of its choanocytes. Water enters the sponge through small pores and passes into water canals or an open atrium, where the choanocytes capture food particles from the water. The spicules are supportive, skeletal structures.

and physiology of living animals, in the structure of animal proteins, and in gene sequences. Increasingly, studies of the phylogenetic relationships among major animal groups have come to depend on genomic sequence comparisons.

A few basic developmental patterns differentiate major animal groups

Differences in patterns of embryonic development have until recently provided many of the important clues to animal phylogeny. Analyses of gene sequences, however, are now showing that some developmental patterns are more evolutionarily variable than previously thought. Here we describe the basic developmental patterns that vary among the major animal clades.

The early cell divisions of an embryo are known as **cleavage**. As described in Section 44.1, several different patterns of cleavage exist among animals. Although these patterns can be useful for characterizing major animal groups, genomic analyses have shown that many changes have occurred in cleavage patterns throughout animal evolution.

Cleavage patterns are influenced by the configuration of the yolk, the acellular nutritive material that nourishes the growing embryo. The eggs of many animal groups contain a small amount of yolk that is evenly distributed throughout the egg cytoplasm. In some of these groups, the zygote and its descendant cells divide completely and evenly in a pattern known as **radial cleavage**. Radial cleavage is thought to be the ancestral condition for the animals other than sponges, as it is widely distributed among the major lineages. **Spiral cleavage**—a complicated permutation of radial cleavage—is found among many lophotrochozoans (a group that includes earthworms and clams). Lophotrochozoans with spiral cleavage are thus sometimes known as spiralian. The early branches of the ecdysozoans (molting animals, such as insects and nematodes) have radial cleavage, but most ecdysozoans have an idiosyncratic

cleavage pattern that is neither radial nor spiral in organization (see Figure 44.3C). In reptiles, the presence of a large body of yolk within the fertilized egg creates an incomplete cleavage pattern in which the dividing cells form an embryo on top of the yolk mass.

Distinct layers of cells form during the early development of most animals. These cell layers differentiate into specific organs and organ systems as development continues. The embryos of **diploblastic** animals have two cell layers: an outer **ectoderm** and an inner **endoderm**. Embryos of **triploblastic** animals have, in addition to ectoderm and endoderm, a third distinct cell layer, **mesoderm**, which lies between the ectoderm and the endoderm. The existence of three cell layers in embryos is a synapomorphy of the triploblastic animals (which form a clade), whereas the diploblastic animals (ctenophores, placozoans, and cnidarians, which are not a clade) exhibit the ancestral condition (see Figure 31.1). Some biologists consider sponges to be diploblastic, but since they do not have clearly differentiated tissue types or embryonic cell layers, the term is not usually applied to them.

During early development in many animals, in a process known as gastrulation, a hollow ball one cell thick indents to form a cup-shaped structure. The opening of the cavity formed by this indentation is called the blastopore (**Figure 31.3**). The process of gastrulation is detailed in Section 44.2; the point to remember here is that the *overall pattern* of gastrulation immediately after formation of the blastopore divides the triploblastic animals into two major groups:

Blastopore

31.3 Gastrulation Illuminates Evolutionary Relationships The blastopore is clear in this scanning electron micrograph of a sea urchin gastrula. Because sea urchins (echinoderms) are deuterostomes, this blastopore will eventually become the anal end of the animal's gut.

- In the **protostomes** (Greek, “mouth first”), the mouth arises from the blastopore, and the anus forms later.
- In the **deuterostomes** (“mouth second”), the blastopore becomes the anus, and the mouth forms later.

Although the developmental patterns of animals are more varied than suggested by this simple dichotomy, sequencing data indicate that the protostomes and deuterostomes represent distinct animal clades. Together these two groups are known as the **bilaterians** (named for their usual bilateral symmetry), and they account for the vast majority of animal species.

RECAP 31.1

The animals are thought to be monophyletic because they share several derived traits, especially among their gene sequences. Major developmental differences also provide evidence of their evolutionary relationships.

- What general features of animals distinguish this group from other living organisms? [See p. 630](#)
- Describe the difference between diploblastic and triploblastic embryos. [See p. 633](#)
- Describe the difference between protostomes and deuterostomes. [See p. 634](#)

We will begin our exploration of animal diversity by discussing the general features of animal body plans. Later in this chapter we will describe several groups of animals that diverged before the origin of the bilaterians. We will devote Chapter 32 to the protostomes and Chapter 33 to the deuterostomes.

31.2 What Are the Features of Animal Body Plans?

The general structure of an animal, the arrangement of its organ systems, and the integrated functioning of its parts are referred to as its **body plan**. As Chapter 20 described, the regulatory and

signaling genes that govern the development of body symmetry, body cavities, segmentation, and appendages are widely shared among the different animal groups. Thus we might expect animals to share body plans. Although animal body plans vary tremendously, they can be seen as variations on five key features:

- The *symmetry* of the body
- The structure of the *body cavity*
- The *segmentation* of the body
- *External appendages* that are used for sensing, chewing, locomotion, mating, and other functions
- The development of the *nervous system*

Each of these features affects how an animal moves and interacts with its environment.

Most animals are symmetrical

The overall shape of an animal can be described by its **symmetry**. An animal is said to be symmetrical if it can be divided along at least one plane into similar halves. Animals that have no plane of symmetry are said to be asymmetrical. Placozoans and many sponges are asymmetrical, but most other animals have some kind of symmetry, which is governed by the expression of regulatory genes during development.

The simplest form of symmetry is **spherical symmetry**, in which body parts radiate out from a central point. An infinite number of planes passing through the central point can divide a spherically symmetrical organism into similar halves. Spherical symmetry is widespread among unicellular protists, but most animals possess other forms of symmetry.

In organisms with **radial symmetry**, body parts are arranged around one main axis at the body's center (**Figure 31.4A**). Ctenophores (comb jellies) are radially symmetrical, as are many cnidarians (such as sea anemones and jellyfishes) and echinoderms. A perfectly radially symmetrical animal can be divided into similar halves by any plane that contains the main axis. However, most radially symmetrical animals—including the adults of echinoderms such as sea stars—are slightly modified, so that only some planes can divide them into identical halves. Some radially symmetrical animals are sessile (they remain fixed in one place) or drift with water currents. Others move about slowly but can move equally well in any direction.

Bilateral symmetry is characteristic of animals that have a distinct front end, which typically precedes the rest of the body as the animal moves. A bilaterally symmetrical animal can be divided into mirror-image (left and right) halves by a single plane that passes through the midline of its body. This plane runs from the front, or **anterior**, end of the body, to the rear, or **posterior**, end (**Figure 31.4B**). A plane at right angles to the midline divides the body into two dissimilar sides. The back of a bilaterally symmetrical animal is its **dorsal** surface; the underside is its **ventral** surface.

Bilateral symmetry is strongly correlated with **cephalization** (Greek *kephalos*, “head”), which is the concentration of sensory organs and nervous tissues at the anterior end of the animal.

31.4 Body Symmetry Most animals are either (A) radially or (B) bilaterally symmetrical.

Cephalization has been favored by natural selection because the anterior end of a bilaterally symmetrical animal typically encounters new environments first.

The structure of the body cavity influences movement

The body plans of triploblastic animals can be divided into three types based on the presence and structure of an internal, fluid-filled **body cavity**.

- **Acoelomate** animals such as flatworms lack an enclosed, fluid-filled body cavity. Instead, the space between the gut (derived from endoderm) and the muscular body wall (derived from mesoderm) is filled with masses of cells called **mesenchyme** (Figure 31.5A). These animals typically move by beating cilia.
- **Pseudocoelomate** animals have a body cavity called a pseudocoel, a fluid-filled space lying between the mesoderm and endoderm. Many of the internal organs are suspended in the pseudocoel, which is enclosed by muscles (mesoderm) only on its outside; there is no inner layer of mesoderm surrounding the internal organs (Figure 31.5B).
- **Coelomate** animals have a body cavity, the coelom, that develops within the mesoderm. The coelom is lined with a thin layer of tissue called the **peritoneum**, which also surrounds the internal organs. The coelom is thus completely enclosed by mesoderm (Figure 31.5C).

The structure of an animal's body cavity strongly influences the ways in which it can move. The body cavities of many animals function as **hydrostatic skeletons**. Fluids are relatively

31.5 Animal Body Cavities (A) Acoelomates do not have enclosed body cavities. (B) Pseudocoelomates have a body cavity enclosed by mesoderm only on its outside. (C) Coelomates have a body cavity that is enclosed by mesoderm on both its inside and its outside.

Go to Activity 31.1 Animal Body Cavities
[Life10e.com/ac31.1](https://life10e.com/ac31.1)

incompressible, so when the muscles surrounding a fluid-filled body cavity contract, fluids shift to another part of the cavity. If the body tissues around the cavity are flexible, fluids squeezed out of one region can cause some other region to expand. The moving fluids can thus move specific body parts. (You can see how a hydrostatic skeleton works by watching a snail emerge from its shell.) A coelomate animal has better control over the movement of the fluids in its body cavity than a pseudocoelomate animal does. An animal that has longitudinal muscles (running along the length of the body) as well as

(A) *Hermodice carunculata*

31.6 Segmentation (A) All of the segments of this marine fireworm, an annelid, are similar. Its appendages are tipped with bristles (setae) that are used for locomotion and (in this species) for protection—the setae contain a noxious toxin. (B) Segmentation allows the evolution of differentiation among the segments. The segments of this scorpion, an arthropod, differ in their form, their function, and the appendages they bear. (C) Muscular segmentation is clearly visible in the abdomen of this body builder.

(B) *Hadrurus arizonensis*(C) *Homo sapiens*

circular muscles (encircling the body cavity) has even greater control over its movement.

In terrestrial environments, the hydrostatic function of fluid-filled body cavities applies mostly to relatively small, soft-bodied organisms. Most larger animals (as well as many smaller ones) have hard skeletons that provide protection and facilitate movement. Muscles are attached to those firm structures, which may be inside the animal or on its outer surface (in the form of a shell or cuticle).

Segmentation improves control of movement

Segmentation—the division of the body into segments—is seen in many animal groups. Segmentation facilitates specialization of different body regions. It also allows an animal to alter the shape of its body in complex ways and to control its movements precisely. If an animal's body is segmented, muscles in each individual segment can change the shape of that segment independently of the others. In only a few segmented animals is the body cavity separated into discrete compartments, but even partly separated compartments allow better control of movement. As we will see in Chapters 32 and 33, segmentation occurs in several groups of protostomes and deuterostomes.

In many animals, such as annelids (earthworms and their relatives), similar body segments are repeated many times (Figure 31.6A). In other animals, including most arthropods, segments differ strikingly from one another (Figure 31.6B). As we'll describe in Chapter 32, the dramatic evolutionary radiation of the arthropods (including the insects, spiders, centipedes, and crustaceans) was based on modifications of a segmented body plan that features muscles attached to the inner

surface of an external skeleton, including a variety of external appendages that move these animals. In some animals, distinct body segments are not apparent externally (as with the segmented vertebrae of vertebrates, including humans). Nonetheless, muscular segmentation is clearly visible in humans with well-defined, muscular bodies (Figure 31.6C).

Appendages have many uses

Getting around under their own power is important to many animals. It allows them to obtain food, to avoid predators, and to find mates. Even some species that are sessile as adults, such as sea anemones, have larval stages that use cilia to swim, thus increasing the animal's chances of finding a suitable habitat.

Appendages that project from the body greatly enhance an animal's ability to move around. Many echinoderms, including sea urchins and sea stars, have myriad tube feet that allow them to move slowly across the substrate (see Figure 33.3B). Animals whose appendages have become modified into specialized limbs are capable of better controlled, more rapid movement. The presence of jointed limbs has been a prominent factor in the evolutionary success of the arthropods and the vertebrates. In four independent instances—among the arthropod insects and among the vertebrate pterosaurs, birds, and bats—body plans emerged in which limbs were modified into wings, allowing these animals to use powered flight.

Appendages also include many structures that are not used for locomotion. Many animals have antennae, which are specialized appendages used for sensing the environment. Other appendages (such as the claws and mouthparts of many arthropods) are adaptations for capturing prey or chewing food. In

some species, appendages are used for reproductive purposes, such as sperm transfer or egg incubation.

Nervous systems coordinate movement and allow sensory processing

The bilaterian animals have a well-coordinated central nervous system. More diffuse nervous systems, called **nerve nets**, are present in some other animals, such as cnidarians and ctenophores. Nervous systems appear to be completely absent in a few groups, such as sponges and placozoans.

The central nervous system of bilaterians coordinates the actions of muscles, which allows coordinated movement of appendages and body parts. This coordination of muscles permits highly effective and efficient movement on land, in water, or through the air. The central nervous system is also essential for the processing of sensory information gathered from a wide variety of sensory systems. Many animals have sensory systems for detecting light, for forming images of their environment (sight), for mechanical touch, for detecting movement, for detecting sounds (hearing), for detecting electric fields, and for chemical detection (e.g., taste and smell). These sensory systems allow animals to find food, and the ability of animals to move allows them to capture or collect food from their environment. These same abilities also allow most animals to move to avoid potential predators or to search for suitable mates. Most animals can also assess the suitability of different environments and move appropriately in response to that information.

Nervous Systems Lead to Efficient Predators

Life10e.com/mc31.1

RECAP 31.2

The body plans of animals are variations on patterns of symmetry, body cavity structure, segmentation, appendages, and nervous systems.

- Describe the main types of symmetry found in animals and explain how an animal's symmetry can influence the way it moves. [See p. 634 and Figure 31.4](#)
- Explain several ways in which body cavities, segmentation, and centralized nervous systems improve control over movement. [See pp. 635–637](#)

Many of the modifications to the body plans of animals affect their ways of finding, capturing, and processing food. Evolutionary changes in symmetry, body cavities, appendages, segmentation, and sensory systems have played key roles in enabling animals to obtain food from their environment as well as helping them avoid becoming food for other animals.

31.3 How Do Animals Get Their Food?

As noted in Section 31.1, animals are heterotrophs, or “other-feeders.” Although some animals rely on photosynthetic endosymbionts to nourish them (see Figure 27.21), most animals must expend energy to obtain an outside source of nutrition, otherwise known as food.

The need to locate food has favored the evolution of sensory structures that provide animals with detailed information about their environment as well as nervous systems that can receive, process, and coordinate that information. Furthermore, in order to acquire food, animals must either move through the environment to where food is located, or move the environment and the food it contains to them. Animals that move from one place to another are **motile**; animals that stay in one place are **sessile**.

The principal feeding strategies that animals use fall into five broad categories:

- **Filter feeders** (or **suspension feeders**) strain small organisms from their environment.
- **Herbivores** eat plants or parts of plants.
- **Predators** capture and eat other animals.
- **Parasites** live in or on other, generally much larger, organisms, from which they obtain energy and nutrients.
- **Detritivores** feed on dead organic material.

Each of these strategies can be found in many different animal groups, and none of them is limited to a single group. Individuals of some species employ more than one of these feeding strategies, and some animals employ different feeding strategies at different stages of their life cycle. The constant and ongoing need to obtain food, the variety of nutrient sources available in a given environment, and the necessity of competing with other animals to obtain food means that a variety of feeding strategies can be found among all the major animal groups.

Filter feeders capture small prey

Air and water often contain small organisms and organic molecules that are potential food for animals. Moving air and water may carry those items to an animal that positions itself in a good location. Other animals can move through the environment, filtering out prey items as they move. In either case, filter feeders use some kind of straining device to filter the food from the environment.

Many sessile aquatic animals rely on water currents to bring prey to them (**Figure 31.7A**). Some sessile filter feeders (such as sponges; see **Figure 31.2**) expend energy to move water past their food-capturing devices. Motile filter feeders move their bodies to the nutrient source. Flamingos, for example, use their serrated beaks to filter small organisms out of the muddy mixture they pick up as they wade through shallow water (**Figure 31.7B**). Blue whales—the largest animals that have ever lived—are filter feeders that strain tiny crustaceans from the water column as they swim.

Go to Media Clip 31.2

Filter Feeders

Life10e.com/mc31.2

Herbivores eat plants

An individual plant has many different structures—leaves, wood, roots, sap, flowers, fruits, nectar, and seeds—that animals can consume. Not surprisingly, then, many different kinds of herbivores—animals that feed only on plants—may

(A) *Spirobranchus* sp.(B) *Phoenicopterus ruber***31.7 Filter-Feeding Strategies**

(A) Sessile marine filter feeders such as this Christmas tree worm, a polychaete, allow the ocean currents to bring their food—plankton—to them. (B) The greater flamingo of South America is a motile filter feeder. It uses its appendages (legs) to stir up mud as it wades through ocean lagoons and salty lakes. The bird then uses its beak (inset) to strain small organisms out of the muddy mixture.

feed on a single kind of plant, consuming different parts of the plant or feeding on the same part in different ways. Whereas an individual animal that is captured by a predator is likely to die, herbivores often feed on plants without killing them.

Animals do not need to expend energy subduing and killing plants in order to feed on them. However, plant matter can be difficult to digest and can pose special challenges to terrestrial herbivores because the dominant land plants tend to have several different kinds of tissues, many of which are tough or fibrous. Herbivorous animals typically have long, complex guts to accomplish the tasks involved in digesting plants (see Section 51.2). Animals also must expend energy to detoxify plants' defensive chemicals.

Predators and omnivores capture and subdue prey

Predators possess features that enable them to capture and subdue other animals (referred to as their **prey**). Many vertebrate predators have sensitive sensory organs that enable them to locate prey, as well as sharp teeth or claws that allow them to capture and subdue prey (**Figure 31.8**). Predators may stalk and pursue their prey or wait (often camouflaged) for their prey to come to them.

Omnivores ("all-devouring") are animals, such as raccoons and humans, that eat both plants and other animals. The diets of some omnivores differ at different life stages; many songbirds, for example, eat fruit or seeds as adults but feed insects to their young.

Parasites live in or on other organisms

Parasites obtain nutrients from another organism—a **host**—by living on or within the host. Some animal parasites consume parts of the host itself (such as ticks that suck body fluids); others hijack nutrients the host would otherwise consume (such as tapeworms that may live in the intestines of mammals).

(A) *Haliaeetus leucocephalus*(B) *Tropidolaemus wagleri*

31.8 Active and Sit-and-Wait Predators (A) The appendages (legs and wings) of the bald eagle, along with its strong beak, are adaptations to the life of an active predatory hunter. (B) Many snakes, such as Wagler's pit viper, rely on camouflage to conceal it from potential prey. These snakes typically sit motionless, waiting in one spot for unsuspecting prey to walk within striking range.

Most animal parasites are much smaller than their hosts, and many parasites can consume parts of their host without killing it. To set up residence within a host, a parasite must first overcome the host's defenses. Parasites often have complex life cycles that rely on multiple hosts, as we will see in Section 31.4.

Parasites that live inside their hosts are called endoparasites, and these are often morphologically very simple. Endoparasites often function without a digestive system, absorbing their food directly from the host's gut or body tissues. Many flatworms are endoparasites of humans and other mammals, as we will describe in Chapter 32.

Parasites that live outside their hosts are called ectoparasites; they are generally more complex morphologically than endoparasites. Ectoparasites have digestive tracts and mouthparts that enable them to pierce the host's tissues or suck on the host's body fluids. Fleas and ticks are ectoparasitic arthropods that feed on many vertebrates, including humans.

Detritivores live on the remains of other organisms

Detritivores feed on the dead bodies or waste products of other organisms, organic matter known as **detritus**. Detritivores (sometimes called decomposers) perform an important ecosystem function by breaking down dead organic matter and returning the nutrients it contains to the environment in a form that can be used by other organisms. Detritivores are common in any soil with high organic content, as well as on the ocean floor. Well-known detritivores include earthworms and other annelids, millipedes, and many insects and crustaceans.

Charles Darwin became fascinated with earthworms and wrote a book called *The Formation of Vegetable Mould through the Action of Worms*. He was particularly impressed by the importance of earthworms in soil formation. Darwin conducted many interesting experiments to establish how quickly earthworms break down organic matter and build up rich soils.

RECAP 31.3

Animals are heterotrophs that must expend energy to acquire food from their environment. Most animals either move through the environment to where food is located or move the environment and the food it contains to them.

- How can you distinguish among filter feeders, predators, and parasites—all of which may feed on other animals?
See pp. 637–639
- What adaptations are necessary for animals that eat plants? What adaptations are needed for a predatory lifestyle?
See pp. 638–639

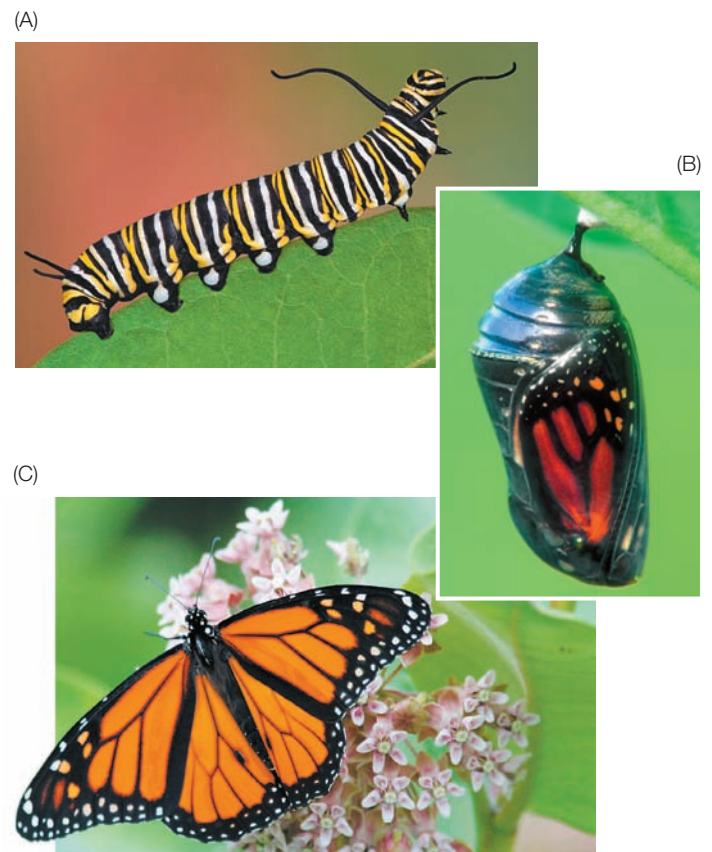

As an animal grows from a single-celled zygote into a larger, more complex adult, its body structure, its diet, and the environment in which it lives may all change. In the next section we will describe some animal life cycles and discuss why they are so varied.

31.4 How Do Life Cycles Differ among Animals?

The life cycle of an animal encompasses its embryonic development, birth, growth to maturity, reproduction, and death. During its life an individual animal ingests food, grows, interacts with other individuals of the same and other species, and reproduces.

Many animal life cycles feature specialized life stages

In some groups of animals, newborns look much like miniature versions of the adults (a pattern called **direct development**). Newborns of most animal species, however, differ dramatically from adults. Many animal species have a life stage called a **larva** (plural *larvae*), which is an immature form that the animal takes early in its life before assuming an adult form. Some of the most striking life cycle changes are found among insects such as beetles, flies, moths, butterflies, and bees, which undergo radical change (called **metamorphosis**) between their larval and adult stages (Figure 31.9). In these animals, one stage may be specialized for feeding and the other for reproduction. Adults

31.9 A Life Cycle with Complete Metamorphosis (A) The larval stage (caterpillar) of the monarch butterfly (*Danaus plexippus*) is specialized for feeding. (B) The pupa is the stage during which the transformation to the adult form occurs. (C) The adult butterfly is specialized for dispersal and reproduction.

of most moth species, for example, do not eat. In some animal species, individuals eat during all life cycle stages, but what they eat changes with the stage. For example, butterfly larvae (known as caterpillars) eat leaves and flowers, whereas most adult butterflies eat only nectar. Having different life cycle stages that are specialized for different activities may increase the efficiency with which an animal performs those activities.

Most animal life cycles have at least one dispersal stage

At some time during their lives, most animals move, or are moved, so few animals die exactly where they were born. Movement of organisms away from a parent organism or from an existing population is called **dispersal**.

Animals that are sessile as adults typically disperse as eggs or larvae. Most sessile marine animals discharge their eggs and sperm into the water, where fertilization takes place. A larva soon hatches and floats freely in the plankton, where it filters small food items from the water. Many animals that live on the seafloor, including polychaete worms and mollusks, have a radially symmetrical larval form known as a **trochophore** (Figure 31.10A). Other animals, such as crustaceans, have a

bilaterally symmetrical larval form called a **nauplius** (Figure 31.10B). Both types of larvae feed for some time in the plankton and may travel long distances before settling on the ocean floor and transforming into adults.

Other animal species that are motile as adults disperse when they are mature. A caterpillar, for example, may spend its entire larval stage feeding on a single plant, but after it metamorphoses into a flying adult—a butterfly—it may fly to and lay eggs on other plants located far from the one where it spent its caterpillar days. In some species, individuals disperse during several different life cycle stages.

Parasite life cycles facilitate dispersal and overcome host defenses

Animals that live as endoparasites are bathed in the nutritious tissues of their host or in the digested food that fills their host's digestive tract. Thus they may not need to exert much energy to obtain food, but to survive they must overcome the host's defenses. Furthermore, either they or their offspring must disperse to new hosts while their host is still living, because they die when their host dies.

The fertilized eggs of some parasites are voided with the host's feces and later ingested directly by other host individuals. Most parasite species, however, have complex life cycles involving one or more intermediate hosts and several larval stages (Figure 31.11). Some intermediate hosts transport individual parasites directly between other host species. Others house and support the parasite until another host ingests them. Complex life cycles may thus facilitate the transfer of individual parasites among hosts.

Some animals form colonies of genetically identical, physiologically integrated individuals

Most people tend to view the distinction between individuals and populations as clear-cut. In several groups of animals, however, asexual reproduction without fission leads to the formation of colonies composed of many physiologically integrated individuals. At first appearance, these colonies may look much like a single integrated organism. The individuals in the colony are clonal copies of one another, so they are genetically homogeneous.

Coloniality has arisen several times among animal groups, with widely varying levels of integration and specialization among the individuals. In some species, colonies are composed of loosely connected but integrated individuals that all function alike (Figure 31.12). In other colonial species, the individuals may become specialized for different functions, just as different cell types in multicellular organisms do. The Portuguese man-of-war (a cnidarian; see Figure 31.19) is an example of such a colonial animal, as it is composed of many individuals of four different specialized body forms, all integrated and functioning together. The individuals in the colony are themselves multicellular, however, unlike the cells of a single multicellular organism.

31.10 Planktonic Larval Forms of Marine Animals (A) The trochophore ("wheel-bearer") is a distinctive larval form found in several marine animal clades with spiral cleavage, most notably the polychaete worms and the mollusks. (B) This nauplius larva will mature into a crustacean with a segmented body and jointed appendages.

31.11 Reaching a New Host by a Complex Route The broad fish tapeworm *Diphyllobothrium latum* must pass through the bodies of a copepod (a type of crustacean) and at least one fish before it can reinfect its primary host, a mammal. Such complex life cycles assist the parasite's colonization of new host individuals, but they also provide opportunities for humans to break the cycle with hygienic measures (such as thoroughly cooking food to kill the parasites).

No life cycle can maximize all benefits

A common saying, "a jack-of-all-trades is master of none," suggests why there are constraints on the evolution of life cycles. The characteristics an animal has in any one life cycle stage may improve its performance in one activity but reduce its performance in another—a situation known as a trade-off. An animal that is good at filtering small food items from the water, for example, is unlikely to be good at capturing large prey. Similarly, energy devoted to building protective structures such as shells cannot be used for growth.

Some major trade-offs can be seen in animal reproduction. Some animals produce large numbers of small eggs, each with a small energy store (Figure 31.13A). Other animals produce a small number of large eggs, each with a large energy store (Figure 31.13B). With a fixed amount of energy available for reproduction, a female animal can produce many small eggs or a few large eggs, but she cannot produce many large eggs. Thus there is a trade-off between

Plumatella repens

31.12 Colonial Animals This bryozoan colony consists of many asexually reproducing, genetically homogeneous, physiologically interacting individuals. The colony looks much like a single individual with many parts, but in fact is a group of individuals acting together.

31.13 Many Small or Few Large Allocation of energy to eggs requires trade-offs. (A) This wood frog has divided her reproductive energy among a large number of small eggs. (B) This King penguin has invested all of her reproductive energy in one large egg.

(A) *Rana sylvatica*(B) *Aptenodytes patagonicus*

the number of offspring produced and the energy resources each offspring receives from its mother.

The larger the energy store in an egg, the longer an offspring can develop before it must either find its own food or be fed by its parents. Birds of all species lay relatively small numbers of relatively large eggs, but incubation periods vary. In some species, eggs hatch when the young are still helpless (**Figure 31.14A**). Such **altricial** young must be fed and cared for until they can feed themselves; parents can provide for only a small number of altricial offspring. In contrast, some bird species incubate their eggs longer, and the hatchlings are developed to the point that they are able to forage for themselves almost immediately (**Figure 31.14B**). The young of such species are called **precocial**.

RECAP 31.4

Many animals have life cycle stages that differ from one another morphologically. In some animals, the larval form is a dispersal stage; in other species, the adults are more likely to disperse than are larvae. In several groups of organisms, asexual reproduction without fission leads to coloniality.

- How do trade-offs constrain the evolution of life cycles?
See pp. 641–642
- Explain the difference between multicellularity and coloniality. **See p. 641 and Figure 31.12**

Variations in body symmetry, body cavity structure, life cycles, patterns of development, and survival strategies differentiate

millions of animal species. In the remainder of this chapter and in Chapters 32 and 33, we will become acquainted with the major animal groups and learn how the general characteristics we have just described apply to each of them.

31.5 What Are the Major Groups of Animals?

The bilaterians make up a large monophyletic group embracing all animals other than sponges, ctenophores, placozoans, cnidarians, and a few poorly known groups of parasitic animals (see Figure 31.1). Some of the traits that support the monophyly of bilaterians are the presence of three distinct cell layers in embryos (triploblasty) and the presence of at least seven Hox genes (see Chapters 19 and 20). Although bilateral symmetry is often viewed as a synapomorphy of bilaterians (and the trait gives the group its name), some groups of cnidarians are also bilaterally symmetrical. Recent studies have shown that the genetic basis of bilateral symmetry in bilaterians and in those cnidarian groups that have this trait is similar, so this feature may have been present in the ancestor of both groups.

Bilaterian animals can be divided into the two major clades mentioned earlier, the protostomes and the deuterostomes. These two groups have been diversifying separately for more than 500 million years—ever since the “Cambrian explosion” that we described in Chapter 25. We will describe the protostomes in Chapter 32 and the deuterostomes in Chapter 33.

Go to Activity 31.2 Sponge and Diploblast Classification
Life10e.com/ac31.2

The remainder of this chapter describes those animal groups that are not bilaterians. The simplest animals, the sponges, have no distinct tissue types. All other animals are usually known as **eumetazoans**. Two groups treated here as eumetazoans, the ctenophores and placozoans, have weakly differentiated tissue layers (placozoans also lack a nervous system), so some biologists exclude these two groups from Eumetazoa as well. Most eumetazoans have some form of body symmetry, a gut, and tissues organized into distinct organs (although there have been secondary losses of some of these features in some eumetazoans).

Sponges are loosely organized animals

Sponges are the simplest animals. Although they have some specialized cells, they have no distinct embryonic cell layers and no true organs. Early naturalists classified sponges as plants because they were sessile and lacked body symmetry.

Sponges have hard skeletal elements called **spicules**, which may be small and simple or large and complex (see Figure 31.2B). Three major groups of sponges, which separated soon after the split between sponges and the rest of the animals, are distinguished by their spicules. Members of two groups (glass sponges and demosponges) have skeletons composed of siliceous spicules made of hydrated silicon dioxide (**Figure 31.15A,B**). These spicules are remarkable in having greater flexibility and toughness than synthetic glass rods of similar length. Members of the third group, the calcareous sponges,

(A) *Xestospongia testudinaria*

(B) *Euplectella aspergillum*

(C) *Sycon* sp.

31.15 Sponge Diversity (A) The majority of sponge species are demosponges, such as these Pacific barrel sponges. The system of pores and water canals (see Figure 31.2) that is typical of the sponge body plan is apparent in this photograph. (B) The supporting structures of both demosponges and glass sponges are siliceous spicules, seen here in the skeleton of a glass sponge. (C) The spicules of calcareous sponges are made of calcium carbonate.

take their name from their calcium carbonate spicules (**Figure 31.15C**). There is some question about the monophyly of sponges. Analyses of some gene sequences have suggested that calcareous sponges are actually more closely related to the eumetazoans than to the other groups of sponges. However, genomic analyses that combine information from many genes support the monophyly of sponges.

The body plan of sponges of all three groups—even large ones, which may reach 1 meter or more in length—is an aggregation of cells built around a water canal system. Sponges bring water into their bodies by beating the flagella of their specialized feeding cells, called **choanocytes** (see Figure 31.2B). Water, along with any food particles it contains, enters the sponge by way of small pores and passes into the water canals or a central atrium, where the choanocytes capture food particles. (You may recall from Section 31.1 that the choanocytes are similar in structure to protists known as choanoflagellates; that similarity provides evidence for the close relationship of animals to choanoflagellates.)

A skeleton of simple or branching spicules, often combined with a complex network of elastic fibers, supports the body of most sponges. Sponges also produce an extracellular matrix, composed of collagen, adhesive glycoproteins, and other molecules, that holds the cells together. Most species are filter feeders; a few species are predators that trap prey on hook-shaped spicules that protrude from the body surface.

Most of the 8,500 species of sponges are marine animals; only about 50 species live in fresh water. Sponges come in a wide variety of sizes and shapes that are adapted to different movement patterns of water. Sponges living in intertidal or shallow subtidal environments with strong wave action are firmly attached to the substrate. Most sponges that live in slowly flowing water are flattened and are oriented at right

angles to the direction of current flow. They intercept water and the food items it contains as it flows past them.

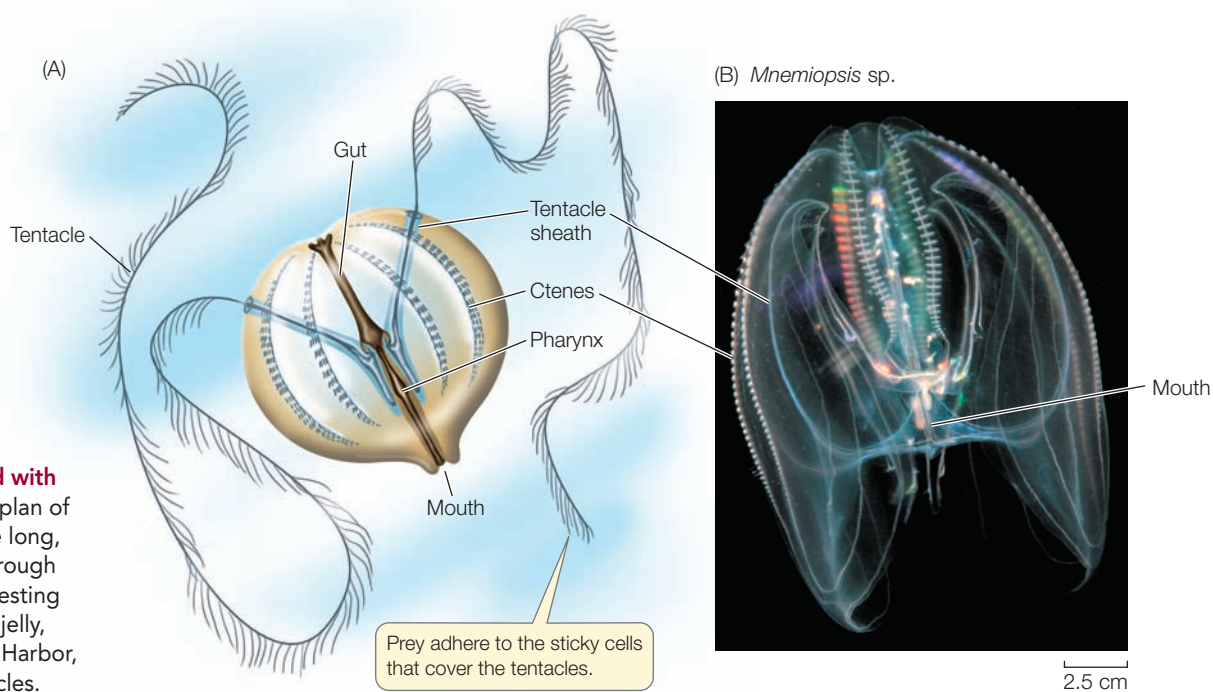

Sponges reproduce both sexually and asexually. In most species, a single individual produces both eggs and sperm, but individuals do not self-fertilize. Water currents carry sperm from one individual to another. Sponges also reproduce asexually by budding and fragmentation.

Ctenophores are radially symmetrical and diploblastic

Ctenophores, also known as comb jellies, were until recently thought to be most closely related to the cnidarians (jellyfishes, corals, and their relatives). But ctenophores lack most of the Hox genes found in all other eumetazoans, and recent studies of their genomes have indicated that ctenophores were probably among the earliest lineages to split from the remaining animals. Most recent phylogenetic analyses place the ctenophores as the sister group of all other animals except sponges.

Ctenophores have a radially symmetrical, diploblastic body plan. The two cell layers are separated by an inert, gelatinous extracellular matrix called **mesoglea**. Ctenophores, unlike sponges, have a **complete gut**: food enters through a mouth, and wastes are eliminated through two anal pores.

Ctenophores move by beating cilia rather than by muscular contractions. Most of the 250 known species have eight comb-like rows of cilia-bearing plates, called **ctenes** (**Figure 31.16**). The feeding tentacles of ctenophores are covered with cells that discharge adhesive material when they contact prey. After capturing its prey, a ctenophore retracts its tentacles to bring

the food to its mouth. In some species, the entire surface of the body is coated with sticky mucus that captures prey. Most ctenophores eat small planktonic organisms, although some eat other ctenophores. They are common in open seas and can become abundant in coastal bays, where large populations of ctenophores may inhibit the growth of other organisms.

Ctenophore life cycles are uncomplicated. Gametes are released into the gut and discharged through the mouth or the anal pores. Fertilization takes place in open seawater. In nearly all species, the fertilized egg develops directly into a miniature ctenophore, which gradually grows into an adult.

 **Go to Media Clip 31.4**
Ctenophores
Life10e.com/mc31.4

Placozoans are abundant but rarely observed

As discussed at the start of this chapter, **placozoans** are structurally very simple animals with only a few distinct cell types (**Figure 31.17A**). Individuals in the mature, asymmetrical life stage are usually observed adhering to surfaces (such as the glass of aquariums, where they were first discovered, or to rocks and other hard substrates in nature). Their structural simplicity—they have no mouth, gut, or nervous system—initially led biologists to suspect they might be the sister group of all other animals. Most phylogenetic analyses have not supported this hypothesis, however, and some aspects of the placozoans' structural simplicity may be secondarily derived. They are generally considered to have a diploblastic body plan, with upper and lower surface layers that sandwich a layer of contractile fiber cells.

Recent studies have found that placozoans have a pelagic (open-ocean) life stage that is capable of swimming (**Figure 31.17B**), but the life history of placozoans is incompletely known. Most studies have focused on the larger adherent stages that are most easily observed in aquariums. The transparent nature and small size of placozoans make them very difficult to observe in nature. Nonetheless, it is known that placozoans

can reproduce both asexually and sexually, although the details of their sexual reproduction are poorly understood. As we noted at the opening of this chapter, placozoans have been studied mainly in aquariums, where they appear after being inadvertently collected with other marine organisms, although we now know that pelagic-stage placozoans are abundant in warm seas around the world.

Cnidarians are specialized predators

The **cnidarians** (jellyfishes, sea anemones, corals, and hydrozoans) make up the largest and most diverse group of non-bilaterian animals. The mouth of a cnidarian is connected to a blind sac called the **gastrovascular cavity** (a cnidarian thus does not have a complete gut). The gastrovascular cavity functions in digestion, circulation, and gas exchange, and it also acts as a hydrostatic skeleton. The single opening serves as both mouth and anus.

The life cycle of many cnidarians has two distinct stages, one sessile and the other motile (**Figure 31.18**), although one or the other of these stages is absent in some groups. In the sessile **polyp** stage, a cylindrical stalk attaches the animal to the substrate. The motile **medusa** (plural *medusae*) is a free-swimming stage shaped like a bell or an umbrella. It typically floats with its mouth and feeding tentacles facing downward.

Mature polyps produce medusae by asexual budding. Medusae then reproduce sexually, producing eggs or sperm by meiosis and releasing the gametes into the water. A fertilized egg develops into a free-swimming, ciliated larva called a **planula**, which eventually settles to the bottom and develops into a polyp.

Cnidarians are specialized predators adapted for capturing and subduing relatively large and complex prey. Their tentacles are covered with specialized cells that contain stinging organelles called **nematocysts**, which inject toxins into their prey (**Figure 31.19**). Some cnidarians, including many corals and anemones, gain additional nutrition from photosynthetic endosymbionts that live in their tissues.

31.17 Placozoan Simplicity (A) As seen in this artist's rendition, adult placozoans are tiny (1–2 mm across), flattened, asymmetrical animals. (B) Recent studies have found a symmetrical, weakly swimming pelagic stage of placozoan to be abundant in many warm tropical and subtropical seas.

31.18 The Life Cycle of Most Cnidarians Has Two Stages

The life cycle of a scyphozoan (jellyfish) exemplifies the typical cnidarian body forms: the sessile, asexual polyp and the motile, sexual medusa. Some species of cnidarians have life cycles that lack polyps or medusae.

Go to Animated Tutorial 31.1
Life Cycle of a Cnidarian
Life10e.com/at31.1

Cnidarians have cells containing muscle fibers whose contractions enable the animals to move, as well as simple nerve nets that integrate the body's activities. Their bodies also contain specialized structural molecules (collagen, actin, and myosin). Yet cnidarians, like ctenophores, are largely made up of inert mesoglea. They have low metabolic rates and can survive in environments where they encounter prey only infrequently.

Of the roughly 12,500 living cnidarian species, all but a few live in the oceans (**Figure 31.20**). The smallest cnidarians can barely be seen without a microscope. One small group, known as myxozoans, consists of tiny parasites, usually with a two-host life cycle that includes a fish and an annelid worm or a bryozoan. The largest known jellyfish is 2.5 meters in diameter, and some colonial hydrozoans (which include the Portuguese man-of-war; see **Figure 31.19**) can reach lengths in excess of 30 meters. Here we describe the three clades of cnidarians that contain the most species: anthozoans, scyphozoans, and hydrozoans.

ANTHOZOANS Members of the **anthozoan** clade include sea anemones, sea pens, and corals. Sea anemones (see **Figure 31.20A**), all of which are solitary, are widespread in both warm and cold ocean waters. Sea pens (see **Figure 31.20B**), by contrast, are colonial. Each colony consists of two or more different kinds of polyps. The primary polyp has a lower portion anchored in the bottom sediment and a branched upper portion that projects above the substrate. Along the upper portion, the primary polyp produces smaller secondary polyps by budding. Some of these secondary polyps differentiate into feeding polyps; in some species, other secondary polyps differentiate to circulate water through the colony.

The common names of coral groups—brain corals, staghorn corals, and organ pipe corals, among others—often describe their appearance (**Figure 31.21A**). Corals are sessile and colonial. The polyps of most species form a skeleton by secreting a matrix of organic molecules on which they then deposit calcium carbonate. As the colony grows, old polyps

31.19 Nematocysts Are Potent Weapons The tentacles of the Portuguese man-of-war, a hydrozoan, are rife with specialized cells called cnidocytes. These cells contain stinging organelles called nematocysts, which inject toxins into their prey. The Portuguese man-of-war is a colonial organism, composed of many physiologically integrated individuals with specialized functions.

die, but their calcium carbonate skeletons remain. Living corals form a layer on top of a growing bank of skeletal remains, eventually forming chains of islands and reefs (**Figure 31.21B**). The Great Barrier Reef along the northeastern

31.20 Diversity among Cnidarians (A) Sea anemones are sessile, living attached to marine substrates. Water currents carry prey into the nematocyst-studded tentacles. (B) The sea pen is a colonial cnidarian that lives in soft bottom sediments and projects polyps above the substrate. (C) This jellyfish illustrates the complexity of a scyphozoan medusa. (D) The internal structure of the medusa of a North Atlantic colonial hydrozoan is visible here.

coast of Australia is a system of coral formations more than 2,000 kilometers long, which is about the distance from New York City to St. Louis. A single coral reef in the Red Sea has been calculated to contain more material than all the buildings in the major cities of North America combined.

Corals flourish at shallow depths in clear, nutrient-poor tropical waters. They grow well in such environments because unicellular photosynthetic dinoflagellates live endosymbiotically within their cells. These dinoflagellates provide the corals with products of photosynthesis; the corals, in turn, provide the dinoflagellates with nutrients and a place to live. This endosymbiotic relationship explains why reef-forming corals are restricted to clear surface waters, where light levels are high enough to support photosynthesis.

Coral reefs throughout the world are threatened by rising CO₂ levels (which result in increased ocean temperatures) and acidification of ocean waters. Polluted runoff from development on adjacent shorelines is an additional threat to corals. Warmer temperatures lead to the loss of coral endosymbionts (known as coral bleaching; see Figure 27.21), and acidification can cause coral skeletons to dissolve. An overabundance of nitrogen in runoff is advantageous to algae, which overgrow and eventually smother the corals.

SCYPHOZOANS The several hundred species of **scyphozoans** are all marine. The mesoglea of their medusae is thick and firm, giving rise to their common name of jellyfish (or sea jellies). The medusa rather than the polyp dominates the life cycle of scyphozoans. An individual medusa is male or female, releasing eggs or sperm into the open sea. A fertilized egg develops into a small planula larva that quickly settles on a substrate and develops into a small polyp. This polyp feeds and grows and may produce additional polyps by budding. After a period of growth, the polyp begins to bud off small medusae, which feed, grow, and transform into adult medusae (see Figures 31.18 and 31.20C).

HYDROZOANS The polyp typically dominates the life cycle of **hydrozoans**, but some species have only medusae (see Figure 31.19) and others have only polyps. Most hydrozoans are colonial. A single planula larva eventually gives rise to a colony of

31.21 Corals (A) The descriptive common name of this Caribbean coral is "brain coral." (B) Many different coral species form this reef in the Red Sea between Egypt and the Arabian Peninsula.

31.22 Many Hydrozoans Are Colonial The polyps in a hydrozoan colony may differentiate to perform specialized tasks. In the species whose life cycle is diagrammed here, the medusa is the sexual reproductive stage, producing eggs and sperm in organs called gonads.

many polyps, all interconnected and sharing a continuous gastrovascular cavity (**Figure 31.22**). Within such a colony, some polyps have tentacles with many nematocysts; they capture prey for the colony. Other individuals lack tentacles and are unable to feed, but are specialized for the asexual production of medusae. Still others are fingerlike and defend the colony with their nematocysts.

Some small groups of parasitic animals may be the closest relatives of bilaterians

Two small groups of tiny marine parasites are listed in Table 31.1 but are not depicted in the phylogeny in Figure 31.1: the orthonectids and the rhombozoans. Recent genomic analyses suggest that these groups may be among the closest surviving relatives of the bilaterians, although their exact phylogenetic placement is uncertain. Both groups are highly reduced parasites that lack many of the structures that traditionally have been used to study animal relationships. As their genomes become more completely known, the relationships of these two groups to other animals should become clearer. Two other small groups (also listed in Table 31.1 but not shown in Figure 31.1) have been proposed as also falling just outside the bilaterians: the xenoturbellids and acoels. Recent genomic analyses, however, have suggested that these animals are actually highly specialized deuterostomes.

Which animal groups are involved in the earliest split in the animal tree?

ANSWER

Most data support the placement of sponges as the sister group of all other animals. Morphologically, sponges are the most similar to the choanoflagellates, and most genomic analyses continue to place sponges at the base of the animal tree. The ctenophores share some superficial similarities with cnidarians and were traditionally considered their sister group, but more recent studies increasingly support the placement of the ctenophores closer to the base of the animal tree. A few studies even suggest that the ctenophores are the sister group of all other animals, including sponges, although most studies place the ctenophores as the sister group of all animals except sponges, and this is the phylogeny we show in Figure 31.1.

Although placozoans, with only four cell types and no true organs, are less structurally complex than ctenophores, this structural simplicity is now thought to represent an evolutionary reversal in the placozoan lineage. The alternative possibility, which seems less likely, is that the organ systems of ctenophores evolved independently from those of the cnidarians and bilaterians.

RECAP 31.5

Bilateria animals are classified into two major clades, protostomes and deuterostomes. The non-bilateria animals comprise the sponges, ctenophores, placozoans, cnidarians, and some small groups of parasitic animals.

- Why are sponges considered to be animals even though they lack the complex body structures found among most other animal groups? [See pp. 643–644](#)
- Describe some major features of the following groups: sponges, ctenophores, placozoans, and cnidarians.

CHAPTER SUMMARY 31

31.1 What Characteristics Distinguish the Animals?

- Animals share a set of derived traits not found in other groups of organisms. These traits include similarities in the sequences of many of their genes, the structure of their cell junctions, and the components of their extracellular matrix.
- Patterns of embryonic development provide clues to the evolutionary relationships among animals. **Diploblastic** animals, which include the ctenophores, placozoans, and cnidarians, develop two embryonic cell layers. **Triploblastic** animals develop three cell layers. **Review Figure 31.1**
- Differences in their patterns of early development characterize two major triploblastic clades, the **protostomes** and the **deuterostomes**.

31.2 What Are the Features of Animal Body Plans?

- Animal **body plans** can be described in terms of symmetry, **body cavity** structure, **segmentation**, types of appendages, and nervous system development.
- A few animals have no symmetry, but most animals have either **radial symmetry** or **bilateral symmetry**. **Review Figure 31.4**
- Many bilaterally symmetrical animals exhibit **cephalization**: the concentration of sensory organs and nervous tissues in an anterior head.
- On the basis of their body cavity structure, animals can be described as **acoelomates**, **pseudocoelomates**, or **coelomates**. **Review Figure 31.5, ACTIVITY 31.1**
- Segmentation, which takes many forms, improves control of movement, as do appendages. **Review Figure 31.6**
- The development of a nervous system is important for the coordination of muscular movement and the processing of sensory information.

31.3 How Do Animals Get Their Food?

- **Motile** animals can move to find food; **sessile** animals stay in one place, but may expend energy to move the environment and the food it contains to them
- **Filter feeders** strain small organisms and organic molecules from their environment.
- **Herbivores** consume plants, usually without killing them.
- **Predators** have morphological features such as sharp teeth, beaks, and claws that enable them to capture and subdue animal prey.
- **Parasites** live in or on other organisms and obtain nutrition from those **host** individuals.

- **Detritivores** consume dead organic matter and return the nutrients it contains to the ecosystem.

31.4 How Do Life Cycles Differ among Animals?

- The stages of an animal's life cycle may be specialized for different activities. An immature stage whose morphology is dramatically different from that of the adult stage is called a **larva**.
- Most animal life cycles have at least one **dispersal** stage. Many sessile marine animals can be grouped by the presence of one of two distinct larval dispersal stages: **trochophore** or **nauplius**. **Review Figure 31.10**
- A characteristic of an animal or a life cycle stage may improve the animal's performance in one activity but reduce its performance in another, a situation known as a trade-off.
- Parasites have complex life cycles that may involve one or more hosts and several larval stages. **Review Figure 31.11**
- In some groups of animals, asexual reproduction without fission leads to the formation of colonies composed of many genetically homogeneous, physiologically integrated individuals.

31.5 What Are the Major Groups of Animals?

- **Eumetazoans** include all animals except sponges. Animals other than sponges, ctenophores, placozoans, and cnidarians—that is, the triploblastic protostomes and deuterostomes—belong to a large monophyletic group called **bilaterians**. **Review Figure 31.1, ACTIVITY 31.2**
- **Sponges** are simple animals that lack differentiated cell layers and true organs. They have skeletons made up of siliceous or calcareous **spicules**. They create water currents and capture food with flagellated feeding cells called **choanocytes**. **Review Figure 31.2**
- **Ctenophores** are radially symmetrical and have two cell layers separated by an inert extracellular matrix called **mesoglea**. **Review Figure 31.16**
- **Placozoans** are asymmetrical as adults. They have only a few cell types and lack true organs, although their simplicity may be secondarily derived.
- The life cycle of most **cnidarians** has two distinct stages: a sessile **polyp** stage and a motile **medusa** stage that reproduces sexually. A fertilized egg develops into a free-swimming **planula** larva, which settles to the bottom and develops into a polyp. **Review Figures 31.18, 31.22, ANIMATED TUTORIAL 31.1**

CHAPTER REVIEW

REMEMBERING

1. A bilaterally symmetrical animal can be divided into mirror-image halves by
 - a. any plane through the midline of its body.
 - b. any plane from its anterior to its posterior end.
 - c. any plane from its dorsal to its ventral surface.
 - d. a single plane through the midline of its body from its anterior to its posterior end.
 - e. a single plane that divides it into dorsal and ventral halves.
2. In the common ancestor of eumetazoans, the pattern of early cleavage was
 - a. spiral.
 - b. radial.
 - c. biradial.
 - d. deterministic.
 - e. haphazard.
3. A fluid-filled body cavity can function as a hydrostatic skeleton because
 - a. fluids are moderately compressible.
 - b. fluids are highly compressible.
 - c. fluids are relatively incompressible.
 - d. fluids have the same density as body tissues.
 - e. fluids can be moved by ciliary action.
4. Many parasites evolved complex life cycles because
 - a. they are too simple to disperse readily.
 - b. they are poor at recognizing new hosts.
 - c. they were driven to it by host defenses.
 - d. complex life cycles increase the probability of a parasite's transfer to a new host.
 - e. their nonparasitic ancestors had complex life cycles and they simply retained them.
5. The endosymbiotic dinoflagellates present in many corals
 - a. provide the corals with products of photosynthesis.
 - b. allow corals to flourish in clear, nutrient-poor tropical waters.
 - c. can be lost when environmental conditions change.
 - d. All of the above
 - e. None of the above

UNDERSTANDING & APPLYING

6. Differentiate among the members of each of the following sets of related terms:

radial symmetry/bilateral symmetry
protostome/deuterostome
diploblastic/triploblastic
coelomate/pseudocoelomate/acoelomate
7. In this chapter we listed some of the traits shared by all animals that have convinced most biologists that all animals are descendants of a single common ancestral lineage. In your opinion, which of these traits provides the most compelling evidence that animals are monophyletic?
8. Why is bilateral symmetry strongly associated with cephalization, the concentration of sensory organs in an anterior head?
9. How does a slow metabolic rate enable an animal to live in an unproductive environment?

ANALYZING & EVALUATING

10. The discoveries that the pelagic stages of placozoans are abundant in warm seas and that the mature stages settle on smooth surfaces suggest how these organisms might be collected and surveyed. What sampling procedures might you use to discover whether placozoans occur at a particular location along a coast?

CHAPTER OUTLINE

- 32.1** What Is a Protostome?
- 32.2** What Features Distinguish the Major Groups of Lophotrochozoans?
- 32.3** What Features Distinguish the Major Groups of Ecdysozoans?
- 32.4** Why Are Arthropods So Diverse?

How Many Species? In an important study, entomologist Terry Erwin fogged tree canopies in a Panamanian rainforest with insecticide. Using the number of species represented among the fallen insects as a base, he extrapolated to estimate the total number of insect species on Earth.

OF THE 1.8 MILLION ANIMAL SPECIES that have been discovered and named by biologists, a large majority are protostomes. One group of protostomes, the insects, accounts for more than 1 million of these species, or more than half of all known species of living organisms. Although these numbers may seem incredibly large, they represent a relatively small fraction of the total protostome diversity that is thought to exist on Earth.

As recently as the 1980s, many biologists thought that about half of existing insect species had been described, but today they think that the number of described insect species may be a much smaller fraction of the total number of living species. Why did they change their minds?

A simple but important field study suggested that the number of existing insect species had been significantly underestimated. Knowing that the insects of tropical rainforests—the most species-rich habitat on Earth—were poorly known, entomologist Terry Erwin made a comprehensive sample of one group of insects, the beetles, in the canopies of a single species of tropical forest tree, *Luehea seemannii*, in Panama. Erwin fogged the canopies of 19 large *L. seemannii* trees with an insecticide and collected the insects that fell from the trees in collection nets. He collected about 1,200 species of beetles—many of them previously undescribed—from this one species of tree.

Erwin then used a set of assumptions to estimate the total number of insect species in tropical rainforests. His assumptions included estimates of the number of species of trees in these forests; the proportion of beetles that specialize on a specific species of host tree; the relative proportion of beetles to other insect groups; and the proportion of beetles that live in trees versus those that live in leaf litter on the ground. From this and similar studies, Erwin estimated that there may be 30 million or more species of insects on Earth. Although recent tests of Erwin's assumptions suggest that 30 million was an overestimate, it is clear that the vast majority of insect species remain to be discovered.

Erwin's pioneering study highlighted the fact that we live on a poorly known planet, most of whose species have yet to be named and described. Much of that undiscovered diversity occurs among several groups of protostomes.

Which groups of protostomes are thought to contain the most undiscovered species?

See answer on p. 675.

32.1 What Is a Protostome?

You may recall that the embryos of diploblastic animals (the ctenophores, placozoans, and cnidarians, which we discussed in Chapter 31) have two cell layers: an outer ectoderm and an inner endoderm (see Section 31.1). Sometime after the origin of the diploblastic animals, a third embryonic cell layer evolved: the mesoderm, which lies between the ectoderm and the endoderm. Mesoderm is found in the two major triploblastic animal clades, the protostomes and the deuterostomes. If we were to judge solely on the basis of numbers, both of species and of individuals, the protostomes would emerge as by far the more successful of the two groups.

As noted in Section 31.1, the name “protostome” means “mouth first.” In protostomes, the embryonic blastopore becomes the mouth as the animal develops. In contrast, in deuterostomes (“mouth second”), the blastopore becomes the anal opening of the gut. The protostomes are extremely varied, but they are all bilaterally symmetrical animals whose bodies exhibit two major derived traits:

- An anterior brain that surrounds the entrance to the digestive tract
- A ventral nervous system consisting of paired or fused longitudinal nerve cords

Other aspects of protostome body organization differ widely from group to group (**Table 32.1**). Before gene sequences were available for phylogenetic analysis, biologists considered the structure of the body cavity to be a critical feature in animal classification. But the results of genetic analyses have shown that body cavity forms have undergone considerable convergence in the course of protostome evolution. Although the common ancestor of the protostomes had a coelom, subsequent modifications of the coelom distinguish many protostome lineages. In some lineages (such as the flatworms and entoprocts), the coelom has been lost (that is, these groups reverted to an acoelomate state). Some lineages are characterized by a pseudocoel, a body cavity lined with mesoderm in which the internal organs are suspended (see Figure 31.5B). In two of the most prominent protostome clades, the coelom has been highly modified:

- Arthropods lost the ancestral condition of the coelom over the course of evolution. Their internal body cavity has become a **hemocoel**, or “blood chamber,” in which fluid from an open circulatory system bathes the internal organs before returning to blood vessels.
- Most mollusks have an open circulatory system with some of the attributes of the hemocoel, but they retain vestiges of an enclosed coelom around their major organs.

The protostomes can be divided into two major clades—the lophotrochozoans and the ecdysozoans—largely on the basis of DNA sequence analysis (**Figure 32.1**).

Horsehair worms	Pseudocoel	Greatly reduced	None
Arthropods	Hemocoel	Complete	Open

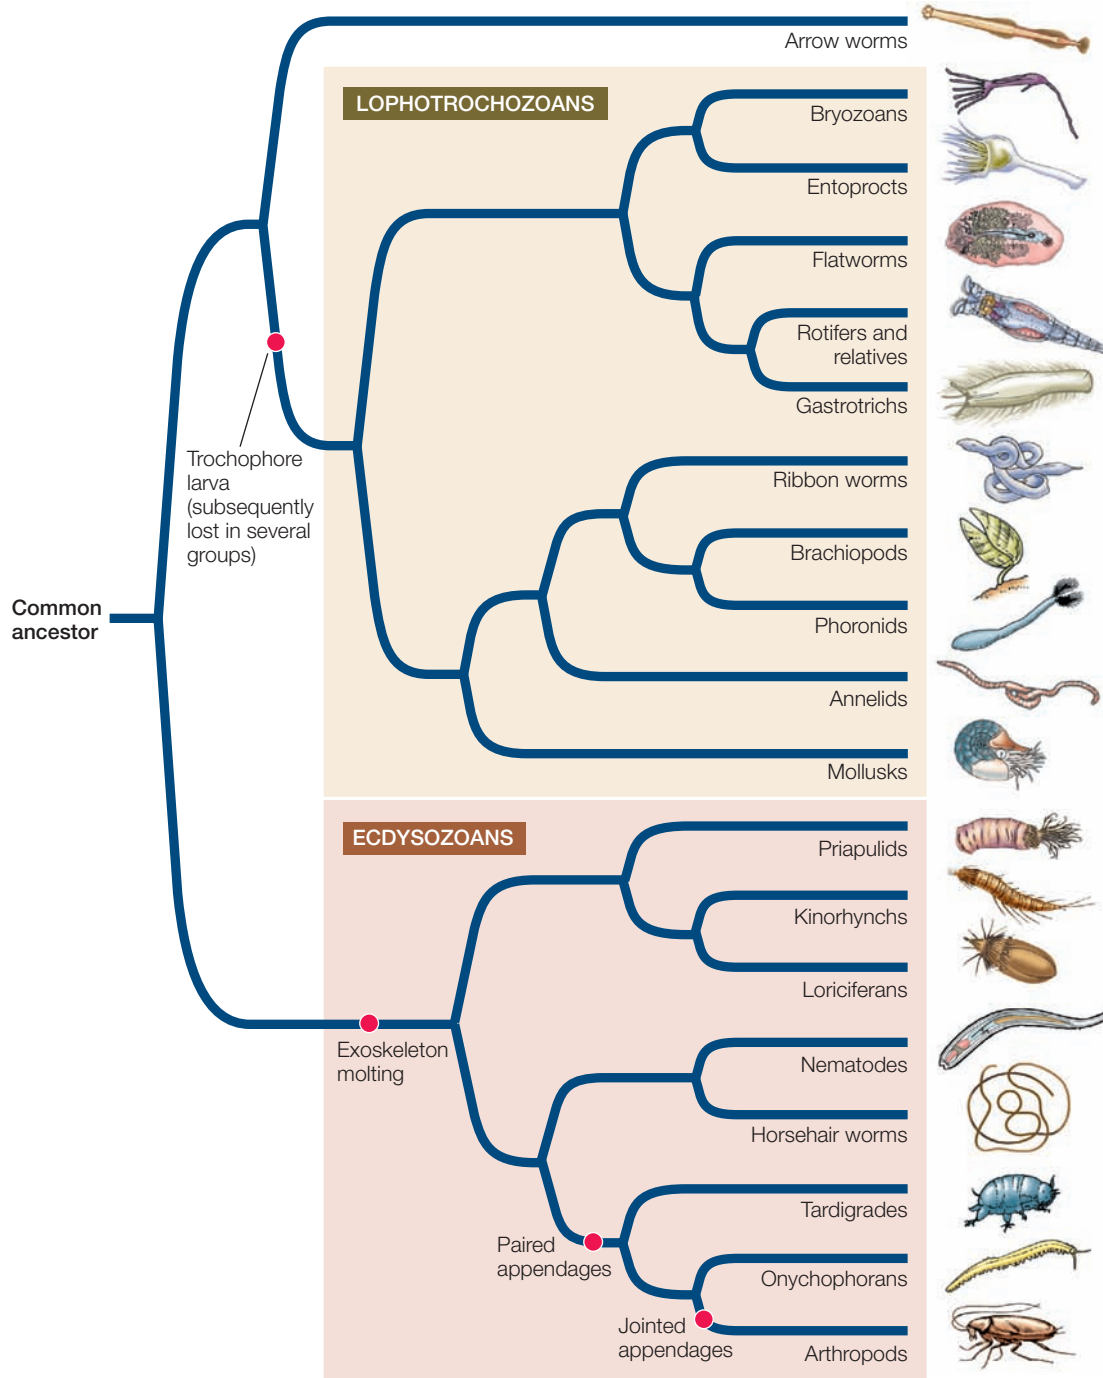

Cilia-bearing lophophores and trochophores evolved among the lophotrochozoans

Lophotrochozoans derive their name from two different ciliated features: a feeding structure known as a lophophore and a free-living larval form known as a trochophore. Neither the lophophore nor the trochophore is universal to all lophotrochozoans, however.

Several distantly related groups of lophotrochozoans (including bryozoans, entoprocts, brachiopods, and phoronids) have a **lophophore**, a circular or U-shaped ring of ciliated, hollow tentacles around the mouth (**Figure 32.2**). This complex organ is used for both food collection and gas exchange. Biologists once grouped taxa that have lophophores together as “lophophorates,” but it is now clear that they are not one another’s closest relatives. The lophophore appears to have evolved independently at least twice, or else it is an ancestral feature of lophotrochozoans and has been lost in many groups. Nearly all animals with a lophophore are sessile as adults. They use the tentacles and cilia of the lophophore to capture small floating organisms from the water. Other sessile lophotrochozoans have less well developed tentacles that they use for the same purpose.

32.1 Phylogenetic Tree of Protostomes Two major lineages, the lophotrochozoans and the ecdysozoans, dominate the protostome tree. Some small groups are not included in this tree. The phylogenetic relationships shown here are supported mainly by genomic sequence data. Although genomic studies are contributing greatly to our knowledge of animal phylogeny, most species of protostomes have yet to be studied in detail.

Go to Activity 32.2
Protosome Classification
Life10e.com/ac32.2

Some lophotrochozoans, especially in their larval form, use cilia for locomotion. The larval form known as a **trochophore** moves by beating a band of cilia (see Figure 31.10A). This movement of cilia also brings plankton closer to the larva, where it can capture and ingest them (its cilia are therefore similar in function to the cilia of the lophophore). Trochophore larvae are found among many of the major groups of lophotrochozoans, including the mollusks, annelids, ribbon worms, entoprocts, and bryozoans. This larval form was probably present in the common ancestor of lophotrochozoans but has been subsequently lost in several lineages.

As we discussed in Chapter 31, some lophotrochozoans (including flatworms, ribbon worms, annelids, and mollusks) exhibit a form of cleavage in early development known as spiral cleavage. Some biologists group these taxa together as “spiralian,” although phylogenetic analyses of gene sequences do not support a spiralian monophyly. Nonetheless, spiral cleavage may have been present in the lophotrochozoan ancestor and subsequently lost in several descendant lineages.

Many lineages of lophotrochozoans have a wormlike body form, which means that they are bilaterally symmetrical, legless, soft-bodied, and at least several times longer than they

*Plumatella repens*

100 μm

32.2 Bryozoans Use the Lophophore to Feed The extended lophophore dominates the anatomy of the colonial bryozoans. This species inhabits fresh water, although most bryozoans are marine.

are wide. A wormlike body form enables animals to burrow efficiently through marine sediment or soil. However, as we will see in Section 32.2, the mollusks—the most familiar of the lophotrochozoans to many people—have a very different body organization.

Ecdysozoans must shed their cuticles

Ecdysozoans have an external covering, or **cuticle**, that is secreted by the underlying epidermis (the outermost cell layer). The cuticle provides these animals with both protection and support. Once formed, however, the cuticle cannot grow. How, then, can ecdysozoans increase in size? They do so by shedding, or **molting**, the cuticle and replacing it with a new, larger one. This molting process gives the clade its name (Greek *ecdysis*, “to get out of”).

 **Go to Media Clip 32.2**
Molting a Cuticle
Life10e.com/mc32.2

A fossil Cambrian arthropod preserved in the process of molting shows that molting evolved more than 500 million years ago (**Figure 32.3A**). An increasingly rich array of molecular and genetic evidence, including a set of Hox genes shared by all ecdysozoans, suggests they have a single common ancestor. Thus molting of a cuticle is a trait that may have evolved only once during animal evolution.

Before an ecdysozoan molts, a new cuticle is already forming underneath the old one. Once the old cuticle is shed, the new one expands and hardens. Until it has hardened, though,

(A)

(B) *Heterophrynus batesii*

Molted exoskeleton

The newly emerged whip scorpion's body is still soft and vulnerable.

32.3 Molting: Past and Present (A) This 500-million-year-old fossil from the Cambrian, an individual of a long-extinct arthropod species captured in the process of molting, shows that the molting process is an evolutionarily ancient trait. (B) This tailless whip scorpion has just emerged from its discarded exoskeleton. It will be highly vulnerable until its new cuticle has hardened.

the animal is vulnerable to its enemies, both because its outer surface is easy to penetrate and because an individual with a soft cuticle can move only slowly or not at all (**Figure 32.3B**).

In many ecdysozoans that have wormlike bodies, the cuticle is relatively thin and flexible; it offers the animal some protection but provides only modest body support. A thin cuticle allows the exchange of gases, minerals, and water across the body surface, but it restricts the animal to moist habitats. Many species of ecdysozoans with thin cuticles live in marine sediments from which they obtain food, either by ingesting sediments and extracting

32.4 Arthropod Skeletons Are Rigid and Jointed This cross section through a thoracic segment of a generalized arthropod illustrates the arthropod body plan, which is characterized by a rigid exoskeleton with jointed appendages.

organic material from them or by capturing larger prey using a toothed **pharynx** (a muscular organ at the anterior end of the digestive tract). Some freshwater species absorb nutrients directly through their thin cuticles, as do parasitic species that live within their hosts (endoparasites). Many wormlike ecdysozoans are predators, eating protists and small animals.

The cuticles of other ecdysozoans, mainly arthropods, function as external skeletons, or **exoskeletons**. These exoskeletons are thickened by layers of protein and a strong, waterproof polysaccharide called **chitin**. An animal with a rigid, chitin-reinforced exoskeleton can neither move in a wormlike manner nor use cilia for locomotion. A hard exoskeleton also impedes the passage of oxygen and nutrients into the animal, presenting new challenges in other areas besides growth. Thus new mechanisms of locomotion and gas exchange evolved in those ecdysozoans with hard exoskeletons.

To move rapidly, an animal with a rigid exoskeleton must have body extensions that can be manipulated by muscles. Such appendages evolved in the late Precambrian, leading to the **arthropod** (“jointed foot”) clade. Arthropod appendages exist in an amazing variety of forms. They serve many functions, including walking and swimming, gas exchange, food capture and manipulation, copulation, and sensory perception. Arthropods grasp food with their mouths and associated appendages and digest it internally. Their muscles are attached to the inside of the exoskeleton. Each segment has muscles that operate that segment and the appendages attached to it (**Figure 32.4**).

The arthropod exoskeleton has had a profound influence on the evolution of these animals. Encasement within a rigid body covering provides support for walking on dry land, and the waterproofing provided by chitin keeps the animal from dehydrating in dry air. Thus aquatic arthropods were, in short, excellent candidates to invade terrestrial environments. As we will see, they did so several times.

Arrow worms retain some ancestral developmental features

Nearly all triploblastic animal groups can be readily classified as either protostomes or deuterostomes, but the evolutionary relationships of one small group, the **arrow worms**, were debated for many years. Although the early development of arrow worms seems similar to that of deuterostomes, it is now

known that arrow worms merely retain developmental features that are ancestral to triploblastic animals in general. Recent studies of gene sequences clearly identify arrow worms as protostomes. There is still some question as to whether they are the closest relatives of the lophotrochozoans (as shown in **Figure 32.1**) or possibly the sister group of all other protostomes.

The arrow worm body is divided into three compartments: head, trunk, and tail (**Figure 32.5**). The body is transparent or translucent. Most arrow worms swim in the open sea. A few species live on the seafloor. Their abundance as fossils indicates that they were common more than 500 million years ago. The 180 or so living species of arrow worms are small enough—ranging from 3 millimeters to 12 centimeters in length—that their gas exchange and waste excretion requirements are met by diffusion through the body surface. They lack a circulatory system; wastes and nutrients are moved around the body in the coelomic fluid, which is propelled by cilia that line the coelom.

Arrow worms are hermaphroditic; that is, each individual produces both male and female gametes. Eggs are fertilized internally following elaborate courtship between two individuals. Miniature adults hatch directly from the eggs; these animals have no distinct larval stage.

Arrow worms are stabilized in the water by means of one or two pairs of lateral fins and a tail fin. They are major predators of planktonic organisms in the open ocean, ranging in size from

32.5 An Arrow Worm Arrow worms have a three-part body organization. Their fins and grasping spines are adaptations for a predatory lifestyle. Individuals are hermaphroditic, producing both eggs in an ovary and sperm in a testis.

small protists to young fish as large as the arrow worms themselves. An arrow worm typically lies motionless in the water until water movement signals the approach of prey. The arrow worm then darts forward and uses the stiff spines adjacent to its mouth to grasp its prey.

RECAP 32.1

The shared derived traits of protostomes include a blastopore that develops into a mouth, an anterior brain, and a ventral nervous system. Several lophotrochozoan groups are characterized by a filter-feeding structure known as a lophophore or by cilia-bearing larvae known as trochophores. Ecdysozoans, which have a body covering known as a cuticle, must molt periodically in order to grow.

- How does an animal's body covering influence the way it exchanges gases, feeds, and moves? [See pp. 654–655](#)
- What features made arthropods well adapted for colonizing terrestrial environments? [See p. 655](#)

In the next section we continue our survey of the protostomes with a more detailed look at the major groups of lophotrochozoans and the diverse body forms that are found among them.

32.2

What Features Distinguish the Major Groups of Lophotrochozoans?

Lophotrochozoans come in a variety of sizes and shapes, ranging from relatively simple animals with a blind gut (that is, a gut with only one opening) and no internal transport system to animals with a complete gut (having separate entrance and exit openings) and a complex internal transport system. They include some species-rich groups, such as flatworms, annelids, and mollusks. A number of these groups have wormlike bodies, but the lophotrochozoans encompass a wide variety of morphologies, including a few groups with external shells. Some lophotrochozoan groups have only recently been discovered by biologists.

Most bryozoans and entoprocts live in colonies

Most of the 5,500 species of **bryozoans** (“moss animals”) and 170 species of **entoprocts** (meaning “anus inside”) are colonial animals that live in a “house” made of material secreted by the external body wall. The colonial species are sessile, but the few solitary species can slowly move around in their environment. Almost all bryozoans and entoprocts are marine, although a few species occur in fresh or brackish water.

A bryozoan colony consists of many small (1–2 mm) individuals connected by strands of tissue along which nutrients

can be moved (see Figure 31.12). Bryozoan colonies can grow to contain more than 2 million individuals, all stemming from the asexual reproduction of the colony's founder. Rocks in coastal regions in many parts of the world are covered with luxuriant growths of bryozoans. Some bryozoans create miniature reefs in shallow waters. In some species, the individual colony members are differentially specialized for feeding, reproduction, defense, or support. Individual bryozoans in a colony are able to oscillate their lophophore to increase contact with prey. They can also retract it into their “house” (see Figure 32.2).

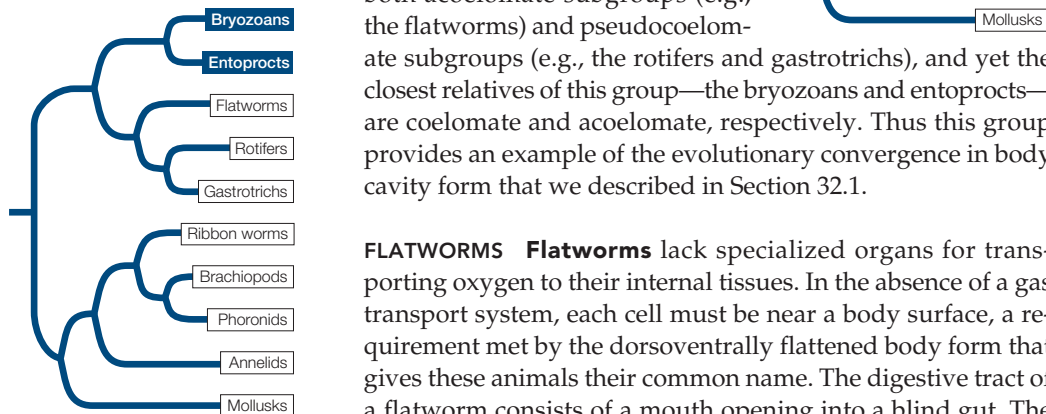

Bryozoans can reproduce sexually by releasing sperm into the water, which carries the sperm to other individuals. Eggs are fertilized internally; developing embryos are brooded before they exit as larvae to seek suitable sites for attachment to the substrate. Entoprocts can also reproduce both sexually and asexually. Some species of entoprocts release unfertilized eggs into the water for fertilization, whereas other species brood their developing young as bryozoans do.

Bryozoans and entoprocts differ in the placement of the anus. In bryozoans, the anus is located outside the ring of tentacles that make up the lophophore, whereas the anus of entoprocts is located in the center of this ring. The lophophores of the two groups also function differently: food particles are carried from the tips to the bases of the tentacles in bryozoans, but from the bases to the tips of the tentacles in entoprocts. Entoprocts lack a coelom, whereas bryozoans have a three-part coelom.

Flatworms, rotifers, and gastrotrichs are structurally diverse relatives

Flatworms, rotifers, gastrotrichs, and their close relatives are a structurally diverse group of organisms whose relationships to one another has been hypothesized only recently. If recent genomic studies prove correct, this monophyletic lophotrochozoan group includes both acoelomate subgroups (e.g., the flatworms) and pseudocoelomate subgroups (e.g., the rotifers and gastrotrichs), and yet the closest relatives of this group—the bryozoans and entoprocts—are coelomate and acoelomate, respectively. Thus this group provides an example of the evolutionary convergence in body cavity form that we described in Section 32.1.

FLATWORMS Flatworms lack specialized organs for transporting oxygen to their internal tissues. In the absence of a gas transport system, each cell must be near a body surface, a requirement met by the dorsoventrally flattened body form that gives these animals their common name. The digestive tract of a flatworm consists of a mouth opening into a blind gut. The gut is often highly branched, forming intricate patterns that increase the surface area available for the absorption of nutrients. Some small free-living flatworms are cephalized, with a

(A) *Eurylepta californica*, a free-living flatworm

(B) Diagram of a typical parasitic flatworm

32.6 Flatworms Include Both Parasites and Free-Living Forms (A) Some flatworm species, such as this Pacific marine flatworm, are free-living. (B) The fluke diagrammed here lives endoparasitically in the gut of sea urchins and is typical of endoparasitic flatworms. Because their hosts provide all the nutrition they need, these internal parasites do not require elaborate feeding or digestive organs and can devote most of their bodies to reproduction.

head bearing chemoreceptor organs, two simple eyes, and a tiny brain composed of anterior thickenings of the longitudinal nerve cords. Free-living flatworms glide over surfaces, powered by broad bands of cilia (**Figure 32.6A**).

Although many flatworms are free-living, most flatworm species are parasites. Of the parasitic species, most are endoparasites. There are also flatworms that feed externally on animal tissues (living or dead), and some graze on plants. A likely evolutionary transition was from feeding on dead organisms to feeding on the body surfaces of dying hosts to invading and consuming parts of healthy hosts.

Most of the 30,000 species of living flatworms are tapeworms and flukes; members of these two groups are endoparasites, particularly of vertebrates (**Figure 32.6B**). Because they absorb digested food from the digestive tracts of their hosts, many endoparasitic flatworms lack digestive tracts of their own. Some cause serious human diseases, such as schistosomiasis, which is common in parts of Asia, Africa, and South America. The species that causes this devastating disease has a complex life cycle involving both freshwater snails and mammals as hosts. Members of another flatworm group, the monogeneans, are ectoparasites of fishes and other aquatic vertebrates. The turbellarians include most of the free-living species.

ROTIFERS Most species of **rotifers** are tiny (50–500 μm long)—smaller than some ciliate protists—but they have specialized internal organs (**Figure 32.7A and B**). A complete gut passes from an anterior mouth to a posterior anus; the body cavity is a pseudocoel that functions as a hydrostatic skeleton. Rotifers typically propel themselves through the water by means of rapidly beating cilia rather than by muscular contraction.

The most distinctive organ of rotifers is a conspicuous ciliated organ called the corona, which surmounts the head of many species. Coordinated beating of the cilia sweeps particles

of organic matter from the water into the animal's mouth and down to a complicated structure called the mastax, in which food is ground into small pieces. By contracting muscles around the pseudocoel, a few rotifer species that prey on protists and small animals can protrude the mastax through the mouth and seize small objects with it.

Go to Media Clip 32.3
Rotifer Feeding
Life10e.com/mc32.3

Most of the known species of rotifers live in fresh water. Some species rest on the surfaces of mosses or lichens in a desiccated, inactive state until it rains. When rain falls, they absorb water and become mobile, feeding in the films of water that temporarily cover the plants. Most rotifers live no longer than a few weeks.

Both males and females are found in some species of rotifers, but only females are known among the bdelloid rotifers (the b in “bdelloid” is silent). Biologists have concluded that the bdelloid rotifers may have existed for tens of millions of years without regular sexual reproduction. Lack of genetic recombination generally leads to the buildup of deleterious mutations, so long-term asexual reproduction typically leads to extinction (see Section 21.4). Recent studies, however, have indicated that bdelloid rotifers may avoid this problem by picking up fragments of genes from their environment during the desiccation–rehydration cycle, which allows genetic recombination among individuals in the absence of direct sexual exchange.

A few highly reduced lineages appear to have descended from the free-living rotifers. The spiny-headed worms are parasites with complex life cycles, often parasitizing several animal hosts (**Figure 32.7C**). The jaw worms are tiny marine organisms that glide between sand grains in shallow marine environments. Although spiny-headed worms and jaw worms are

32.7 Rotifers and Gastrotrichs (A) The rotifer diagrammed here reflects the general structure of many rotifers. (B) A micrograph reveals the internal complexity of the microscopic rotifers. (C) Spiny-headed worms are parasitic rotifer relatives. The spines of the proboscis anchor the animal to the organs of its host. (D) Gastrotrichs superficially resemble rotifers but have flattened ventral surfaces covered with cilia, as flatworms do.

structurally quite distinct, molecular analyses have revealed that both groups are essentially highly modified rotifers.

GASTROTRICHS The 800 species of **gastrotrichs** (also called “hairy backs”) are abundant, tiny (0.05–3 mm) animals that live in marine sediments, in fresh waters, and in the water films that surround grains of soil. Their transparent bodies have a flat ventral surface that is covered with cilia (Figure 32.7D). Most species are simultaneous hermaphrodites, with both male and female reproductive organs, although the male organs have been greatly reduced or lost in some species that reproduce asexually.

Ribbon worms have a long, protrusible feeding organ

Ribbon worms (nemerteans) have simple nervous and excretory systems similar to those of flatworms. Unlike flatworms, however, they have a complete digestive tract with a mouth at one end and an anus at the other. Small ribbon worms move slowly by beating their cilia. Larger ones employ waves of muscle contraction to move over the surface of sediments or to burrow into them.

Within the body of nearly all of the 1,200 species of ribbon worms is a fluid-filled cavity called the rhynchocoel, within which lies a hollow, muscular **proboscis**. The proboscis, which is the worm’s feeding organ, may extend much of the length

of the body. Contraction of the muscles surrounding the rhynchocoel causes the proboscis to evert explosively through an anterior pore (Figure 32.8A). The proboscis may be armed with sharp stylets that pierce prey and discharge paralysis-causing toxins into the wound.

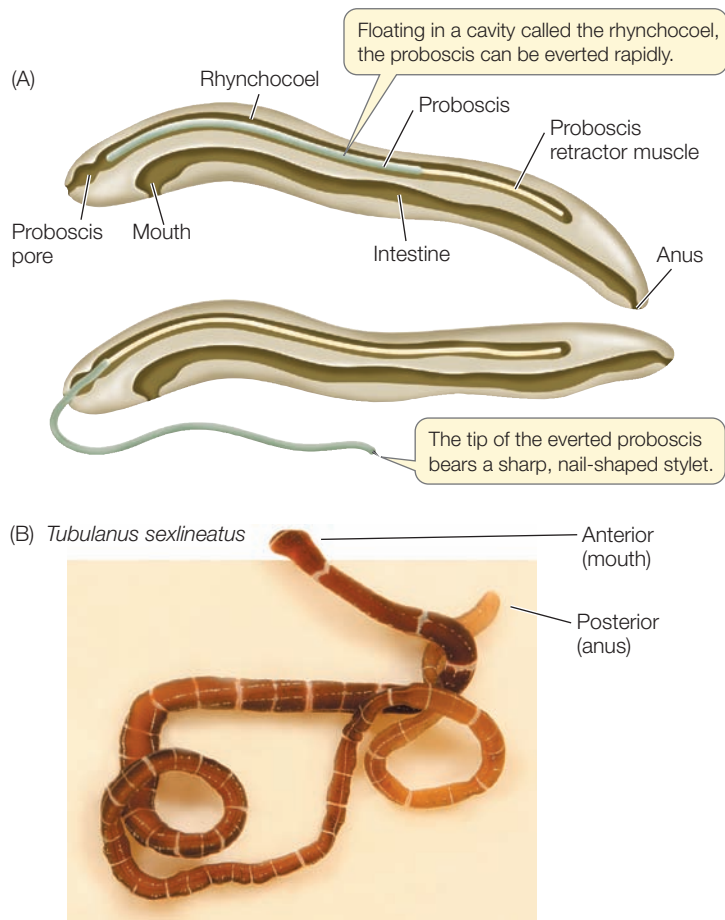

Go to Media Clip 32.4
Explosive Extrusion of Ribbon Worm Proboscis
Life10e.com/mc32.4

Most ribbon worm species are marine, although there are species that live in fresh water or on land. Most species are less than 20 centimeters long, but individuals of some species reach 20 meters or more. Some genera feature species that are conspicuous and brightly colored (Figure 32.8B). Recent molecular analyses suggest that ribbon worms may be most closely related to the brachiopods and phoronids.

Brachiopods and phoronids use lophophores to extract food from the water

Recall that the bryozoans and entoprocts use a lophophore to feed. Brachiopods and phoronids also feed using a lophophore, but this structure may have evolved separately in these groups. Although neither the brachiopods nor the phoronids are represented by many living species, the brachiopods (which have hard external shells and thus leave an excellent

32.8 Ribbon Worms (A) The proboscis is the ribbon worm's feeding organ. (B) This large marine nemertean is found in harbors and bays along the Pacific Coast of North America. Its proboscis is not everted in this photograph.

fossil record) are known to have been much more abundant in the past.

BRACHIOPODS **Brachiopods** (lampshells) are solitary marine animals. They have a rigid shell that is divided into two parts connected by a ligament (Figure 32.9). The two halves can be pulled shut to protect the soft body. Brachiopods superficially resemble bivalve mollusks, but shells have evolved independently in the two groups. The two halves of the brachiopod shell are dorsal and ventral, rather than lateral as in bivalves. The lophophore is located within the shell. The beating of cilia on the lophophore draws water into the slightly opened shell. Food is trapped in the lophophore and directed to a ridge, along which it is transferred to the mouth.

Most brachiopods are 4 to 6 centimeters long. They live attached to a solid substrate or embedded in soft sediments. Most species are attached by means of a short, flexible stalk that holds the animal above the substrate. Gases are exchanged across body surfaces, especially the tentacles of the lophophore. Most brachiopods release their gametes into the water, where they are fertilized. The larvae remain among the plankton for only a few days before they settle and develop into adults.

Laqueus sp.

32.9 A Brachiopod's Lophophore The lophophore of this North Pacific brachiopod can be seen between the valves of its shell.

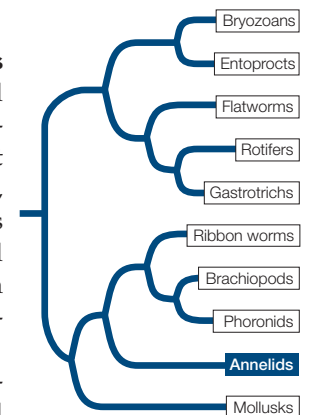

Brachiopods reached their peak abundance and diversity in Paleozoic and Mesozoic times. More than 26,000 fossil species have been described. Only about 450 species survive, but they remain common in some marine environments.

PHORONIDS The ten known species of **phoronids** are small (5–25 cm long), sessile worms that live in muddy or sandy sediments or attached to rocky substrates. Phoronids are found in marine waters from the intertidal zone to about 400 meters deep. They secrete tubes made of chitin, within which they live, and have a U-shaped gut with the anus located outside the lophophore (Figure 32.10). Their cilia drive water into the top of the lophophore, and the water exits through the narrow spaces between the tentacles. Suspended food particles are caught and transported to the mouth by ciliary action. Some species release eggs into the water, where they are fertilized, but other species produce large eggs that are fertilized internally and retained in the parent's body, where they are brooded until they hatch.

Annelids have segmented bodies

The wormlike bodies of **annelids** are clearly segmented. As described in Section 31.2, segmentation allows an animal to move different parts of its body independently, giving it much better control of its movement. The earliest segmented worms, preserved as fossils from the middle Cambrian, were burrowing marine annelids.

In most large annelids, the coelom in each segment is isolated from those in other segments (Figure 32.11). A separate nerve center called a ganglion (plural ganglia) controls each segment; nerve cords that connect the ganglia coordinate their

32.10 Phoronids (A) The tentacles of this phoronid's lophophore form a spiral. (B) The phoronid gut is U-shaped, as seen in this generalized diagram.

functioning. Most annelids lack a rigid external protective covering; instead they have a thin, permeable body wall that serves as a general surface for gas exchange. Most annelids are thus restricted to moist environments because they lose body water rapidly in dry air. The approximately 19,000 described species live in marine, freshwater, and moist terrestrial environments.

POLYCHAETES More than half of all annelid species are commonly known as **polychaetes** ("many hairs"), although this is a descriptive term rather than the name of a single clade. Recent molecular studies indicate that polychaetes are paraphyletic with respect to the remaining annelids. Most polychaetes are marine, and many live in burrows in soft sediments. Most of them have one or more pairs of eyes and one or more pairs of tentacles, with which they capture prey or filter food from the surrounding water, at the anterior end of the body (Figure 32.12A; see also Figure 31.6A). In some species, the body wall of most segments extends laterally as a series of thin outgrowths called parapodia. The parapodia function in gas exchange, and some species use them to move. Stiff bristles called setae protrude from each parapodium, forming temporary contact with

the substrate and preventing the animal from slipping backward when its muscles contract.

Members of one polychaete clade, the **pogonophorans**, secrete tubes made of chitin and other substances, in which they live (Figure 32.12B). Pogonophorans have lost their digestive tract (they have no mouth or gut). So how do they obtain nutrition? Part of the answer is that pogonophorans can take up dissolved organic matter directly from the sediments in which they live or from the surrounding water. Much of their nutrition, however, is provided by endosymbiotic bacteria that the pogonophorans house in a specialized organ known as the trophosome. These bacteria oxidize hydrogen sulfide and other sulfur-containing compounds, fixing carbon from methane in the process. Uptake of the hydrogen sulfide, methane, and oxygen used by the bacteria is facilitated by hemoglobin in the pogonophorans' tentacles. It is this hemoglobin that gives the tentacles their red coloration.

Pogonophorans were not discovered until early in the twentieth century, when the first species were discovered on the seafloor at depths of up to a few hundred meters. In recent decades, deep-sea explorers have found them living many thousands of meters below the ocean surface. In these deep oceanic sediments, they may reach densities of many thousands per

32.11 Annelids Have Many Body Segments The segmented structure of annelids such as this earthworm is apparent both externally and internally. Many organs are repeated serially.

(A) *Spirographis spallanzanii*(B) *Riftia* sp.(C) *Lumbricus terrestris*(D) *Hirudo medicinalis*

32.12 Diversity among the Annelids (A) “Fan worms” or “feather duster worms” are sessile marine polychaetes that grow in masses, filtering food from the water with their tentacles. This individual has been removed from its chitinous tube. (B) Pogonophorans live around hydrothermal vents deep in the ocean. Their tentacles can be seen protruding from their chitinous tubes. (C) Earthworms, like all oligochaetes, are hermaphroditic; when they copulate, each individual donates and receives sperm. (D) The medicinal leech has been a tool of physicians and healers for centuries. Even today, leeches have uses in clinical practice.

square meter. About 160 species have been described. The largest and most remarkable pogonophorans are 2 meters or more in length and live near deep-sea hydrothermal vents—volcanic openings in the seafloor through which hot, sulfide-rich water pours. The methane and hydrogen sulfide from these vents provide the raw materials for carbon fixation by the pogonophorans’ endosymbiotic bacteria.

CLITELLATES The approximately 3,000 described species of **clitellates**, which form a well-supported clade within the annelids, are found in freshwater, marine, and terrestrial environments. The clitellates appear to be phylogenetically nested among various groups of polychaetes, although the exact relationships are not yet clear. There are two major groups of clitellates, the oligochaetes and the leeches.

Oligochaetes (“few hairs”) have no parapodia, eyes, or anterior tentacles, and they have only four pairs of setae bundles per segment. Earthworms—the most familiar oligochaetes—burrow in and ingest soil, from which they extract food particles. All oligochaetes are hermaphroditic. Sperm are exchanged simultaneously between two copulating individuals (**Figure 32.12C**). Eggs and sperm are deposited in a cocoon outside the adult’s body. Fertilization occurs within the cocoon after it

is shed, and when development is complete, miniature worms emerge and immediately begin independent life.

Leeches, like oligochaetes, lack parapodia and tentacles. The coelom of leeches is not divided into compartments; the coelomic space is largely filled with undifferentiated tissue. Groups of segments at each end of the body are modified to form suckers, which serve as temporary anchors that aid the leech in its movement. With its posterior sucker attached to a substrate, the leech extends its body by contracting its circular muscles. The anterior sucker is then attached, the posterior one detached, and the leech shortens itself by contracting its longitudinal muscles. Leeches live in freshwater or terrestrial habitats.

Most leeches are ectoparasites that feed by making an incision in a host, from which blood flows. A leech can ingest so much blood in a single feeding that its body may enlarge severalfold. The leech secretes an anticoagulant into the wound that keeps the host’s blood flowing. For centuries, medical practitioners employed leeches to draw blood to treat diseases they believed were caused by an excess of blood or by “bad blood.” Although most leeching practices (such as inserting a leech in a person’s throat to alleviate swollen tonsils) have been abandoned, *Hirudo medicinalis* (the medicinal leech; **Figure 32.12D**) is used today to reduce fluid pressure and prevent

blood clotting in damaged tissues, to eliminate pools of coagulated blood, and to prevent scarring. The anticoagulants of certain other leech species also contain anesthetics and blood vessel dilators and are being studied for possible medical uses.

Mollusks have undergone a dramatic evolutionary radiation

Mollusks are the most diverse group of lophotrochozoans, both in numbers of species and in the environments they occupy. Although the major groups of mollusks differ dramatically in morphology, they all share the same three major body components: a foot, a visceral mass, and a mantle (**Figure 32.13A**).

- The molluscan **foot** is a large, muscular structure that originally was both an organ of locomotion and a support for the internal organs. In squids and octopuses, the foot has been modified to form arms and tentacles borne on a head with complex sensory organs. In other groups, such as clams, the foot is a burrowing organ. In some groups the foot is greatly reduced.
- The heart and the digestive, excretory, and reproductive organs are concentrated in a centralized, internal **visceral mass**.
- The **mantle** is a fold of tissue that covers the organs of the visceral mass. The mantle secretes the hard, calcareous shell that is typical of many mollusks.

In most mollusks, the mantle extends beyond the visceral mass to form a mantle cavity. Within this cavity lie gills that are used for gas exchange. When cilia on the gills beat, they create a current of water. The tissue of the gills, which is highly vascularized (contains many blood vessels), takes up oxygen from the water and releases carbon dioxide. Many mollusk species use their gills as filter-feeding devices, whereas others feed using a rasping structure known as a **radula** to scrape algae from rocks. In some mollusks, such as the marine cone snails, the radula has been modified into a drill or poison dart.

In all mollusks except cephalopods, the blood vessels do not form a closed system. Blood and other fluids empty into a large, fluid-filled hemocoel, through which fluids move and deliver oxygen to the internal organs. Eventually the fluids re-enter the blood vessels and are moved by a heart.

Monoplacophorans were the most abundant mollusks during the Cambrian period, 500 million years ago, but only a few species survive today. In monoplacophorans, in contrast to all other living mollusks, the gas exchange organs, muscles, and excretory pores are repeated over the length of the body.

(C) Gastropods

(D) Bivalves

(E) Cephalopods

32.13 Organization and Diversity of Molluscan Bodies (A) The major molluscan groups display different variations on a body plan that includes three major components: a foot, a visceral mass of internal organs, and a mantle. In many species, the mantle secretes a calcareous shell. (B) Chitons have eight overlapping calcareous plates surrounded by a girdle. (C) Most gastropods have a single dorsal shell, into which they can retreat for protection. (D) Bivalves get their name from their two hinged shells, which can be tightly closed. (E) Cephalopods are active predators; they use their arms and tentacles to capture prey. This cuttlefish has an internal shell but no external shell.

(A) *Flabellina iodinea*(B) *Ariolimax columbianus*

32.14 Mollusks in Some Groups Have Lost Their Shells (A) Nudi-branches (“naked gills”), also called sea slugs, are shell-less gastropods. This species is brightly colored, alerting potential predators of its toxicity. (B) Banana slugs are terrestrial, shell-less gastropods that feed on decomposing vegetation on the damp forest floor. (C) Octopuses have neither an external nor an internal shell, which allows these cephalopods to squeeze through tight spaces.

allow the animal to control the water content of the mantle cavity (**Figure 32.13E**). The modification of the mantle into a device for forcibly ejecting water from the cavity through the siphon enables these animals to move rapidly through the water by “jet propulsion.” With their greatly enhanced mobility, cephalopods became the major predators in the open waters of the Devonian oceans. They remain important marine predators today.

As is typical of active, rapidly moving predators, cephalopods have a head with complex sensory organs—most notably eyes that are comparable to those of vertebrates in their ability to resolve images (see Figure 46.14). The head is closely associated with a large, branched foot that bears the arms and/or tentacles and a siphon. Arms are distinguished by the presence of suckers along most of their length. Tentacles, in contrast, have suckers only near the tips or lack suckers altogether. Octopuses typically have eight arms and no tentacles, whereas squids and cuttlefishes have eight arms plus two tentacles. Cephalopods use their arms and tentacles to capture and subdue prey; octopuses also use their arms to move over the substrate. The large, muscular mantle provides a solid external supporting structure. The gills hang in the mantle cavity.

Many early cephalopods had an external chambered shell divided by partitions. The only surviving cephalopods with such shells are the nautilus (genus *Nautilus*). The chambers inside nautilus shells are connected by a strand of tissue that runs through ducts in the partitions. Blood in this tissue carries water *from* the chambers and gases *into* the chambers, thus providing buoyancy. Most cephalopods retain an internal shell that functions for internal support and, in some species, is also chambered and buoyant. Octopuses have completely lost their shells, which allows them to compress their bodies through very small openings.

RECAP 32.2

Lophotrochozoans include animals with diverse body types. Wormlike forms include some flatworms, ribbon worms, phoronids, and annelids. There has been convergent evolution of lophophores (in bryozoans and entoprocts versus brachiopods and phoronids) and of external two-part shell coverings (in brachiopods versus bivalve mollusks).

- How do flatworms survive without an internal transport system? **See pp. 656–657 and Figure 32.6**
- Why are most annelids restricted to moist environments? **See p. 660**
- Briefly describe how the basic body organization of mollusks has been modified to yield a wide variety of body forms. **See pp. 662–664 and Figure 32.13**

The second of the two major protostome clades, the ecdysozoans, contains the vast majority of Earth’s animal species. What evolutionary innovations led to this massive diversity?

32.3

What Features Distinguish the Major Groups of Ecdysozoans?

Many ecdysozoans are wormlike in form, although others—the arthropods, onychophorans, and tardigrades—have limbs. In this section we will look at the two clades of wormlike ecdysozoans: the priapulids, kinorhynchs, and loriciferans in one clade and the nematodes and horsehair worms in the other. Section 32.4 will be devoted to the most diverse ecdysozoans—the arthropods and their relatives—and the many forms their appendages take.

Several marine ecdysozoan groups have relatively few species

Members of several species-poor groups of wormlike marine ecdysozoans—the priapulids, kinorhynchs, and loriciferans—have relatively thin cuticles that are molted periodically as the animals grow to full size. In 2004, embryos of a fossil species related to these ecdysozoans were discovered in sediments laid down in China about 500 million years ago. This remarkable discovery shows that the ancestors of these animals developed directly from an egg to the adult form, as most of their modern descendants do.

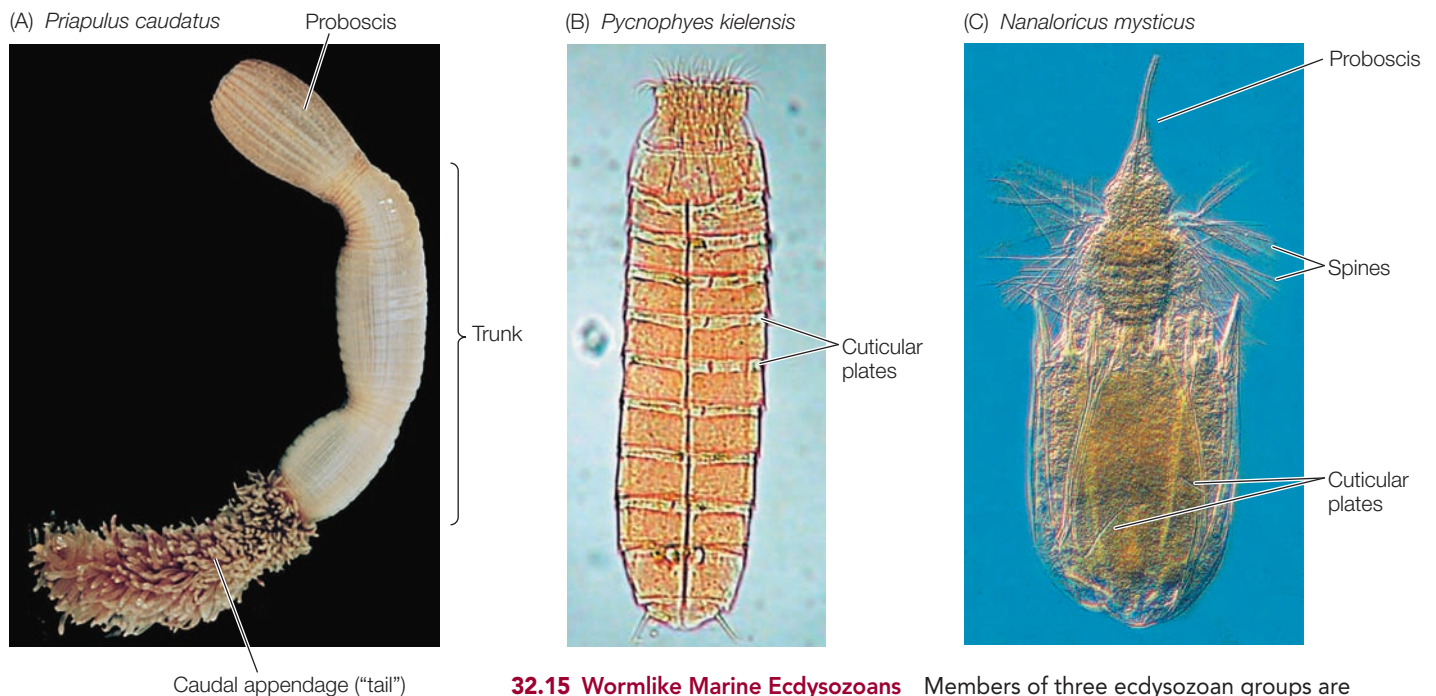

The 20 species of **priapulids** are cylindrical, unsegmented, wormlike animals with a three-part body plan consisting of a

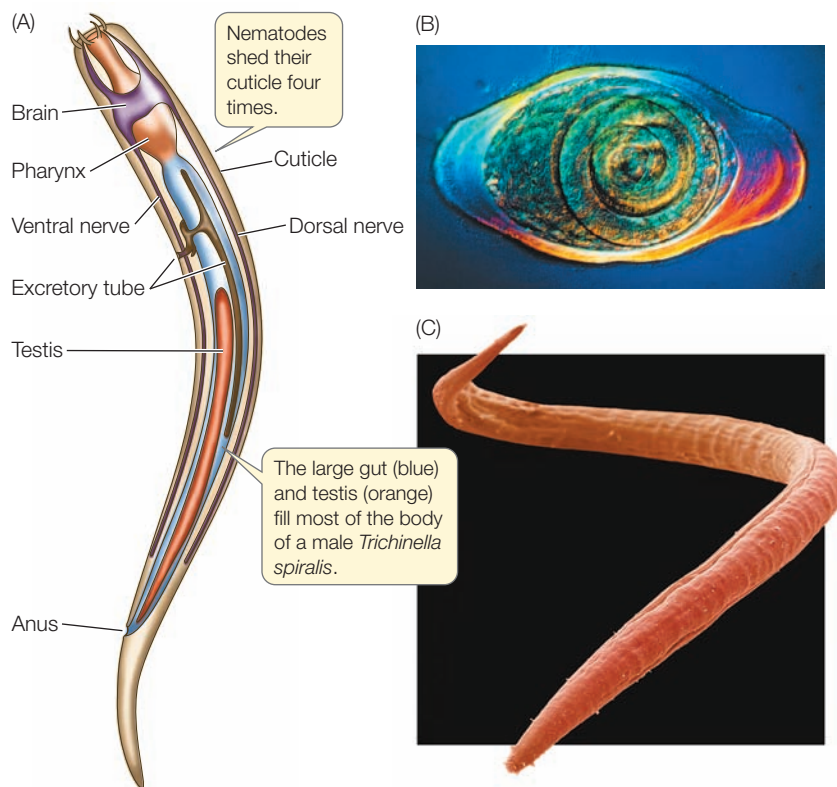

proboscis, trunk, and caudal appendage (“tail”). It should be clear from their appearance why they were named after the Greek fertility god Priapus (**Figure 32.15A**). Priapulids range in length from 0.5 millimeters to 20 centimeters. They live in burrows in fine marine sediments and prey on soft-bodied invertebrates such as polychaetes, which they capture with a toothed, muscular pharynx that they evert through the mouth and then withdraw into the body together with the grasped prey. Fertilization is external, and most species have a larval form that also lives in the mud.

About 180 species of **kinorhynchs** have been described. They live in marine sands and muds and are virtually microscopic; no kinorhynchs are longer than 1 millimeter. Their bodies are divided into 13 segments, each covered with a separate cuticular plate (**Figure 32.15B**). These plates are periodically molted during growth. Kinorhynchs feed by ingesting sediments through a retractable proboscis (the group name means “movable snout”). They then digest the organic material found in the sediment, which may include living algae as well as dead matter. Kinorhynchs have no distinct larval stage; fertilized eggs develop directly into juveniles, which emerge from their egg cases with 11 of the 13 body segments already formed.

Loriciferans are also minute animals less than 1 millimeter long. They were not discovered until 1983. About 100 living species are known to exist, although only about 30 of these have been formally described to date. The body is divided into a head, neck, thorax, and abdomen and is covered by six plates, from which the loriciferans get their name (*Latin lorica*,

32.15 Wormlike Marine Ecdysozoans Members of three ecdysozoan groups are marine bottom-dwellers. (A) Most priapulid species live in burrows on the ocean floor, extending the proboscis to feed. (B) Kinorhynchs are virtually microscopic. The cuticular plates that cover their bodies are molted periodically. (C) Six cuticular plates form a “corset” around the minute loriciferan body.

32.16 Nematodes (A) The body plan of *Trichinella spiralis*, which causes trichinosis, is typical of parasitic nematodes. (B) This polarized light micrograph shows a cyst of *T. spiralis* in the muscle tissue of a host. (C) This free-living nematode lives in freshwater environments.

“corset”). The plates around the base of the neck bear anterior-directed spines of unknown function (Figure 32.15C). Loriciferans live in coarse marine sediments. Little is known about what they eat, but some species apparently eat bacteria.

Nematodes and their relatives are abundant and diverse

Nematodes (roundworms) have a thick, multilayered cuticle that gives their unsegmented body its shape (Figure 32.16). As a nematode grows, it sheds its cuticle four times. Nematodes exchange oxygen and nutrients with their environment through both the cuticle and the gut wall, which is only one cell layer thick. Materials are moved through the gut by rhythmic contraction of a highly muscular pharynx. Nematodes move by contracting their longitudinal muscles.

Nematodes are probably the most abundant and universally distributed of all animal groups. Many nematodes are microscopic; the largest known nematode, which reaches a length of 9 meters, is a parasite in the placentas of sperm whales. About 25,000 species have been described, but the actual number of living species may be more than 1 million. Countless nematodes live as scavengers in the upper layers of the soil, on the bottoms of lakes and streams, and in marine sediments. The topsoil of rich

farmland may contain from 3 to 9 billion nematodes per acre. A single rotting apple may contain as many as 90,000 individuals.

One soil-inhabiting nematode, *Caenorhabditis elegans*, serves as a model organism in the laboratories of geneticists and developmental biologists. It is ideal for such research because it is easy to cultivate, matures in 3 days, and has a fixed number of body cells. Its genome has been completely sequenced.

Many nematodes are predators, feeding on protists and small animals (including other roundworms). Most significant to humans, however, are the many species that parasitize plants and animals. The nematodes that parasitize humans (causing serious diseases such as trichinosis and elephantiasis), domestic animals, and economically important plants have been studied intensively in an effort to find ways of controlling them.

The structure of parasitic nematodes is similar to that of free-living species, but the life cycles of many parasitic species have special stages that facilitate the transfer of individuals among hosts. *Trichinella spiralis*, the species that causes the human disease trichinosis, has a relatively simple life cycle. A person may become infected by eating the flesh of an animal (usually a pig) that has *Trichinella* larvae encysted in its muscles (see Figure 32.16B). The larvae are activated in the person’s digestive tract, emerge from their cysts, and attach to the intestinal wall, where they feed. Later they bore through the intestinal wall and are carried in the bloodstream to muscles, where they form new cysts. If present in great numbers, these cysts can cause severe pain or death.

About 350 species of the unsegmented **horsehair worms** have been described. As their name implies, these animals are extremely thin in diameter; horsehair worms range from a few millimeters up to 1 meter in length. Most adult worms live in fresh water, among leaf litter and algal mats near the edges of streams and ponds. A few species live in damp soil.

Horsehair worm larvae are endoparasites of freshwater crayfishes and of terrestrial and aquatic insects (Figure 32.17). An adult horsehair worm has no mouth, and its gut is greatly reduced and probably nonfunctional. Some species may feed only as larvae, absorbing nutrients from their hosts across the body wall. But other species continue to shed their cuticles and grow after they have left their hosts, suggesting that adult worms may also absorb nutrients from their environment.

RECAP 32.3

Priapulids, kinorhynchs, and loriciferans are relatively small, poorly known groups of wormlike marine ecdysozoans. Nematodes and horsehair worms have unsegmented wormlike bodies. Nematodes are probably the most abundant and universal animal group.

- Describe at least three different ways in which nematodes have a significant impact on humans. **See p. 666**

32.17 Horsehair Worm Larvae Are Parasitic The larva of this horsehair worm (*Paragordius tricuspidatus*) can manipulate its host's behavior. The hatching worm causes the cricket to jump into water, where the worm emerges from the insect's body to continue its life cycle as a free-living adult. The cricket, having delivered its parasitic burden, drowns.

We will next turn to the animals that not only dominate the ecdysozoan clade but also constitute the most diverse group of animals on Earth.

32.4 Why Are Arthropods So Diverse?

Arthropods and their relatives are ecdysozoans with paired appendages. Arthropods are the most diverse group of animals in numbers of species (more than 1.2 million have been described, and many more remain to be discovered). Furthermore, the number of individual arthropods alive at any one time is estimated to be about 10^{18} , or 1 billion billion. Among the animals, only the nematodes are thought to exist in greater numbers.

Several key features have contributed to the success of the arthropods. As we have seen, their muscles are attached to the inside of their rigid exoskeletons. Their bodies are segmented, and each segment has muscles that operate that segment and the jointed appendages attached to it (see Figure 32.4). Jointed appendages permit complex movements, and different appendages are specialized

for different functions. Encasement of the body within a rigid exoskeleton provides the animal with support for walking in the water or on dry land and provides some protection against predators. The waterproofing provided by chitin keeps the animal from dehydrating in dry air.

The four major arthropod groups living today are all species-rich: chelicerates (including the arachnids—spiders, scorpions, mites, and their relatives), myriapods (millipedes and centipedes), crustaceans (including shrimps, crabs, and barnacles), and hexapods (insects and their wingless relatives). The latter three groups are together known as mandibulates.

The jointed appendages of arthropods gave the clade its name, from the Greek words *arthron*, “joint,” and *podos*, “foot”

or “limb.” Arthropods evolved from ancestors with simple, unjointed appendages. The exact forms of those ancestors are unknown, but some arthropod relatives with segmented bodies and unjointed appendages survive today. Before we describe the modern arthropods, we will discuss those arthropod relatives, as well as an early clade that went extinct but left an important fossil record.

Arthropod relatives have fleshy, unjointed appendages

The two living groups most closely related to the arthropods provide us with clues about the likely appearance of ancestral arthropod appendages. **Tardigrades** (water bears) have fleshy, unjointed legs and use their fluid-filled body cavities as hydrostatic skeletons (**Figure 32.18A**). Tardigrades are tiny (0.5–1.5 mm long) and lack both a circulatory system and gas exchange organs. The 1,200 known extant species live in marine sands and on temporary water films on plants. When these films dry out, the animals also lose water and shrink to small, barrel-shaped objects that can survive for at least a decade in

(A) *Echiniscus* sp.

(B) *Macroperipatus torquatus*

32.18 Arthropod Relatives with Unjointed Appendages

(A) Tardigrades (“water bears”) can be abundant on the wet surfaces of mosses and plants and in temporary pools of water. (B) Onychophorans (“velvet worms”) have unjointed legs and use the body cavity as a hydrostatic skeleton. They are sometimes referred to as “living fossils,” meaning they are an ancient group that has changed very little over millennia.

a dormant state. Tardigrades have been found at densities as high as 2 million per square meter of moss.

Until fairly recently, biologists debated whether the **onychophorans** (velvet worms) were more closely related to annelids or to arthropods, but molecular evidence clearly links them to the latter. Indeed, with their soft, fleshy, unjointed, claw-bearing legs and elongate bodies, onychophorans may be similar in appearance to the ancestors of arthropods (**Figure 32.18B**). The 180 species of onychophorans live in leaf litter in humid tropical environments. They have soft, segmented bodies that are covered by a thin, flexible cuticle that contains chitin. Like the tardigrades, they use their fluid-filled body cavities as hydrostatic skeletons. Fertilization is internal, and the large, yolky eggs are brooded within the body of the female.

Jointed appendages appeared in the trilobites

The **trilobites** flourished in Cambrian and Ordovician seas, but they disappeared in the great Permian extinction at the close of the Paleozoic era (251 mya). Because they had heavy exoskeletons that readily fossilized, they left behind an abundant record of their existence (**Figure 32.19**). About 10,000 species have been described.

The trilobites are the earliest known arthropods to have had jointed appendages. The body segmentation and appendages of trilobites followed a relatively simple, repetitive plan, but some of their appendages were modified for different functions. This specialization of appendages is a theme in the continuing evolution of the arthropods.

Chelicerates have pointed, nonchewing mouthparts

In the **chelicerates**, the head bears two pairs of pointed appendages modified to form mouthparts, called chelicerae, that

(A) *Endeis* sp.

(B) *Limulus polyphemus*

32.20 Two Small Chelicerate Groups (A) Although they are not spiders, it is easy to see how sea spiders got their common name. (B) A spawning aggregation of horseshoe crabs. Horseshoe crabs, like the onychophorans (see Figure 32.18B), are an example of “living fossils.”

are used to grasp (rather than chew) prey. Chelicerates typically have a two-part body plan, with anterior segments fused to form a cephalothorax, and rear segments fused to form an abdomen. In some groups, such as mites and ticks, there is no clear distinction between these two body parts. Most chelicerates have four pairs of walking legs. The 114,000 described species are grouped into three major clades: pycnogonids, horseshoe crabs, and arachnids.

The pycnogonids, or sea spiders, make up a poorly known group of about 1,000 marine species (**Figure 32.20A**). Most are small, with leg spans less than 1 cm, but some deep-sea species have leg spans up to 60 cm. A few pycnogonids eat algae, but most are carnivorous, eating a variety of small invertebrates.

There are only four living species of horseshoe crabs, but many close relatives are known from fossils. Horseshoe crabs, which have changed very little morphologically over their long history, have a large horseshoe-shaped covering over most of the body. They are common in shallow waters along the eastern coast of North America and the southern and eastern coasts of Asia, where they scavenge and prey on bottom-dwelling

Cheirurus ingricus

32.19 A Trilobite Fossil The relatively simple, repetitive segments of the now-extinct trilobites are illustrated by a fossil trilobite from the shallow seas of the Ordovician period, some 450 million years ago.

(A) *Poecilotheria metallica*(B) *Pseudouroctonus minimus*(C) *Leiobunum rotundum*(D) *Brevipalpus phoenicis*

32.21 Arachnid Diversity (A) Tarantulas encompass several hundred species of hairy, ground-dwelling spiders, some of which can grow to the size of a dinner plate. Their venomous bite, although painful, is usually not dangerous to humans. (B) Scorpions are nocturnal predators. (C) Harvestmen, also called daddy longlegs, are scavengers. (D) Mites include many free-living species as well as blood-sucking ectoparasites.

animals. Periodically they crawl into the intertidal zone in large numbers to mate and lay eggs (Figure 32.20B).

Arachnids are abundant in terrestrial environments. Most arachnids have a simple life cycle in which miniature adults hatch from internally fertilized eggs and begin independent lives almost immediately. Some arachnids retain their eggs during development and give birth to live young.

The most species-rich and abundant arachnids are the spiders, scorpions, harvestmen, mites, and ticks (Figure 32.21). More than 60,000 described species of mites and ticks live in soil, leaf litter, mosses, and lichens, under bark, and as parasites of plants and animals. Mites are vectors for wheat and rye mosaic viruses; they cause mange in domestic animals and skin irritation in humans.

Spiders, of which about 50,000 species have been described, are important terrestrial predators with hollow chelicerae, which they use to inject venom into their prey. Some have excellent vision that enables them to chase and seize their prey.

Others spin elaborate webs made of protein threads in which they snare prey. The threads are produced by modified abdominal appendages connected to internal glands that secrete the proteins, which solidify on contact with air. The webs of different groups of spiders are strikingly varied, and this variation enables the spiders to position their snares in many different environments for many different types of prey.

Mandibles and antennae characterize the remaining arthropod groups

The remaining three arthropod groups—the myriapods, crustaceans, and hexapods—have mouthparts that are mandibles, rather than chelicerae, so they are collectively called **mandibulates**. Mandibles can be used for chewing as well as for biting and holding food. Another distinctive characteristic of the mandibulates is the presence of sensory antennae on the head.

MYRIAPODS The **myriapods** comprise the centipedes, millipedes, and their close relatives. Centipedes and millipedes have a well-formed head that bears the mandibles and antennae characteristic of mandibulates. Their distinguishing feature is a long, flexible, segmented trunk that bears many pairs of legs. Centipedes, which have one pair of legs per segment (Figure 32.22A), prey on insects and other small animals. In

32.22 Myriapods (A) Centipedes have modified appendages that function as poisonous fangs for capturing active prey. They have one pair of legs per segment. (B) Millipedes are scavengers and plant eaters; they have smaller jaws and legs than centipedes do, and they have two pairs of legs per segment.

(A) *Scolopendra hardwicki*(B) *Sigmoria trimaculata*

millipedes, two adjacent segments are fused so that each fused segment has two pairs of legs (**Figure 32.22B**). Millipedes scavenge and eat plants. More than 3,000 species of centipedes and 9,000 species of millipedes have been described; many more species probably remain unknown. Although most myriapods are less than a few centimeters long, some tropical species are ten times that size.

CRUSTACEANS Crustaceans are the dominant marine arthropods today, and they are also common in fresh water and some terrestrial environments. The most familiar crustaceans are the shrimps, lobsters, crayfishes, and crabs (all decapods; **Figure 32.23A**) and the sow bugs (isopods; **Figure 32.23B**). Additional species-rich groups include the amphipods, ostracods, branchiopods (**Figure 32.23C**), and copepods (**Figure 32.23D**), all of which are found in freshwater and marine environments.

Barnacles are unusual crustaceans that are sessile as adults (**Figure 32.23E**). Adult barnacles look more like mollusks than like other crustaceans, but as the zoologist Louis Agassiz

(A) *Randallia ornata*(C) *Triops longicaudatus*(B) *Armadillidium vulgare*

(D) Cyclopoid copepod

(E) *Lepas pectinata*

32.23 Crustacean Diversity (A) This decapod crustacean, a purple sand crab, is also called a “globe crab” based on its body shape. (B) This pillbug, a terrestrial isopod, can roll into a tight ball when threatened. (C) This tadpole shrimp, a branchiopod, is common in seasonal pools of the southwestern United States. (D) This minute copepod from a freshwater pond is brooding eggs. (E) Gooseneck barnacles attach to a substrate by their muscular stalks and feed by protruding and retracting their feeding appendages.

32.24 Crustacean Body Plan The bodies of crustaceans are divided into three regions: the head, thorax, and abdomen. Each body region bears specialized appendages. A shell-like carapace covers the head and thorax.

remarked more than a century ago, a barnacle is “nothing more than a little shrimp-like animal, standing on its head in a limestone house and kicking food into its mouth.”

Go to Media Clip 32.7
Barnacles Feeding
Life10e.com/mc32.7

Most of the 67,000 described species of crustaceans have a body that is divided into three regions: head, thorax, and abdomen (**Figure 32.24**). The segments of the head are fused together, and the head bears five pairs of appendages. Each of the multiple thoracic and abdominal segments usually bears one pair of appendages. The appendages on different parts of the body are specialized for different functions, such as gas exchange, chewing, capturing food, sensing, walking, and swimming. In many species, a fold of the exoskeleton, the carapace, extends dorsally and laterally back from the head to cover and protect some of the other segments.

The fertilized eggs of most crustacean species are attached to the outside of the female’s body, where they remain during their early development (see **Figure 32.23D**). At hatching, the young of some species are released as larvae; those of other species are released as juveniles that are similar in form to the adults. Still other species release eggs into the water or attach them to an object in the environment.

More than half of all described species are insects

During the Devonian period, more than 400 million years ago, some mandibulates colonized terrestrial environments. Of the several groups (including some crustacean isopods and decapods) that successfully colonized the land, none is more prominent today than the six-legged **hexapods**, which include the **insects** and their wingless relatives.

The wingless relatives of the insects—the springtails, two-pronged bristletails, and proturans—are probably the most similar of living forms to insect ancestors (**Figure 32.25**). These hexapods have a simple life cycle: they hatch from eggs as miniature adults. They differ from insects in having internal mouthparts. Springtails can be extremely abundant (up to 200,000 per m²) in soil, leaf litter, and on vegetation and are the most abundant hexapods in the world in terms of number of individuals (as opposed to number of species).

As we saw at the opening of this chapter, more than 1 million of the 1.8 million described living species on Earth are insects. Like crustaceans, insects have a body with three regions: head, thorax, and abdomen. They have a single pair of antennae on the head and three pairs of legs attached to the thorax. In most groups of insects, the thorax also bears two pairs of wings. Unlike other arthropods, insects have no appendages growing from their abdominal segments (**Figure 32.26**). Insects are distinguished from springtails and other hexapods by their external mouthparts and by antennae that contain a motion-sensitive receptor called Johnston’s organ. In addition, insects have a derived mechanism for gas exchange in air: a system of air sacs and tubular channels called tracheae (singular trachea) that extend from external openings called spiracles inward to tissues throughout the body (see **Figure 49.4**).

Table 32.2 lists the major insect groups. Two groups—the jumping bristletails and silverfish—are wingless and have simple life cycles, like the springtails and other non-insect hexapods. The remaining groups are all pterygote insects. **Pterygotes** have two pairs of wings, except in some groups in which one or both pairs of wings have been secondarily lost. These secondarily wingless groups include the parasitic lice and fleas, some beetles, and the worker individuals of many ant species.

Hatchling pterygotes do not look like adults; they undergo substantial changes at each molt. The immature stages of insects between molts are called **instars**. A substantial change that

Tomocerus minor

32.25 Wingless Hexapods The wingless hexapods, such as this springtail, have a simple life cycle. They hatch looking like miniature adults, then grow by successive molts of the cuticle.

32.26 Insect Body Plan Like those of crustaceans, the bodies of insects are divided into three regions: head, thorax, and abdomen. In insects, however, the thorax bears three pairs of legs and, in most groups, two pairs of wings. Unlike other arthropods, insects have no appendages growing from their abdominal segments.

occurs between one developmental stage and another is called **metamorphosis**. If the changes between stages are gradual, an insect is said to have **incomplete metamorphosis**. If the change between at least some stages is dramatic, an insect is said to have **complete metamorphosis**. In many insects with complete metamorphosis, different stages are specialized for different functions and use different food sources. In many species the larvae are specialized for feeding and growing, whereas the adults are specialized for reproduction and dispersal.

Go to Media Clip 32.8
Complete Metamorphosis
Life10e.com/mc32.8

The adults of most flying insects have two pairs of stiff, membranous wings attached to the thorax. True flies, however, have one pair of wings and a pair of stabilizers called halteres. In winged beetles, one pair of wings—the forewings—forms heavy, hardened wing covers.

Two groups of pterygotes, the mayflies and dragonflies (**Figure 32.27A**), cannot fold their wings against their bodies. This is the ancestral condition for pterygote insects, and the mayflies and dragonflies are not closely related to one another. Members of both groups have predatory or herbivorous aquatic larvae that transform into flying adults after they crawl out of the water. Dragonflies (and their relatives the damselflies) are active predators as adults. In contrast, adult mayflies lack functional digestive tracts. Mayflies live only about a day, just long enough to mate and lay eggs.

All other pterygote insects—the **neopterans**—can tuck their wings out of the way upon landing and crawl into crevices and other tight places. Some neopteran groups undergo incomplete metamorphosis, so hatchlings of these insects are sufficiently

TABLE 32.2
The Major Insect Groups^a

Group	Approximate Number of Described Living Species
Jumping bristletails (Archaeognatha)	515
Silverfish (Thysanura)	560
PTERYGOTE (WINGED) INSECTS (PTERYGOTA)	
Mayflies (Ephemeroptera)	3,250
Dragonflies and damselflies (Odonata)	5,900
Neopterans (Neoptera)^b	
Ice-crawlers (Grylloblattodea)	35
Gladiators (Mantophasmatodea)	15
Stoneflies (Plecoptera)	3,750
Webspinners (Embioptera)	465
Angel insects (Zoraptera)	40
Earwigs (Dermaptera)	2,000
Grasshoppers and crickets (Orthoptera)	24,000
Stick insects (Phasmida)	3,000
Cockroaches (Blattodea)	4,650
Termites (Isoptera)	2,700
Mantids (Mantodea)	2,400
Booklice and barklice (Psocoptera)	5,750
Thrips (Thysanoptera)	6,000
Lice (Phthiraptera)	5,100
True bugs, cicadas, aphids, leafhoppers (Hemiptera)	104,000
Holometabolous neopterans (Holometabola)^c	
Ants, bees, wasps (Hymenoptera)	117,000
Beetles (Coleoptera)	388,000
Strepsipterans (Strepsiptera)	610
Lacewings, ant lions, and mantidflies (Neuroptera)	5,900
Dobsonflies, alderflies, and fishflies (Megaloptera)	350
Snakeflies (Raphidioptera)	250
Scorpionflies (Mecoptera)	760
Fleas (Siphonaptera)	2,100
True flies (Diptera)	155,000
Caddisflies (Trichoptera)	14,300
Butterflies and moths (Lepidoptera)	158,000

^aThe hexapod relatives of insects include the springtails (Collembola; 3,000 spp.), two-pronged bristletails (Diplura; 600 spp.), and proturans (Protura; 10 spp.). All are wingless and have internal mouthparts.

^bNeopteran insects can tuck their wings close to their bodies.

^cHolometabolous insects are neopterans that undergo complete metamorphosis.

WORKING WITH DATA:

How Many Species of Insects Exist on Earth?

Original Papers

Erwin, T. L. 1988. The tropical forest canopy: The heart of biotic diversity. In E. O. Wilson, ed., *Biodiversity*, 123–129. National Academy Press, Washington, D.C.,

Erwin, T. L. 1997. Biodiversity at its utmost: Tropical forest beetles. In M. L. Reaka-Kudla, D. E. Wilson, and E. O. Wilson, eds., *Biodiversity II*, 27–40. Joseph Henry Press, Washington, D.C.

Analyze the Data

The data in the table were used by entomologist Terry Erwin to estimate the undescribed diversity of insects. Review the design of Erwin's experiment in the opening story of this chapter. Then use Erwin's data to answer the questions.

QUESTION 1

From the data in the table, estimate the number of insect species in an average hectare of Panamanian forest. Assume that the data for beetles on *L. seemannii* are representative of the other tree species, and that all the species of beetles that are *not* host-specific were collected in the original sample. Remember to sum your estimates of the number of (a) host-specific beetle species in the forest canopy; (b) non-host-specific beetle species in the forest canopy; (c) beetle species on the forest floor; and (d) species of all insects other than beetles.

QUESTION 2

There are about 50,000 species of tropical forest trees. Assume that the data for beetles on *L. seemannii* are representative of other species of tropical trees and calculate the number of host-specific beetles found on these trees. Add an estimated 1 million species of non-host-specific beetles that are expected across different species of trees (including those in temperate regions). Estimate the number of ground-dwelling beetle species based on the percentage used in Question 1. Now use this information to estimate the number of insect species on Earth, based on the percentage of beetles among all insect species.

Approximate number of beetle species collected from <i>Luehea seemannii</i> trees	1,200
Estimated number of host-specific beetles in this sample	163
Number of tree species per hectare of Panamanian forest	70
Percent of beetle species living in tree canopy (as opposed to ground-dwelling species)	75%
Percent of beetles among all insect species	40%

Go to **BioPortal** for all **WORKING WITH DATA** exercises

similar in form to adults to be recognizable. Examples include the grasshoppers (**Figure 32.27B**), roaches, mantids, stick insects, termites, stoneflies, earwigs, thrips, true bugs (**Figure 32.27C**), aphids, cicadas, and leafhoppers. These groups acquire adult organ systems, such as wings and compound eyes, gradually through several juvenile instars.

More than 80 percent of all insects belong to a subgroup of the neopterans called the **holometabolous** insects (see Table 32.2), which undergo complete metamorphosis (**Figure 32.27D**). The many species of beetles account for almost half of this group (**Figure 32.27E**). Also included are lacewings and their relatives; caddisflies; butterflies and moths (**Figure 32.27F**); sawflies; true flies (**Figure 32.27G**); and bees, wasps, and ants, some species of which display unique and highly specialized social behaviors (**Figure 32.27H**).

Molecular data suggest that insects began to diversify about 450 million years ago, about the time of the appearance of the first land plants. These early hexapods evolved in a terrestrial environment that lacked any other similar organisms, which in part accounts for their remarkable success. But the success of the insects is also due to their wings. Pterygote insects were the first animals in evolutionary history to achieve the ability to fly. Homologous genes control the development of insect wings and crustacean appendages, suggesting that the insect wing evolved from a dorsal branch of a crustacean-like limb (**Figure 32.28**). The dorsal limb branch of crustaceans is used for gas exchange. Thus the insect wing probably evolved from a gill-like structure that had a gas exchange function.

Flight opened up many new lifestyles and feeding opportunities that only the insects could exploit, such as pollination of

(and coevolution with) flowering plants. Flight is almost certainly one of the reasons for the remarkable numbers of both insect species and individual insects, and for their unparalleled evolutionary success.

RECAP 32.4

All arthropods have segmented bodies. Muscles in each segment operate that segment and the appendages attached to it. Jointed, specialized appendages permit complex patterns of movement, including, in insects, the ability to fly. With flight, insects took advantage of new feeding and lifestyle opportunities, which contributed to the unparalleled evolutionary success of this group.

- What features have contributed to making arthropods among the most abundant animals on Earth, both in number of species and number of individuals? **See p. 667**
- Describe the difference between incomplete and complete metamorphosis. **See pp. 671–672**

An Overview of Protostome Evolution

The protostomes encompass a staggering number of different body forms and lifestyles. The following aspects of protostome evolution have contributed to this enormous diversity:

- The evolution of *segmentation* permitted some groups of protostomes to move different parts of the body independently of one another. Species in some groups gradually evolved the ability to move rapidly over and through the substrate, through water, and through air.

(A) *Libellula quadrimaculata*(B) *Phymateus morbillosus*(C) *Coquerelia ventralis*(D) *Limnephilus* sp. (larva)(E) *Eupholus magnificus*(F) *Argema mittrei*(G) *Lucilia caesar*(H) *Polistes nymphe*

32.27 Diverse Pterygotes (A) Unlike most flying insects, a dragonfly cannot fold its wings over its back. (B) Orthopteran insects such as grasshoppers have incomplete metamorphosis: they undergo several molts, but the juvenile instars resemble small adults (incomplete metamorphosis). (C) Hemipterans such as this Madagascan shield bug are known as “true” bugs. (D–H) Holometabolous insects undergo complete metamorphosis. (D) A larval caddisfly (right) emerges from its dark pupal case. (E) The beetles (Coleoptera) comprise the largest insect group; beetles such as this New Guinea weevil account for more than half of all holometabolous species. (F) Butterflies and moths are the lepidopterans, whose phases of complete metamorphosis are familiar to many (see Figure 31.9). (G) Blowflies are among the “true” flies, the Dipterans. Adult blowflies feed on pollen or nectar, but lay their eggs on carrion, upon which the larvae feed. (H) These paper wasps are hymenopterans, a group in which most members display social behaviors.

- **Complex life cycles** with dramatic changes in form between one stage and another allow individuals of different stages to specialize on different resources.
- **Parasitism** has evolved repeatedly, and many protostome groups parasitize plants and animals.

- The evolution of *diverse feeding structures* allowed protostomes to specialize on many different food sources. Specialization on food sources undoubtedly contributed to reproductive isolation and further diversification.
- Predation was a major selection pressure favoring the development of *hard external body coverings* (exoskeletons and

32.28 The Origin of Insect Wings? Insect wings may be derived from an ancestral appendage similar to that of modern crustaceans. (A) A diagram of the ancestral, multibranching arthropod limb. The uppermost dorsal branch may have been used for gas exchange. (B, C) The *pdm* gene, a Hox gene, is expressed throughout the dorsal limb branch and walking leg of the thoracic limb of a crayfish (B) and in the wings and legs of *Drosophila* (C).

shells). Such coverings evolved independently in many lophotrochozoan and ecdysozoan groups. In addition to providing protection, these coverings became key elements in the development of new systems of locomotion.

- *Better locomotion* permitted prey to escape from predators, but also allowed predators to pursue their prey more effectively. Thus the evolution of animals has been, and continues to be, a complex “arms race” among predators and prey.

Go to Animated Tutorial 32.1
An Overview of the Protostomes
Life10e.com/at32.1

Many major evolutionary trends among the protostomes are shared by the deuterostomes, which include the chordates, the group to which humans belong. We turn to the deuterostomes in the next chapter.

Which groups of protostomes are thought to contain the most undiscovered species?

ANSWER

It is perhaps easier to list the groups of protostomes for which a nearly complete inventory of living species has been done than to list all the groups for which many new species remain to be described. Among the insects, the best-studied group, in terms of species, is the butterflies, which are widely collected and studied. There are still many species of other lepidopterans (such as moths), however, remaining to be discovered. Most other major insect groups contain many undescribed species.

New species discovery and description rates remain high for almost all other major groups of protostomes. Second to the insects, and perhaps even rivaling the insects in undiscovered diversity, are the nematodes. Although known nematode diversity is only about one-fortieth of known insect diversity (in terms of number of described species), the taxonomy of nematodes has been much more poorly studied than that of insects. Some biologists think there are likely to be species-specific parasitic nematodes specializing on most other species of multicellular organisms. If so, then there may be as many species of nematodes as there are of plants, fungi, and other animals combined.

Most of the other diverse groups of protostomes also contain many as yet undetected species, judging from the rate of new species descriptions. In particular, flatworms (especially the parasitic flukes and tapeworms), marine annelids, mollusks, crustaceans, myriapods, and chelicerates all contain large numbers of undescribed species.

CHAPTER SUMMARY 32

32.1 What Is a Protostome?

- Protostomes (“mouth first”) are bilaterally symmetrical animals with an anterior brain that surrounds the entrance to the digestive tract and a ventral nervous system. The embryonic blastopore of protostomes develops into a mouth.
- There are two major clades of protostomes, the lophotrochozoans and the ecdysozoans. **Review Figure 32.1, Table 32.1, ACTIVITIES 32.1, 32.2, ANIMATED TUTORIAL 32.1**
- **Lophotrochozoans** include a wide variety of body forms. Within this group, **lophophores** (complex organs for both food collection and gas exchange), free-living **trochophore** larvae, and spiral cleavage evolved. Some of these features were subsequently lost in some lineages (or evolved convergently).
- **Ecdysozoans** have a body covering known as the **cuticle**, which they must **molt** in order to grow. Some ecdysozoans have a relatively thin cuticle. Others, especially the **arthropods**, have a rigid cuticle reinforced with **chitin** that functions as an **exoskeleton**. **Review Figure 32.4**

- **Arrow worms** may be most closely related to lophotrochozoans, or they may be the sister group of all other protostomes. **Review Figure 32.5**

32.2 What Features Distinguish the Major Groups of Lophotrochozoans?

- Lophotrochozoans range from animals with a blind gut and no internal transport system to animals with complete digestive tracts and complex internal transport systems. **Review Figure 32.6**
- Most species of **bryozoans** and **entoprocts** live in colonies produced through asexual reproduction. Individuals of both groups feed using a lophophore.
- **Flatworms**, **rotifers**, **gastrotrichs**, and their close relatives form a structurally diverse clade of ciliated lophotrochozoans. **Review Figure 32.7**
- **Ribbon worms** feed using a long, protrusible proboscis. **Review Figure 32.8**

continued

- The shelled **brachiopods** and wormlike **phoronids** use a lophophore to feed; this lophophore may have evolved independently of the lophophore in bryozoans and entoprocts. **Review Figures 32.9, 32.10**
- **Annelids** are a diverse group of segmented worms that live in moist terrestrial and aquatic environments. **Review Figure 32.11**
- **Mollusks** underwent a dramatic evolutionary radiation based on a body plan consisting of three major components: a **foot**, a **mantle**, and a **visceral mass**. The four major living molluscan clades—**chitons**, **bivalves**, **gastropods**, and **cephalopods**—demonstrate the diversity that evolved from this three-part body plan. **Review Figure 32.13**

32.3 What Features Distinguish the Major Groups of Ecdysozoans?

- Members of several species-poor groups of wormlike marine ecdysozoans—**priapulids**, **kinorhynchs**, and **loriciferans**—have thin cuticles.
- **Nematodes** have a thick, multilayered cuticle. Nematodes are among the most abundant and universally distributed of all animal groups. **Review Figure 32.16**
- **Horsehair worms** are extremely thin; many are endoparasites as larvae.

32.4 Why Are Arthropods So Diverse?

- One major ecdysozoan clade, the arthropods, has evolved jointed, paired appendages that have a wide diversity of functions. Collectively, arthropods are the dominant animals on Earth in number of described species, and among the most abundant in number of individuals.

- Encasement within a rigid exoskeleton provides arthropods with support for walking as well as some protection from predators. The waterproofing provided by chitin keeps arthropods from dehydrating in dry air.
- Jointed appendages permit complex movement patterns. Each arthropod segment has muscles attached to the inside of the exoskeleton that operate that segment and the appendages attached to it.
- The **onychophorans** and the **tardigrades** are arthropod relatives that have simple, unjointed appendages. **Trilobites**, the first arthropods known to have had jointed appendages, disappeared in the Permian mass extinction.
- **Chelicerates** have a two-part body and pointed mouthparts that grasp prey; most chelicerates have four pairs of walking legs.
- Mandibles and antennae are synapomorphies of the **mandibulates**, which include the myriapods, crustaceans, and hexapods.
- The bodies of **myriapods** have two regions: a head with mandibles and antennae, and a segmented trunk that bears many pairs of legs.
- **Crustaceans** have segmented bodies that are divided into three regions—head, thorax, and abdomen—with different, specialized appendages in each region. **Review Figure 32.24**
- **Hexapods**—insects and their relatives—are the dominant terrestrial arthropods. They have the same three body regions as crustaceans, but no appendages form in their abdominal segments. **Review Figure 32.26, Table 32.2**
- Wings and the ability to fly first evolved among the **pterygote** insects, allowing them to exploit new lifestyles. **Review Figure 32.28**

CHAPTER REVIEW

REMEMBERING

- Which of the following is *not* part of the molluscan body plan?
 - Mantle
 - Foot
 - Radula
 - Visceral mass
 - Jointed appendages
- The outer covering of ecdysozoans
 - is always hard and rigid.
 - is always thin and flexible.
 - is hard and rigid in larvae but thin in adults.
 - ranges from very thin to hard and rigid, depending on the species.
 - grows throughout life to accommodate a growing body.
- Which groups are arthropod relatives with unjointed legs?
 - Trilobites and onychophorans
 - Onychophorans and tardigrades
 - Trilobites and tardigrades
 - Onychophorans and chelicerates
 - Tardigrades and chelicerates
- The body plan of insects comprises which of the following three regions?
 - Head, abdomen, and trachea
 - Head, abdomen, and cephalothorax
 - Cephalothorax, abdomen, and trachea
 - Head, thorax, and abdomen
 - Abdomen, trachea, and mantle
- Insects whose hatchlings are sufficiently similar in form to adults to be recognizable are said to have
 - instars.
 - neopterous development.
 - accelerated development.
 - incomplete metamorphosis.
 - complete metamorphosis.
- Factors that may have contributed to the remarkable evolutionary success of insects include
 - the lack of any other similar organisms in the terrestrial environments colonized by insects.
 - the ability to fly.
 - complete metamorphosis.
 - a new mechanism for delivering oxygen to their internal tissues.
 - All of the above

UNDERSTANDING & APPLYING

7. Segmentation either has arisen several times during animal evolution, or else arose early in animal evolution and was subsequently lost multiple times. What advantages does segmentation provide? Given these advantages, why might some animals have lost their segmentation?
8. Major structural novelties have arisen only infrequently during the course of evolution. Which of the features of protostomes do you think are major evolutionary novelties? Which of these features may have led to major evolutionary radiations?
9. There are more described and named species of insects than of all other species on Earth combined. However, only a very few insect species live in marine environments, and those species are restricted to the intertidal zone or the ocean surface. What factors may have contributed to the insects' lack of success in the oceans?

ANALYZING & EVALUATING

10. In the Working with Data exercise on page 673, you were asked to make many assumptions to estimate the number of species of insects on Earth. Do you think these assumptions are reasonable? Why or why not? Would you argue for a different set of assumptions? How do you think these changes in assumptions would affect your calculations? Can you think of ways to test these assumptions?

CHAPTER OUTLINE

- 32.1** What Is a Deuterostome?
- 33.2** What Features Distinguish the Echinoderms, Hemichordates, and Their Relatives?
- 33.3** What New Features Evolved in the Chordates?
- 33.4** How Did Vertebrates Colonize the Land?
- 33.5** What Traits Characterize the Primates?

WHY WOULD A FROG swallow its own offspring? That may not sound like a good parenting skill, but female gastric brooding frogs of Australia shut down their digestive system to brood their tadpoles in their stomach. This strategy provides the tadpoles with a safe haven from predators, making it much more likely that they will survive to metamorphosis. That was the case, at least, until gastric brooding frogs went extinct in the early 1980s, after humans introduced pathogenic fungi into their native range.

Not all adult frogs are involved in raising their young. Female bullfrogs, for example, lay thousands of eggs each year and provide no parental care for their offspring. The eggs are fertilized by a male bullfrog and left to develop on their own. The eggs hatch into tadpoles, which transform into tiny frogs—if they aren't eaten first by aquatic predators. Out of the tens of thousands of tadpoles an adult bullfrog produces in its lifetime, an average of only two offspring will survive to reproduce.

Among other species of frogs, complex behaviors associated with parental care change these long odds. Rather than producing huge numbers of offspring, each with a minimal chance of surviving, some frogs invest more energy in each individual offspring and care for the young as they grow. This strategy increases the chances that any one offspring will survive and reproduce—but it also means that far fewer offspring can be produced.

Frogs' strategies for parental care include many behaviors in addition to gastric brooding. The females of many species guard their eggs until they hatch. Other

Good Parent or Cannibal? Young frogs emerge from the digestive tract of a female *Rheobatrachus silus*, one of the now-extinct gastric brooding frogs of Australia. In this unique form of gestation, eggs hatch and tadpoles develop within the protected environment of the mother's stomach.

females carry their tadpoles around with them on their backs, or even in special brood pouches. Males often provide parental care as well. Males of many frog species guard egg masses or carry young, sometimes in unusual ways. In Darwin's frog of South America, for example, the tadpoles develop within the male's vocal sacs.

Parental care can extend beyond protection to feeding the young. Some female poison frogs of the tropical Americas carry each of their tadpoles to one of the many tiny pools of water that collect in bromeliad plants growing on trees. The female then returns to each bromeliad "pond" and lays unfertilized eggs as food for the single tadpole developing there.

Frogs and other vertebrates constitute one of the major groups of deuterostome animals. Deuterostomes are of particular interest to biologists not only because of their often complex behaviors, their importance in many ecosystems, and their widespread use as models in developmental biology and genetics, but because we are deuterostomes.

How has the evolution of complex behaviors affected the diversification of some major groups of deuterostomes?

See answer on p. 705.

33.1 Phylogeny of the Deuterostomes The three principal groups of deuterostomes are the echinoderms, the hemichordates, and the chordates, which include the lancelets, tunicates, and vertebrates. The echinoderms and the vertebrates contain most of the described species.

Go to Activity 33.1 Deuterostome Phylogeny
Life10e.com/ac33.1

33.1 What Is a Deuterostome?

It may surprise you to learn that both you and a sea urchin are deuterostomes. Adult sea stars, sea urchins, and sea cucumbers—the most familiar echinoderms—look so different from adult vertebrates (fishes, frogs, lizards, birds, and mammals) that it may be difficult to believe all these animals are closely related. The evidence that all deuterostomes share a common ancestor that is not shared with the protostomes includes early developmental patterns and phylogenetic analysis of gene sequences, factors that are not apparent in the forms of the adult animals.

Deuterostomes share early developmental patterns

Historically, the deuterostomes were distinguished by three early developmental patterns:

- **Radial cleavage**
- **Development of the blastopore into the anus and formation of the mouth at the opposite end of the embryo from the blastopore** (the pattern that gives the deuterostomes their name)
- **Development of a coelom from mesodermal pockets that bud off from the cavity of the gastrula rather than by splitting of the mesoderm, as occurs among protostomes**

These distinctions, however, are not the strongest evidence for the monophyly of the deuterostomes. Radial cleavage is not exclusive to deuterostomes, and as noted in Section 31.1, it is now thought to be the ancestral condition for all bilaterians. In fact, some of the groups now known to be protostomes were once thought to be deuterostomes because their developmental patterns are similar to those of echinoderms and chordates. The development of the blastopore into an anus does characterize the deuterostomes, but it may be the ancestral condition for bilaterians rather than a derived feature of deuterostomes. Today the strongest support for the shared evolutionary relationships of the deuterostomes comes from phylogenetic analyses of DNA sequences of many different genes.

There are three major deuterostome clades

All deuterostomes are triploblastic, coelomate animals (see Figure 31.5C). Skeletal elements, where present, are internal rather than external. Some species have segmented bodies, but the segments are less obvious than those of annelids and arthropods. Although there are far fewer species of deuterostomes than of protostomes (see Table 31.1), we have a special interest in deuterostomes because we are members of that clade. The deuterostomes are also of interest because they include many large animals that strongly influence the characteristics of ecosystems. Many deuterostome species have been intensively studied in all fields of biology. Complex behaviors, such as the parenting behaviors described at the opening of this chapter, are especially well developed among some deuterostomes.

The major groups of living deuterostomes comprise three distinct clades (Figure 33.1):

- **Echinoderms:** sea stars (starfish), sea urchins, and their relatives
- **Hemichordates:** acorn worms and pterobranchs
- **Chordates:** sea squirts, lancelets, and vertebrates

In addition, some recent genomic analyses suggest that two poorly known groups, the xenoturbellids and the acoels, may also be deuterostomes.

Go to Animated Tutorial 33.1
An Overview of the Deuterostomes
Life10e.com/at33.1

Fossils shed light on deuterostome ancestors

Scientists are learning much about the ancestors of modern deuterostomes from fossils recently discovered in 520-million-year-old rocks in China. Some of these early deuterostomes had skeletons similar to those of echinoderms but, unlike modern adult echinoderms, they had bilateral symmetry and a pharynx with slits through which water flowed. Another early deuterostome group, the yunnanozoans, was discovered in China's Yunnan Province. The well-preserved fossils reveal animals that had large mouths, six pairs of external gills, and a segmented posterior body section bearing a light cuticle (Figure 33.2). The features of these fossil animals, together with

Yunnanozoon lividum

33.2 Ancestral Deuterostomes Had External Gills The extinct yunnanozoans may be ancestral deuterostomes. This fossil, which dates from the Cambrian, shows the six pairs of external gills and segmented posterior body that characterized these animals.

findings from phylogenetic analyses of living species, show that the earliest deuterostomes were bilaterally symmetrical, segmented animals with pharyngeal slits. The adult forms of the living echinoderms with their unique symmetry (in which the body parts are arranged along five radial axes) evolved much later. Other deuterostomes retained the ancestral bilateral symmetry.

RECAP 33.1

The three major clades of deuterostomes are the echinoderms, the hemichordates, and the chordates. The common ancestry of these groups is supported by early developmental similarities and by phylogenetic analyses of DNA sequences.

- Why is radial cleavage no longer considered to be evidence for the monophyly of deuterostomes? [See p. 679](#)
- What three traits did the earliest deuterostomes have in common? [See pp. 679–680](#)

We will begin our survey of the deuterostomes with the echinoderms and hemichordates, the most distant of our relatives within that clade.

33.2 What Features Distinguish the Echinoderms, Hemichordates, and Their Relatives?

About 13,000 species of echinoderms in 23 major groups have been described from their fossil remains. They are probably only a small fraction of the echinoderm species that have ever lived. Only 6 of the 23 major groups known from fossils are represented by species that survive today; many clades were lost during the periodic mass extinctions that have occurred throughout Earth's history. Nearly all of the 7,500 extant species of echinoderms live in marine environments. There are

far fewer species of living hemichordates (about 120 known species).

The echinoderms and hemichordates (together known as **ambulacrarians**) have a bilaterally symmetrical, ciliated larva (**Figure 33.3A**). Adult hemichordates are also bilaterally symmetrical. Echinoderms, however, undergo a radical change in form as they develop into adults (**Figure 33.3B**), changing from a bilaterally symmetrical larva into an adult with **pentaradial symmetry** (symmetry in five or multiples of five). As is typical of animals with radial symmetry, echinoderms have no head, and they move slowly and equally well in many directions. Rather than having an anterior–posterior (head–tail) and dorsal–ventral (back–belly) body organization, most echinoderms have an **oral** side containing the mouth and an opposite **aboral** side containing the anus.

Recent genomic analyses suggest that two groups of small, highly reduced, soft-bodied marine organisms, the xenoturbellids and the acoels, are the sister group of the ambulacrarians. The two known species of **xenoturbellids** are wormlike organisms up to 4 cm long that feed on or parasitize mollusks in the northern Atlantic Ocean. They have a very simple body plan, with almost no well-defined organ systems. The mostly tiny (<2 mm) **acoels** are also highly reduced, wormlike organisms that live as plankton, between grains of sediment, or on other organisms such as corals (**Figure 33.4**). They are among the simplest of bilaterian animals, with no gut, circulatory system, respiratory system, gonads, or excretory system. They feed by forming a vacuole around tiny food items. They are hermaphrodites, and their gametes fill the body between the epidermis and digestive vacuole. There are about 400 known species of acoels.

Echinoderms have unique structural features

In addition to having pentaradial symmetry, adult echinoderms have two unique structural features. One is a system of calcified internal plates covered by thin layers of skin and some muscles. The calcified plates of most echinoderms are thick, and they fuse inside the entire body, forming an **internal skeleton**. The other unique feature of this group is a **water vascular system**, a network of water-filled canals leading to extensions called **tube feet** (see **Figure 33.3B**). This system functions in gas exchange, locomotion, and feeding. Seawater enters the system through a perforated structure called a madreporite. A calcified canal leads from the madreporite to the ring canal, which surrounds the esophagus (the tube leading from the mouth to the stomach). Radial canals branch off from the ring canal, extending through the arms (in species that have arms) and connecting with the tube feet. These structural innovations have been modified in many ways, resulting in a striking array of very different animals.

Members of one major extant echinoderm clade, the crinoids (sea lilies and feather stars), were more abundant and species-rich 300 to 500 million years ago than they are today. There are some 80 described living sea lily species, most of which are

33.3 Echinoderms Are Bilaterally Symmetrical as Larvae but Radially Symmetrical as Adults

(A) The ciliated larva of a sea star has bilateral symmetry. Hemichordates have a similar larval form. (B) An adult sea star displays the pentaradial symmetry of adult echinoderms. The canals and tube feet of the water vascular system, as well as the calcified internal skeleton, are shown in this diagram. The body's orientation is oral–aboral rather than anterior–posterior.

Wamionoa sp.

33.4 Highly Reduced Acoels Are Probably Relatives of the Ambulacrarians Acoels (yellow) are seen here living on bubble coral (white). Acoels ("without coelom") feed by enveloping food particles in a vacuole within which nutrients are digested. These hermaphroditic animals can reproduce rapidly and may become problematic in saltwater aquariums.

sessile organisms attached to the substrate by a stalk. Feather stars (**Figure 33.5A**) grasp the substrate with specialized flexible appendages that allow for limited movement. About 600 living species of feather stars have been described.

Unlike the mostly sessile crinoids, most surviving echinoderms are motile. The two main groups of motile echinoderms are the echinozoans (sea urchins and sea cucumbers) and the asterozoans (sea stars and brittle stars). Sea urchins are hemispherical in shape and lack arms (**Figure 33.5B**). They are covered with spines that are attached to the underlying skeleton with ball-and-socket joints. These joints enable the spines to be moved so they can converge toward a point that has been touched. The spines, which vary among species in size and shape, can be used for locomotion; a few produce toxic substances. They provide effective protection for the urchin, as many a scuba diver has found out the hard way. Sand dollars are flattened, disc-shaped relatives of sea urchins.

Sea cucumbers also lack arms, and their bodies are oriented in an atypical manner for an echinoderm (**Figure 33.5C**). The mouth is anterior and the anus is posterior (front and rear), in contrast to the oral–aboral (top and bottom) orientation of other echinoderms. Sea cucumbers can use most of their tube feet to move, but they use them primarily for attaching to the substrate.

Sea stars, popularly called starfish, are the most familiar echinoderms (**Figure 33.5D**). Their gonads and digestive organs are located in the arms, as seen in **Figure 33.3B**. Their tube feet serve as organs of locomotion, gas exchange, and attachment. Each tube foot of a sea star consists of an internal ampulla connected by a muscular tube to an external suction cup that can stick to the substrate. The tube foot is moved by expansion and contraction of the circular and longitudinal muscles of the tube. Brittle stars are similar in structure to sea stars, but their flexible arms are composed of jointed, hard plates (**Figure 33.5E**).

(A) *Oxycomanthus bennetti*(B) *Sphaerechinus granularis*(C) *Synaptula* sp.

33.5 Echinoderm Diversity (A) The flexible arms of this golden feather star (a crinoid) are clearly visible. (B) Sea urchins are important grazers on algae in the intertidal zones of the world's oceans. (C) Sea cucumbers are unique among echinoderms in having an anterior–posterior, rather than an oral–ab-oral, orientation of the mouth and anus. (D) Sea stars are important predators on bivalve mollusks such as mussels and clams. Suction tips on its tube feet allow a sea star to grasp both shells of the bivalve and pull them open. (E) The arms of the brittle star are composed of hard but jointed plates.

(D) *Marthasterias glacialis*(E) *Ophiopholis aculeata*

Echinoderms use their tube feet in a great variety of ways to capture prey. Sea lilies, for example, feed by orienting their arms in passing water currents. Food particles then strike and stick to the tube feet, which are covered with mucus-secreting glands. The tube feet transfer these particles to grooves in the arms, where ciliary action carries the food to the mouth.

Most sea urchins capture phytoplankton with their tube feet or scrape algae from rocks with a complex rasping structure. Sea cucumbers capture food with their anterior tube feet, which are modified into large, feathery, sticky tentacles that can be protruded from the mouth. Periodically, a sea cucumber withdraws the tentacles, wipes off the material that has adhered to them, and digests it.

Many sea stars use their tube feet to capture large prey such as polychaetes, gastropod and bivalve mollusks, small crustaceans such as crabs, and fishes. With hundreds of tube feet acting simultaneously, a sea star can grasp a bivalve in its arms, anchor the arms with its tube feet, and by steady contraction of the muscles in its arms, gradually exhaust the muscles the bivalve uses to keep its shell closed (see Figure 33.5D). To feed on the bivalve, the sea star can push its stomach out through its mouth and then through the narrow space between the two halves of the bivalve's shell. The sea star's stomach then secretes enzymes that digest the prey.

Sea Star Feeding on a Bivalve
Life10e.com/mc33.1

Most of the 2,000 species of brittle stars ingest particles from the upper layers of sediments and assimilate the organic material from them, although some species filter suspended food particles from the water, and others capture small animals.

Hemichordates are wormlike marine deuterostomes

Hemichordates—acorn worms and pterobranchs—have a bilaterally symmetrical, wormlike body organized in three major parts: a proboscis, a collar (which bears the mouth), and a trunk (which contains the other body parts). The 90 known species of acorn worms range up to 2 meters long (Figure 33.6A). They live in burrows in muddy and sandy marine sediments. The digestive tract of an acorn worm consists of a mouth behind which are a muscular pharynx and an intestine. The pharynx opens to the outside through several pharyngeal slits through which water can exit. Highly vascularized tissue surrounding the pharyngeal slits serves as a gas exchange apparatus. Acorn worms respire by pumping water into the mouth and out through the pharyngeal slits. They capture prey with the large proboscis, which is coated with sticky mucus to which small organisms in the sediment stick. The mucus and its attached prey are conveyed by cilia to the mouth. In the esophagus, the food-laden mucus is compacted into a ropelike mass that is moved through the digestive tract by ciliary action.

The 30 living species of pterobranchs are sedentary marine animals up to 12 millimeters long that live in a tube secreted

33.6 Hemichordates (A) The proboscis of an acorn worm is modified for burrowing. (B) Some pterobranch species form colonies.

by the proboscis. Some species are solitary; others form colonies of individuals joined together (Figure 33.6B). Behind the proboscis is a collar with anywhere from one to nine pairs of arms. The arms bear long tentacles that capture prey and function in gas exchange.

RECAP 33.2

Echinoderms are characterized by pentaradial symmetry, an internal skeleton of calcified plates, and a unique water vascular system. Hemichordates have a bilaterally symmetrical body divided into three parts: proboscis, collar, and trunk.

- How does the body form of echinoderm larvae differ from that of adults? See p. 681 and Figure 33.3
- Describe some of the ways that echinoderms use their tube feet to obtain food. See p. 682
- Explain how hemichordates obtain food. See p. 682

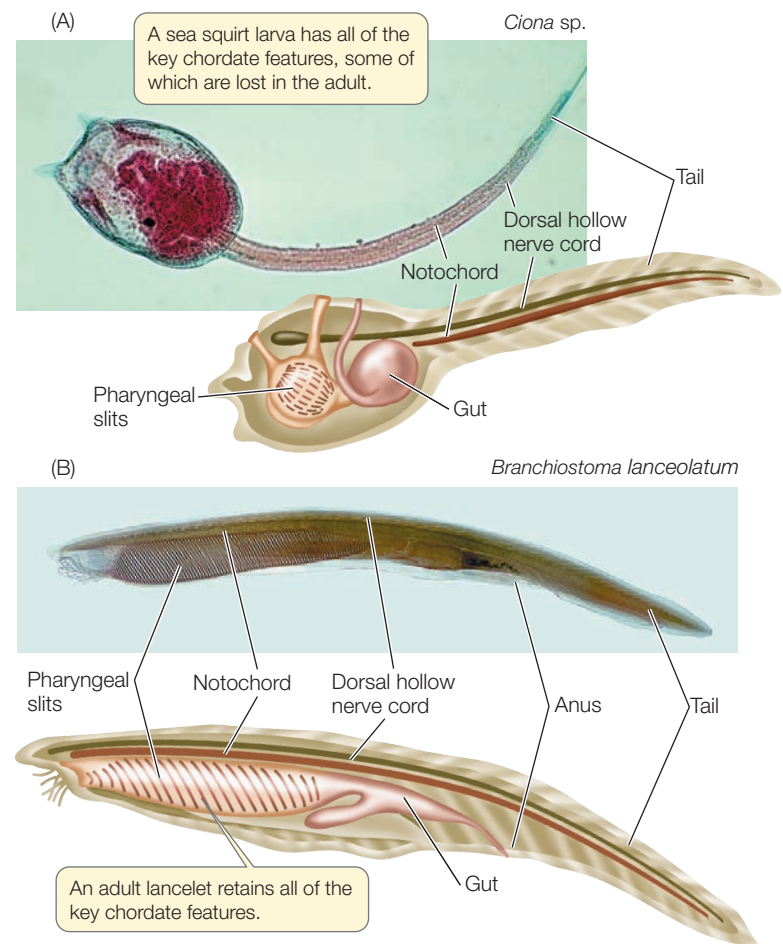

Having described the deuterostome groups that are most distantly related to us, we will next turn our attention to the unique features that evolved in the chordates, a clade dominated by the vertebrates.

33.3 What New Features Evolved in the Chordates?

As we have seen, it is not obvious from examining adult animals that echinoderms and chordates share a common ancestor. The evolutionary relationships among some chordate groups are not immediately apparent either. The features that reveal all of these evolutionary relationships are seen primarily in the larvae—in other words, it is during the early developmental stages that these evolutionary relationships are evident.

There are three principal chordate clades: the **lancelets** (also called cephalochordates), the **tunicates** (also called urochordates), and the **vertebrates** (see Figure 33.1). Adult chordates vary greatly in form, but all chordates display the following derived structures at some stage in their development (Figure 33.7):

- A dorsal hollow nerve cord
- A tail that extends beyond the anus
- A dorsal supporting rod, the *notochord*

33.7 Key Features May Be Most Apparent in Early Development

(A) The sea squirt larva (but not the adult) has all three key features of chordates: a dorsal hollow nerve cord, a post-anal tail, and a notochord. (B) All three chordate synapomorphies are retained in the adult lancelet.

The **notochord** is the most distinctive derived chordate trait. It is composed of a core of large cells with turgid fluid-filled vacuoles, which make it rigid but flexible. In the tunicates the notochord is lost during metamorphosis to the adult stage. In most vertebrate species it is replaced during development by skeletal structures that provide support for the body.

The pharyngeal slits found in the common ancestor of deuterostomes are present at some developmental stage in all chordates but are often lost or greatly modified in adults. In chordates, the pharyngeal slits are separated and supported by structural elements called pharyngeal arches. In tunicates and lancelets, the pharynx functions as a straining device to filter small food particles. In fishes and larval amphibians, some of the pharyngeal arches develop into gill arches, which support the respiratory gills and are often used as feeding structures as well. Developmentally, some pharyngeal arches also develop into elements of the vertebrate jaw, as well as parts of the tongue, larynx, trachea, and middle ear of tetrapods (four-legged vertebrates). Some of the pharyngeal slits are modified in tetrapods to form the eustachian tube and middle ear chamber.

Adults of most lancelets and tunicates are sedentary

The 35 species of lancelets, also known as cephalochordates, are small animals that rarely exceed 5 centimeters in length. The notochord, which provides body support, extends the entire length of the body throughout the animal's life (see Figure 33.7B). Lancelets are found in shallow marine and brackish waters worldwide. Most of the time they lie covered in sand with their head protruding above the sediment, but they can swim. The pharynx has been enlarged and modified to form a structure called a pharyngeal basket, with which the lancelet filters prey from the water. During the reproductive season, the gonads of males and females enlarge greatly. At spawning, the walls of the gonads rupture, releasing eggs and sperm into the water column, where fertilization takes place.

All members of the three major tunicate groups—the sea squirts (also called ascidians), thaliaceans, and larvaceans—are marine animals. More than 90 percent of the 2,800 known species of tunicates are sea squirts. Individual sea squirts range in length from less than 1 millimeter to 60 centimeters. Some sea squirts form colonies by asexual budding from a single founder. Colonies may measure several meters across. The baglike body of an adult sea squirt is enclosed in a tough tunic, which is the basis for the name “tunicate” (Figure 33.8A). The tunic is composed of proteins and a complex polysaccharide secreted by epidermal cells. The sea squirt pharynx is enlarged into a pharyngeal basket that filters prey from the water passing through it.

In addition to its pharyngeal slits, a sea squirt larva has a dorsal hollow nerve cord and a notochord that is restricted mostly to the tail region (see Figure 33.7A). Bands of muscle that surround the notochord provide support for the body.

(A) *Clavelina dellavallei*

(B) *Pegea* sp.

33.8 Adult Tunicates (A) The transparent tunic and the pharyngeal basket are clearly visible in this sea squirt. (B) A chainlike colony of thaliaceans (salps) floats in tropical waters.

After a short time swimming in the plankton, the larvae of most species settle on the seafloor and transform into sessile adults. The swimming, tadpolelike larvae suggest a close evolutionary relationship between tunicates and vertebrates (see Figure 22.6).

Thaliaceans (salps and their relatives) are tunicates that can live singly or in chainlike colonies up to several meters long (Figure 33.8B). They float in tropical and subtropical oceans at depths down to 1,500 meters. Larvaceans are solitary planktonic animals that retain the notochord and dorsal hollow nerve cord throughout their lives. Most larvaceans are less than 5 millimeters long, but some species that live near the bottom of deep ocean waters build delicate casings of mucus that may be more than a meter wide. They snare sinking organic particles (their primary food source) with elaborate filters built into their mucus “houses.” When the old “house” gets clogged with excess debris, the animal builds a new one.

A dorsal supporting structure replaces the notochord in vertebrates

In one chordate group, the vertebrates, a new dorsal supporting structure evolved. This group takes its name from the jointed, dorsal **vertebral column** that replaces the notochord during early development as the primary supporting structure. The individual elements in the vertebral column are called vertebrae. Four other key features characterize the vertebrates as well (Figure 33.9):

33.9 The Vertebrate Body Plan A ray-finned fish is used here to illustrate some of the structural elements common to all vertebrates. In addition to the paired pelvic fins, these fishes have paired pectoral fins on the sides of their bodies (not seen in this cutaway view).

- An anterior *skull* enclosing a large brain
- A rigid internal *skeleton* supported by the vertebral column
- Internal organs *suspended in a coelom*
- A well-developed *circulatory system*, driven by contractions of a ventral *heart*

These structural features can support large, active animals. The internal skeleton provides support for an extensive muscular system, which receives oxygen from the circulatory system and is controlled by the central nervous system. The evolution of these features allowed many vertebrates to become large, active predators, which in turn allowed the vertebrates to diversify widely (**Figure 33.10**).

All of the nonvertebrate deuterostomes (acoels and xenoturbellids, echinoderms, hemichordates, lancelets, and

tunicates) live in marine environments. The lineage that led to the vertebrates is also thought to have evolved in the oceans, although probably in an estuarine environment (where fresh water meets salt water). The first vertebrates appeared in the Cambrian; since then they have radiated into marine, freshwater, terrestrial, and aerial environments worldwide. There are about 65,000 species of living vertebrates.

The phylogenetic relationships of jawless fishes are uncertain

The **hagfishes** are thought by many to be the sister group to the remaining vertebrates (see **Figure 33.10**). Hagfishes (**Figure 33.11A**) have a weak circulatory system

33.10 Phylogeny of the Living Vertebrates This phylogenetic tree shows the evolution of some of the key innovations among the major groups of vertebrates.

*Eptatretus stoutii**Petromyzon marinus*

33.11 Modern Jawless Fishes (A) Hagfishes burrow in the ocean mud, from which they extract small prey. They also scavenge on dead or dying fish. Hagfishes have degenerate eyes, which has led to their being called (inaccurately) “blind eels.” (B) Sea lampreys are ectoparasites that attach to the bodies of living fish and use their large, jawless mouths to suck blood and flesh. They can survive in both fresh and salt water, as this individual attached to a salmon returning to its spawning ground will do.

with three small accessory hearts (rather than a single, large heart); a partial cranium, or skull (containing a brain with no cerebrum or cerebellum, two main regions that characterize the brains of other vertebrates); and no jaws or stomach. They also lack separate, jointed vertebrae and have a skeleton composed of a firm but pliable material called cartilage. Thus some biologists do not consider hagfishes to be vertebrates and instead use the term “craniates” to refer collectively to the hagfishes and the vertebrates. Some analyses of gene sequences suggest, however, that hagfishes may be the sister group of the **lampreys** (Figure 33.11B); in this phylogenetic arrangement, the hagfishes and the lampreys are collectively called the **cyclostomes** (“circle mouths”). If in fact the hagfishes and lampreys do form a monophyletic group, then hagfishes must have secondarily lost many of the major vertebrate morphological features during their evolution.

The 80 known species of hagfishes are unusual marine animals that produce copious quantities of mucus as a defense. They are virtually blind and rely largely on the four pairs of sensory tentacles around the mouth to detect food. Although they have no jaws, hagfishes have a tonguelike structure equipped with toothlike rasps that they use to tear apart dead organisms and to capture their principal prey, polychaete

worms. Hagfishes have direct development (no larvae), and individuals may actually change sex from year to year (from male to female and vice versa).

Go to Media Clip 33.2

Hagfish Slime

Life10e.com/mc33.2

Although the lampreys and hagfishes may look superficially similar (with elongate eel-like bodies and no paired fins), they differ greatly in their biology. Lampreys have a complete skull and distinct and separate (although rudimentary) vertebrae, all cartilaginous rather than bony. Lampreys undergo a complete metamorphosis from filter-feeding larvae, known as ammocoetes, which are morphologically similar to adult lancelets. The adults of many species of lampreys are parasitic, although several lineages of lampreys evolved to become nonfeeding as adults. These nonfeeding adults survive for only a few weeks after metamorphosis—just long enough to breed. In the species that are parasitic as adults, the round mouth is a rasping and sucking organ that is used to attach to prey and rasp at the flesh (see Figure 33.11B).

The nearly 50 species of lampreys either live permanently in fresh water or are anadromous—meaning they live in coastal salt water and move into fresh water to breed. Some species of lampreys are critically endangered because of recent habitat changes and losses.

Jaws and teeth improved feeding efficiency

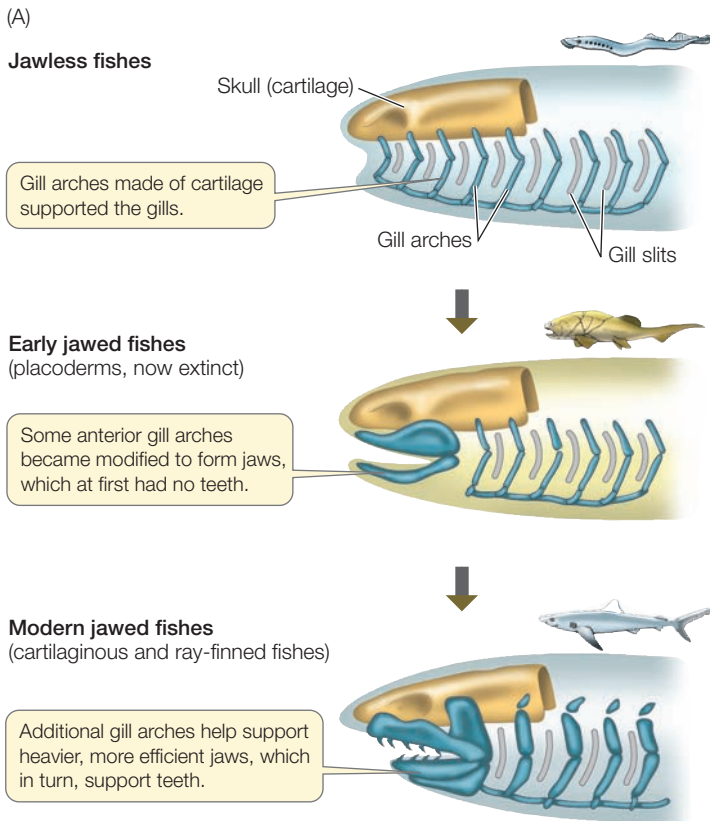

Many kinds of jawless fishes were found in the seas, estuaries, and fresh waters of the Ordovician, Silurian, and Devonian periods, but hagfishes and lampreys are the only jawless fishes that survived beyond the Devonian. Late in the Ordovician, some fishes evolved jaws via modifications of the skeletal arches that supported the gills (Figure 33.12A). Those fishes and their descendants are referred to as **gnathostomes** (Greek, “jaw mouths”). Jaws greatly improved feeding efficiency, as an animal with jaws can grasp, subdue, and swallow large prey. Jawed fishes rapidly diversified during the Devonian period, eventually replacing the jawless fishes in dominance of the seas.

The earliest jaws were simple, but the evolution of teeth made feeding even more efficient (Figure 33.12B). In predators, teeth function crucially both in grasping and in breaking up prey. In both predators and herbivores, teeth enable an animal to chew both soft and hard body parts of their food organisms. Chewing also aids chemical digestion and improves an animal’s ability to extract nutrients from its food, as we will describe in Chapter 51. Vertebrates are remarkable in the diversity of their jaws and teeth.

Fins and swim bladders improved stability and control over locomotion

Most jawed fishes have a pair of pectoral fins just behind the gill slits and a pair of pelvic fins anterior to the anus (see

33.12 Jaws and Teeth Increased Feeding Efficiency (A) These diagrams illustrate one probable scenario for the evolution of jaws from the anterior gill arches of jawless fishes. (B) Jaws of the extinct giant shark *Carcharodon megalodon* display the teeth that indicate an extreme predatory lifestyle.

Figures 33.9 and 33.13A). These paired fins stabilize the fish's position in water (and in some cases, help propel it). Median dorsal and anal fins also stabilize the fish, or may be used for propulsion in some species. In many fishes, the caudal (tail) fin helps propel the animal and enables it to turn rapidly.

Several groups of jawed fishes became abundant during the Devonian. Among them were the **chondrichthyans**—sharks, skates, and rays (about 1,000 living species) and chimaeras (40 living species). Like hagfishes and lampreys, these fishes have a skeleton composed entirely of cartilage. Their skin is flexible and leathery, sometimes bearing scales that give it the consistency of sandpaper. Sharks move forward by means of lateral (side-to-side) undulations of the body and caudal fin (**Figure 33.13A**). Skates and rays propel themselves by means of vertical undulating movements of their greatly enlarged pectoral fins (**Figure 33.13B**).

Most sharks are predators, but some feed by straining plankton from the water. Most skates and rays live on the ocean floor, where they feed on mollusks and other animals buried in the sediments. Nearly all chondrichthyans live in the oceans, but a few are estuarine or migrate into lakes and rivers. One group of stingrays is found in river systems of South America. The less familiar chimaeras (**Figure 33.13C**) live in deep-sea or cold waters.

One lineage of aquatic gnathostomes gave rise to the bony vertebrates, which soon split into two main lineages—the **ray-finned fishes** and the **lobe-limbed vertebrates**. Bony vertebrates have internal skeletons of calcified, rigid bone rather

than flexible cartilage. In early bony vertebrates, gas-filled sacs supplemented the gas exchange function of the gills by giving the animals access to atmospheric oxygen. These features enabled these fishes to live where oxygen was periodically in short supply, as it often is in freshwater environments. In the ray-finned fishes, these lunglike sacs evolved into **swim bladders**, which are organs of buoyancy. By adjusting the amount of gas in its swim bladder, a ray-finned fish can control the depth at which it remains suspended in the water while expending very little energy to maintain its position.

The outer body surface of most species of ray-finned fishes is covered with thin, flat, lightweight scales that provide protection or enhance movement through the water. The gills open into a single chamber covered by a hard flap, called an operculum. Movement of the operculum increases the flow of water over the gills, where gas exchange takes place.

Ray-finned fishes began to diversify during the Mesozoic era and continued to radiate extensively throughout the Tertiary period. Today there are about 32,000 known living species, encompassing a remarkable variety of sizes, shapes, and lifestyles (**Figure 33.14**). The smallest are less than 1 centimeter long; the largest weigh as much as 900 kilograms. Ray-finned fishes exploit nearly all types of aquatic food sources. In the oceans they filter plankton from the water, rasp algae from rocks, eat corals and other soft-bodied colonial animals, dig animals from soft sediments, and prey on virtually all kinds of other fishes. In fresh water they eat plankton, devour insects, eat fruits that fall into the water, and prey on other aquatic vertebrates and, occasionally,

(D) *Gigantactis vanhoeffeni* luring prey

terrestrial vertebrates. Many ray-finned fishes are solitary, but in open water others form large aggregations called schools. Many species perform complicated behaviors to maintain schools, build nests, court mates, and care for their young.

Although ray-finned fishes can readily control their position in open water using their fins and swim bladder, their eggs tend to sink. Some species produce small eggs that are buoyant enough to complete their development in open water, but many marine fishes move to food-rich shallow waters to lay their eggs. That is why coastal waters and estuaries are so important in the life cycles of many marine fishes. Some ray-finned fishes, such as salmon, are anadromous, moving from the ocean to the fresh waters in which they breed.

RECAP 33.3

Chordates are characterized by a dorsal hollow nerve chord, a post-anal tail, and a dorsal supporting rod called a notochord at some point during the life cycle. Specialized structures for support (a vertebral column), locomotion (such as fins), and feeding (jaws and teeth) evolved among the vertebrates.

- What synapomorphies characterize the chordates and the vertebrates, respectively? **See pp. 683–685 and Figures 33.7 and 33.9**
- How do the hagfishes differ from the lampreys in morphology and life history? Why do some biologists contend that hagfishes are not vertebrates? **See pp. 685–686**

In the lobe-limbed vertebrates, the gas-filled sacs that gave rise to swim bladders in ray-finned fishes became specialized for another purpose: breathing air. That adaptation set the stage for the vertebrates to move onto the land.

(A) *Latimeria chalumnae*

33.15 The Closest Relatives of Tetrapods (A) The coelacanth, discovered in deep waters of the Indian Ocean off the South African coast, represents one of two surviving species of a group that was once thought to be extinct. (B) All surviving lungfish species, such as this African lungfish, live in the Southern Hemisphere. (C) *Tiktaalik*, a fossil lobe-limbed vertebrate from the Devonian, is believed to represent a transitional species intermediate between the finned fishes and the limbed tetrapods.

33.4 How Did Vertebrates Colonize the Land?

The evolution of lunglike sacs in fishes set the stage for the vertebrate invasion of the land. Some early ray-finned fishes probably used those sacs to supplement their gills when oxygen levels in the water were low, as many groups of ray-finned fishes do today. But with their unjointed fins, those fishes could only flop around when out of water. Changes in the structure of the fins first allowed lobe-limbed vertebrates to support themselves better in shallow water and, later, to move better on land.

Jointed limbs enhanced support and locomotion on land

In the lobe-limbed vertebrates, the paired pelvic and pectoral fins developed into more muscular fins that were joined to the body by a single enlarged bone. The modern representatives of these lobe-limbed vertebrates include the coelacanths, lungfishes, and tetrapods.

The coelacanths flourished from the Devonian until about 65 million years ago, when they were thought to have become extinct. But in 1938 a commercial fisherman caught a living coelacanth off South Africa. Since that time, hundreds of individuals of this extraordinary fish, *Latimeria chalumnae*, have been collected. A second species, *L. menadoensis*, was discovered in 1998 off the Indonesian island of Sulawesi. *Latimeria*, a predator of other fishes, reaches a length of about 1.8 meters and weighs up to 82 kilograms (**Figure 33.15A**). Its skeleton is composed mostly of cartilage, not bone. The

(B) *Protopterus annectens*

Tiktaalik's pectoral fins show some of the skeletal structures of tetrapod limbs.

(C) *Tiktaalik roseae*

cartilaginous skeleton is a derived feature in this clade because it had bony ancestors.

Lungfishes were important predators in shallow-water habitats in the Devonian, but most lineages died out. The six surviving species live in stagnant swamps and muddy waters in South America, Africa, and Australia (**Figure 33.15B**). Lungfishes have lungs derived from the lunglike sacs of their ancestors as well as gills. When ponds dry up, individuals of most species can burrow deep into the mud and survive for many months in an inactive state while breathing air.

It is believed that some early aquatic lobe-limbed vertebrates began to use terrestrial food sources, became more fully adapted to life on land, and eventually evolved to become ancestral **tetrapods** (“four legs”). How was this transition from an animal that swam in water to one that walked on land accomplished? Early in 2006, scientists reported the discovery of a Devonian fossil lobe-limbed vertebrate, since then named *Tiktaalik*, which possessed intermediate appendages between the fins of fishes and the limbs of terrestrial tetrapods (**Figure 33.15C**). It appears that limbs able to prop up a large fish and make the front-to-rear movements necessary for walking evolved while these animals still lived in water. These limbs appear to have functioned in holding the animals upright in shallow water, perhaps even allowing them to hold their head above the water’s surface. These same structures were then co-opted for movement on land, at first probably for foraging on brief trips out of water.

Among the lobe-limbed vertebrates, limbs capable of movement on land evolved from the short, muscular fins of aquatic ancestors (**Figure 33.16**). The resulting four terrestrial limbs give the tetrapods their name. The basic skeletal elements of those limbs can be traced through major changes in limb form and function among the terrestrial vertebrates.

An early split in the tetrapod tree led to two main groups of terrestrial vertebrates: **amphibians**, most of which remained tied to moist environments; and the **amniotes**, many of which adapted to much drier conditions.

Amphibians usually require moist environments

Most modern amphibians are confined to moist environments because they lose water rapidly through the skin when exposed to dry air. In addition, their eggs are enclosed within delicate membranous envelopes that cannot prevent water loss in dry conditions. In some amphibian species, adults live mostly on land but return to fresh water to lay and fertilize their eggs (**Figure 33.17**). The fertilized eggs give rise to larvae that live in water until they undergo metamorphosis to become terrestrial adults. However, many amphibians (especially those in tropical and subtropical areas) have evolved a wide variety of additional reproductive modes and types of parental care, as described in the opening of this chapter. Internal fertilization, for example, evolved

33.16 Tetrapod Limbs Are Modified Fins The major skeletal elements of the tetrapod limb were already present in aquatic lobe-limbed fishes some 380 million years ago. The relative sizes and positions of these elements changed as lobe-limbed vertebrates moved to a terrestrial environment, where limbs were needed to support and move the animal’s body on land.

many times among amphibian species. Many species develop directly into adultlike forms from fertilized eggs laid on land or carried by the parents. Other species of amphibians are entirely aquatic, never leaving the water at any stage of their lives, and many of these species retain a larval-like morphology.

The more than 7,000 known species of amphibians living today belong to three major groups: the wormlike, limbless, tropical, burrowing, or aquatic caecilians (**Figure 33.18A**), the tailless frogs and toads (collectively called anurans; **Figure 33.18B**), and the tailed salamanders (**Figure 33.18C and D**).

Anurans are most diverse in wet tropical and warm temperate regions, although a few are found at very high latitudes. There are far more anurans than any other amphibians, with well over 6,000 described species and more being discovered every year. Some anurans have tough skins and other adaptations that enable them to live for long periods in deserts, whereas others live in moist terrestrial and arboreal environments. Some species are completely aquatic as adults. All anurans have a short vertebral column and a pelvic region that is

33.17 In and Out of the Water Many amphibian species have life cycles like the one diagrammed here, in which the early stages take place in water and the aquatic tadpole transforms into a terrestrial adult through metamorphosis. Some species of amphibians, however, have direct development (with no aquatic larval stage), and others are aquatic throughout life.

modified for leaping, hopping, or propelling the body through water by kicking the hind legs.

The more than 600 described species of salamanders are most diverse in temperate regions of the Northern Hemisphere and in cool, moist environments in the mountains of Central America, although a few species penetrate into tropical regions. Many salamanders live in rotting logs or moist soil. One major group has lost the lungs, and these species exchange gases entirely through the skin and mouth lining—body parts that all amphibians use, in addition to their lungs, for gas exchange. A completely aquatic lifestyle has evolved several times among the salamanders (see Figure 33.18D). These aquatic species have arisen through a developmental process known as **neoteny**, or the retention of juvenile traits (in this case, gills) by delayed somatic development. Most species of salamanders have internal fertilization, which is usually achieved through the transfer of a small, jellylike, sperm-embedded capsule called a spermatophore.

Many amphibians have complex social behaviors. Most male anurans utter loud, species-specific calls to attract females of their own species (and sometimes to defend breeding territories), and they compete for access to females that arrive at the breeding sites. Many amphibians lay large numbers of eggs, which they abandon once they are deposited and fertilized. As described in the opening of this chapter, however, other amphibians lay only a few eggs, which are fertilized and then cared for. A few species of frogs, salamanders, and caecilians are viviparous, meaning that they give birth to well-developed young that have received nutrition from the female during gestation.

 Answering a Mating Call
Life10e.com/mc33.4

Amphibians are the focus of much attention today because populations of many species are declining rapidly, especially in mountainous regions of western North America, Central and South America, and northeastern Australia. Worldwide, about one-third of amphibian species are now threatened with

extinction or have disappeared completely in the last few decades (as happened with the gastric brooding frogs described at the opening of this chapter). Scientists are investigating several hypotheses to account for these population declines, as described in Chapters 1 and 30.

Amniotes colonized dry environments

Several key innovations for conserving water contributed to the ability of the amniotes to exploit a wide range of terrestrial habitats. The **amniote egg** (which gives the group its name) is relatively impermeable to water and allows the embryo to develop in a contained aqueous environment (Figure 33.19A). Its leathery or brittle, calcium-impregnated shell retards evaporation of the fluids inside but permits passage of oxygen and carbon dioxide. The amniote egg also stores large quantities of food in the form of **yolk**, allowing the embryo to attain a relatively advanced state of development before it hatches. Within the shell are **extraembryonic membranes** that protect the embryo from desiccation and assist it with gas exchange and excretion of nitrogenous waste products of metabolism.

In several different groups of amniotes, modifications of the amniote egg allowed the embryo to develop inside (and exchange nutrients and wastes with) its mother's body (Figure 33.19B). In most mammals the egg lost its shell entirely while the functions of the extraembryonic membranes were retained and expanded; we will examine the roles of these membranes in detail in Section 44.5.

Other innovations evolved in the organs of terrestrial adults. A tough, impermeable skin, covered with scales or modifications of scales such as hair and feathers, greatly reduced water loss. Adaptations of the vertebrate excretory organs, called kidneys, allowed amniotes to excrete concentrated urine, ridding the body of nitrogenous wastes without losing a large amount of water in the process (see Chapter 52).

During the Carboniferous, the amniotes split into two major groups: the **reptiles** and the lineage that eventually led to the **mammals** (Figure 33.20).

33.20 Phylogeny of Amniotes This tree of amniote relationships shows the primary split between mammals and reptiles. The reptile portion of the tree shows that one lineage led to the lepidosaurs (snakes, lizards, and tuataras), another to the turtles, and a third to the archosaurs (the crocodiles, several extinct groups, and the birds).

Reptiles adapted to life in many habitats

The lineage leading to modern reptiles began to diverge from other amniotes more than 300 million years ago. More than 19,000 species of reptiles exist today, more than half of which are birds. Birds are the only living representatives of the otherwise extinct dinosaurs, the dominant terrestrial predators of the Mesozoic.

The **lepidosaurs** constitute the second most species-rich clade of living reptiles. This group is composed of the **squamates** (lizards, snakes, and amphisbaenians—the last a group of mostly legless, wormlike, burrowing reptiles with greatly reduced eyes) and the **tuataras**, which superficially resemble lizards but differ from them in tooth attachment and several internal anatomical features. Many species related to the tuataras lived during the Mesozoic era, but today only two species survive (**Figure 33.21A**), and these are restricted to a few islands off New Zealand.

The skin of a lepidosaur is covered with horny scales that greatly reduce loss of water from the body surface. These scales, however, make the skin unavailable as an organ of gas exchange. Gases are exchanged almost entirely via the lungs, which are proportionally much larger in surface area than those of amphibians. A lepidosaur forces air into and out of its lungs by bellows-like movements of its ribs. The three-chambered lepidosaur heart partially separates oxygenated blood from the lungs from deoxygenated blood returning from the body. With this type of heart, lepidosaurs can generate high blood pressure and can sustain a relatively high metabolism.

Most lizards are insectivores, although some are herbivores and a few prey on other vertebrates. Most lizards walk on four limbs (**Figure 33.21B**), although limblessness has evolved repeatedly among the lizards, especially in burrowing and grassland species. The largest lizard is the predaceous Komodo

dragon of the East Indies, which grows as long as 3 meters and can weigh more than 150 kilograms.

Go to Media Clip 33.5

Komodo Dragons Bring Down Prey

Life10e.com/mc33.5

The major group of limbless squamates is the snakes (**Figure 33.21C**). All snakes are carnivores, and many can swallow objects much larger than themselves. Several snake groups evolved venom glands and the ability to inject venom rapidly into their prey.

The **turtles** comprise a reptilian group that has changed relatively little since the early Mesozoic. In these reptiles, dorsal and ventral bony plates form a shell into which the head and limbs can be withdrawn in many species (**Figure 33.21D**). The dorsal shell is a modification of the ribs. It is a mystery how the pectoral girdles evolved to be inside the ribs of turtles, making them unlike any other vertebrates. Most turtles live in aquatic environments, but several groups, such as tortoises and box turtles, are terrestrial. Sea turtles spend their entire lives at sea except when they come ashore to lay eggs. Human exploitation of sea turtles and their eggs has resulted in worldwide declines of these species, all of which are now endangered. A few species of turtles are strict herbivores or carnivores, but most species are omnivores that eat a variety of aquatic and terrestrial plants and animals.

Crocodilians and birds share their ancestry with the dinosaurs

Another reptilian clade, the **archosaurs**, includes the crocodilians, pterosaurs, dinosaurs, and birds. Only the crocodilians and birds are represented by living species today. Modern **crocodilians**—crocodiles, caimans, gharials, and alligators—are

(A) *Sphenodon punctatus*(B) *Eublepharis macularius*(C) *Diadophis punctatus*(D) *Chelonoidis nigra abingdonii*

33.21 Reptilian Diversity (A) This tuatara represents one of only two surviving species in its lineage. (B) The leopard gecko, a desert-dwelling lizard native to Afghanistan, Pakistan, and northwestern India. (C) The ringneck snake of North America is nonvenomous. It

coils its tail to reveal a bright orange underbelly, which distracts potential predators from the vital head region. (D) Galápagos tortoises are the largest turtles and among the largest reptiles. They have been documented to live for more than 100 years in the wild.

confined to tropical and warm temperate environments (**Figure 33.22A**). All crocodilians are carnivorous; they eat vertebrates of all kinds, including large mammals. Crocodilians spend much of their time in water, but they lay their eggs in nests they build on land or on floating piles of vegetation. The eggs are warmed by heat generated by decaying organic matter that the female places in the nest. The female provides other forms of parental care as well: typically she guards the eggs until they hatch, and in some species she continues to guard and communicate with her offspring after they hatch.

Dinosaurs rose to prominence about 215 million years ago and dominated terrestrial environments for about 150 million years. However, only one group of dinosaurs, the **birds**, survived the mass extinction at the end of the Cretaceous. During the Mesozoic, most terrestrial animals more than a meter long were dinosaurs. Many were agile and could run rapidly; they had special muscles that enabled the lungs to be filled and emptied while the limbs moved. We can infer the existence of such muscles in dinosaurs from the structure of the vertebral column in fossils. Some of the largest dinosaurs weighed as much as 70,000 kilograms.

Biologists have long accepted the phylogenetic position of birds among the reptiles, although birds clearly have many

unique, derived morphological features. In addition to the strong morphological evidence for this placement, fossil and molecular data emerging over the last few decades have provided definitive supporting evidence. Birds are a specialized group of **theropods**, a clade of predatory dinosaurs that shared such traits as a bipedal stance, hollow bones, a furcula (“wishbone”), elongated metatarsals with three-fingered feet, elongated forelimbs with three fingers, and a pelvis that points backward. Modern birds are endothermic, meaning that they regulate their body temperatures by producing and retaining metabolic heat, rather than by absorbing heat from their external environment (see Section 40.5). Although we cannot directly assess this physiological trait in extinct species, many fossil theropods share morphological traits that suggest they may have been endothermic as well.

The living bird species fall into two major groups that diverged about 80 to 90 million years ago from a flying ancestor. The few modern descendants of one lineage include a group of secondarily flightless and weakly flying birds, some of which are very large. This group, called the palaeognaths, includes the South and Central American tinamous and several large flightless birds of the southern continents—the rheas, emu, kiwis, cassowaries, and the world’s largest bird, the ostrich (**Figure 33.22B**). The

(B) *Struthio camelus*

33.22 Archosaurs The two surviving groups of archosaurs are very different. (A) The crocodilians live in tropical and warm temperate climates. This crocodile species lives in saltwater and estuarine environments along Australia's coast. (B) Birds are the only other living archosaur group, represented here by the winged but flightless ostrich.

second lineage, the neognaths, has left a much larger number of descendants, most of which have retained the ability to fly.

Feathers allowed birds to fly

Fossil theropods discovered recently in early Cretaceous deposits in Liaoning Province, in northeastern China, show that the scales of some small predatory dinosaurs were highly modified to form **feathers**. Initially these feathers were simply a body covering that probably provided insulation and enhanced coloration. But the feathers of some later dinosaurs, such as *Microraptor gui*, were structurally similar to those of modern birds (**Figure 33.23A**).

Another theropod that was even more closely related to modern birds, *Archaeopteryx*, lived about 150 million years ago. *Archaeopteryx* had teeth (unlike modern birds), but it was covered with feathers that are virtually identical to those of birds (**Figure 33.23B**). It also had well-developed wings, a long tail, and a furcula to which some of the flight muscles were probably attached. *Archaeopteryx* had clawed fingers on its forelimbs, but it also had typical perching bird claws on its hindlimbs. It probably lived in trees and shrubs and used the fingers to assist it in clambering over branches. It probably glided or flew weakly. The descendants of *Archaeopteryx* and similar Mesozoic theropods were the modern birds, most of which are accomplished fliers.

Go to Media Clip 33.6
Falcons in Flight
Life10e.com/mc33.6

The evolution and specialization of feathers was a major force for diversification. Feathers are lightweight, but they are strong and structurally complex (**Figure 33.24**). The stiff central shaft of the flight feathers on a bird's wings arise from the skin of the forelimbs to create the flying surfaces. Other strong feathers sprout like a fan from the shortened tail and serve as stabilizers during flight. The feathers that cover the body, along with an underlying layer of down feathers, provide birds with insulation that helps them survive in virtually all of Earth's climates.

The bones of theropod dinosaurs, including birds, are hollow with internal struts that increase their strength. Hollow bones would have made early theropods lighter and more mobile; later they facilitated the evolution of flight. The sternum (breastbone) of flying birds forms a large, vertical keel to which the flight muscles are attached.

Flight is metabolically expensive. A flying bird consumes energy at a rate about 15 to 20 times faster than a running lizard of the same weight. Because birds have such high metabolic rates, they generate large amounts of heat. They control the rate of heat loss using their feathers, which may be held close to the body or elevated to alter the amount of insulation they provide. The lungs of birds allow air to flow through unidirectionally rather than pumping air in and out (see Section 49.2). This

33.23 Mesozoic Bird Relatives Fossils support the evolution of birds from other theropods. (A) *Microraptor gui* was a feathered theropod from the early Cretaceous (about 140 mya). (B) *Archaeopteryx* was even more closely related to modern birds.

33.24 Feather Anatomy The flight feathers of birds are attached to the wing's skin by the hollow portion, or quill, of a stiff central shaft. The rachis is the solid portion of the shaft from which radiate fine branches (vanes) with interlocking hooks and barbules. Overall, this structure represents a major evolutionary innovation: a strong, lightweight surface that enables flight.

flow-through structure of the lungs increases the efficiency of gas exchange and thereby supports a high metabolic rate.

There are about 10,000 species of living birds, which range in size from the 150-kilogram ostrich to a tiny hummingbird weighing only 2 grams (**Figure 33.25**). The teeth so prominent among other dinosaurs were secondarily lost in the ancestral birds, but birds nonetheless eat almost all types of animal and plant material. Insects and fruits are the most important dietary items for terrestrial species. Birds also eat seeds, nectar and pollen, leaves and buds, carrion, and other vertebrates. By eating the fruits and seeds of plants, birds serve as major agents of seed dispersal.

Mammals radiated after the extinction of non-avian dinosaurs

Small and medium-sized mammals coexisted with the large dinosaurs throughout most of the Mesozoic era, and most of the major groups of mammals that are alive today arose in the Cretaceous. After the non-avian dinosaurs disappeared during the mass extinction at the end of the Cretaceous, mammals increased dramatically in numbers, diversity, and size. Today mammals range in size from tiny shrews and bats weighing only about 2 grams to the blue whale, the largest animal on Earth, which measures up to 33

(D) *Eudocimus ruber*

meters long and can weigh as much as 160,000 kilograms. Mammals have far fewer, but more highly differentiated, teeth than do fishes, amphibians, or reptiles. Differences among mammals in the number, type, and arrangement of teeth reflect their varied diets (see Figure 51.6).

Four key features distinguish the mammals:

- *Sweat glands*, which secrete sweat that evaporates and thereby cools an animal
- *Mammary glands*, which in females secrete a nutritive fluid (milk) on which newborn individuals feed
- *Hair*, which provides a protective and insulating covering
- A *four-chambered heart* that completely separates the oxygenated blood coming from the lungs from the deoxygenated blood returning from the body (this last characteristic is convergent with the archosaurs, including modern birds and crocodiles)

Mammalian eggs are fertilized within the female's body, and in nearly all mammalian groups the resulting embryos undergo a period of development inside the female's body in an organ called the uterus. In the uterus, the embryo is contained in an amniotic sac that is homologous to one of the three membranes found in the amniote egg (see Figure 33.19). The embryo is connected to the wall of the uterus by an organ called a placenta. The placenta allows for nutrient and gas exchange, as well as waste elimination from the developing embryo, via the female's circulatory system. Most mammals develop a covering of hair (fur), which is luxuriant in some species but has been greatly reduced in others, including cetaceans (whales and dolphins) and humans. Thick layers of insulating fat (blubber) replace hair as a heat-retention mechanism in the cetaceans; humans learned to use clothing for this purpose when they dispersed from warm tropical areas.

The approximately 5,700 species of living mammals are divided into two primary groups: the **prototherians** and the **therians** (Table 33.1). Members of the therian clade are further divided into the **marsupials** and the **eutherians**.

PROTOTHERIANS Only five species of prototherians are known, and they are found only in Australia and New Guinea. These mammals, the duck-billed platypus and four species of echidnas, differ from other mammals in laying shelled eggs and having sprawling legs (Figure 33.26). Prototherians supply milk for their young, but they have no nipples on their mammary glands; the milk simply oozes out and is lapped off the fur by the offspring.

MARSUPIALS Females of most marsupial species have a ventral pouch in which they carry and feed their offspring (see Figure 33.27A). Gestation (pregnancy) in marsupials is brief; the young are born tiny but with well-developed forelimbs, with which they climb to the pouch. They attach to a nipple but cannot suck. The mother ejects milk into the tiny offspring until it grows large enough to suckle. Once her offspring have left the uterus, a female marsupial may become sexually receptive again. She can then carry fertilized eggs that are capable

(A) *Tachyglossus aculeatus*

33.26 Prototherians (A) The short-beaked echidna is one of four surviving species of echidnas. (B) The duck-billed platypus lives in freshwater streams in eastern Australia.

of initiating development to replace the offspring in her pouch should something happen to them.

At one time marsupials were found on all continents, but the approximately 350 living species are now restricted to Australasia (Figure 33.27A and B) and the Americas (especially South America; Figure 33.27C). Of the seven major groups of marsupials shown in Table 33.1, only the New World opossums, the shrew opossums, and the diminutive monito del monte are found in the Americas. Only one species, the Virginia opossum, is found in North America north of Mexico. Marsupials radiated to become herbivores, insectivores, and carnivores, but no marsupials live in the oceans. None can fly, although some arboreal (tree-dwelling) marsupials are gliders. The largest living marsupials are the kangaroos of Australia, which can weigh up to 90 kilograms. Much larger marsupials existed in Australia until humans exterminated them soon after reaching that continent about 40,000 years ago.

EUTHERIANS The majority of mammals are eutherians ("true" therians). Eutherians are sometimes called placental mammals, but this name is inappropriate because some marsupials also have placentas. Eutherians are more developed at birth than are marsupials; no external pouch houses them after they are born.

The more than 5,300 species of living eutherians are divided into 20 major groups (see Table 33.1). The relationships of these groups to one another have been difficult to determine because most of the major groups diverged within a short time during an explosive adaptive radiation. Modern genomic analyses have elucidated these relationships, however (Figure

TABLE 33.1
Major Groups of Living Mammals

Group	Number of Described Species	Examples
PROTOTHERIANS		
Monotremes (Monotremata)	5	Echidnas, duck-billed platypus
THERIANS		
Marsupials		
Diprotodonts (Diprotodontia)	146	Kangaroos, wallabies, possums, koala, wombats
New World opossums (Didelphimorphia)	93	Opossums
Carnivorous marsupials (Dasyuromorphia)	72	Quolls, dunnarts, numbat, Tasmanian devil
Omnivorous marsupials (Peramelemorphia)	22	Bandicoots and bilbies
Shrew opossums (Paucituberculata)	7	Andean rat opossums
Marsupial moles (Notoryctemorphia)	2	Southern and northern marsupial moles
Microbiothere (Microbiotherea)	1	Monito del monte
Eutherians		
Rodents (Rodentia)	2,337	Rats, mice, squirrels, woodchucks, ground squirrels, beaver, capybara
Bats (Chiroptera)	1,171	Fruit bats, echo-locating bats
Even-toed hoofed mammals and cetaceans (Cetartiodactyla)	469	Deer, sheep, goats, cattle, antelopes, giraffes, camels, swine, hippopotamus, whales, dolphins
Shrews, moles, and relatives (Soricomorpha)	428	Shrews, moles, solenodons
Primates (Primates)	396	Lemurs, monkeys, apes, humans
Carnivores (Carnivora)	284	Wolves, dogs, bears, cats, weasels, pinnipeds (seals, sea lions, walruses)
Rabbits and relatives (Lagomorpha)	92	Rabbits, hares, pikas
African insectivores (Afrosoricida)	50	Tenrecs, golden moles
Hedgehogs (Erinaceomorpha)	24	European hedgehog
Armadillos (Cingulata)	21	Giant armadillo, nine-banded armadillo
Tree shrews (Scandentia)	20	Pygmy tree shrew, pen-tailed tree shrew
Odd-toed hoofed mammals (Perissodactyla)	16	Horses, zebras, tapirs, rhinoceroses
Elephant shrews (Macroscelidea)	15	Elephant shrews, jumping shrews, sengis
Anteaters, sloths (Pilosa)	10	Anteaters, tamanduas, two- and three-toed sloths
Pangolins (Pholidota)	8	Asian and African pangolins
Hyraxes and relatives (Hyracoidea)	5	Hyraxes, dassies
Sirenians (Sirenia)	4	Manatees, dugongs
Elephants (Proboscidea)	3	African and Indian elephants
Colugos (Dermoptera)	2	Flying lemurs
Aardvark (Tubulidentata)	1	Aardvark

33.28). These studies have revealed that the major early splits in eutherian lineages are closely associated with the breakup of the continents during the Mesozoic (see Figure 25.14), after which the major groups of mammals radiated independently in Laurasia, Africa, and South America. The reconnection of South America and North America via the Panamanian land

bridge about 3 million years ago resulted in a huge faunal exchange between those continents, which is particularly evident among the mammals. South American groups such as armadillos moved north into North America, and Laurasian groups such as carnivores and odd- and even-toed hoofed animals moved south into South America.

(A) *Macropus giganteus*

(B) *Macrotis lagotis*

(C) *Didelphis virginiana*

33.27 Diversity among the Marsupials

(A) Australia’s eastern gray kangaroo is among the largest living marsupials. This female carries her young offspring in the characteristic marsupial pouch. (B) The greater bilby of Australia’s arid regions is a nocturnal omnivore. The bilby does not require drinking water, obtaining the moisture it needs from its various food items. (C) The North American opossum is the only marsupial found north of Mexico.

Eutherians are extremely varied in their form and ecology (Figure 33.29). The extinction of the non-avian dinosaurs at the end of the Cretaceous may have made it possible for them to diversify and radiate into a large range of ecological niches. Many eutherian species grew large, and some assumed the roles of dominant terrestrial predators previously occupied by the large dinosaurs. Among these predators, social hunting

behavior evolved in several species, including members of the carnivore and primate clades.

The two most diverse groups of eutherians are the rodents and the bats, which together comprise about two-thirds of the species. Rodents are traditionally defined by the unique morphology of their teeth, which are adapted for gnawing through substances such as wood. The bats probably owe much of their

33.28 Major Groups of Eutherians Diversified as the Continents Drifted Apart

This phylogenetic tree shows the relationships among most of the major terrestrial eutherian groups, the location of the earliest fossils found for each group (also indicated in the color distinctions of the various branches), and the current distributions of the groups. The major splits in eutherian evolution correspond in large degree to the tectonic history of the major continents (see Figures 25.14 and 54.12).

(A) *Castor canadensis*(B) *Macroderma gigas*(C) *Rangifer tarandus*(D) *Stenella longirostris*

33.29 Diversity among the Eutherians (A) The North American beaver exhibits the gnawing teeth that characterize rodents. Almost half of all eutherians are rodents. (B) Flight evolved in the ancestor of bats. This ghost bat is endemic to Australia; bats and rodents are the only eutherian groups native to that continent. (C) Large hoofed mammals such as reindeer are important herbivores in terrestrial environments. Although this bull is grazing by himself, reindeer are usually found in huge herds. (D) Spinner dolphins are cetaceans, a cetartiodactyl group that returned to the marine environment.

success to the evolution of flight, which allows them to exploit a variety of food sources and colonize remote locations with relative ease.

Go to Media Clip 33.7
Bats Feeding in Flight
Life10e.com/mc33.7

Grazing and browsing by members of several eutherian groups helped transform the terrestrial landscape. Herds of grazing herbivores fed on open grasslands, whereas browsers fed on shrubs and trees. The effects of these herbivores on plant life favored the evolution of the spines, tough leaves, and difficult-to-eat growth forms found in many plants. In turn, adaptations in the teeth and digestive systems of many herbivore lineages allowed these species to consume many plants despite such defenses—a striking example of coevolution. A large animal can survive on food of lower quality than a small animal can, and large size evolved in several groups of grazing and browsing mammals (see Figure 33.29C). The evolution of large herbivores, in turn, favored the evolution of large carnivores able to attack and overpower them.

Several lineages of terrestrial eutherians subsequently returned to the aquatic environments their ancestors had left

behind (see Figure 33.29D). The completely aquatic cetaceans—whales and dolphins—evolved from even-toed hoofed ancestors (whales are closely related to the hippopotamuses). The seals, sea lions, and walruses also returned to the marine environment, and their limbs became modified into flippers. Weasel-like otters retain their limbs but have also returned to aquatic environments, colonizing both fresh and salt water. The manatees and dugongs colonized estuaries and shallow seas.

RECAP 33.4

The initial vertebrate colonization of dry land was facilitated by the evolution of lunglike sacs and jointed limbs. The amniotes evolved impermeable body coverings, efficient kidneys, and the amniote egg, which resists desiccation.

- What are the similarities and differences between a shelled amniote egg laid by a reptile and the retained amniotic sac of a mammal? **See p. 692 and Figure 33.19**
- How has the diversification of mammals been influenced by mass extinction events and continental drift? **See pp. 697–698 and Figure 33.28**

The biology of one eutherian group—the primates—has been the subject of extensive research. The behavior, ecology,

physiology, and molecular biology of the primates are of special interest to us because this lineage includes humans.

33.5 What Traits Characterize the Primates?

One lineage of small, arboreal, insectivorous eutherians underwent extensive evolutionary radiation to become the **primates** (Figure 33.30). A nearly complete fossil of an early primate, *Carpolestes*, found in Wyoming, was dated at 56 million years ago; it had grasping feet with an opposable big toe that had a nail rather than a claw. Grasping limbs with opposable digits, an adaptation to arboreal life, are one of the major features that distinguish primates from other mammals.

Two major lineages of primates split late in the Cretaceous

About 90 million years ago, late in the Cretaceous period, the primates split into two clades: the **prosimians** and the **anthropoids**.

Prosimians—lemurs, lorises, and galagos—once lived on all continents, but today they are restricted to Africa, Madagascar, and tropical Asia. All mainland prosimian species are arboreal and nocturnal. On the island of Madagascar, however, the site of a remarkable radiation of lemurs, there are also diurnal and terrestrial species (Figure 33.31). Tarsiers were once considered prosimians as well, although today we know that they are more closely related to monkeys and apes than to lemurs, lorises, and galagos.

The second primate lineage, the **anthropoids**—tarsiers, New World monkeys, Old World monkeys, and apes—began to diversify shortly after the mass extinction event at the end of the Cretaceous, in Africa or Asia. New World monkeys diverged from Old World monkeys and apes slightly later, but early enough that they may have originated in Africa and reached South America when those two continents were still close to each other. New World monkeys now live only in South and Central America, and all of them are arboreal (Figure 33.32A). Many of them have a long, prehensile tail with which they can grasp branches. Many Old World monkeys are arboreal as well, but several species are terrestrial (Figure 33.32B). No Old World monkey has a prehensile tail.

About 35 million years ago, a lineage that led to the modern apes separated from the Old World monkeys. Between 22 and 5.5 million years ago, dozens of species of apes lived in Europe, Asia, and Africa. The

33.30 Phylogeny of the Primates The phylogeny of primates is among the best studied of any major group of mammals. This tree is based on evidence from many genes, morphology, and fossils.

Propithecus diadema

33.31 A Prosimian The diademed sifaka is one of the many lemur species found in Madagascar, where it is part of a unique assemblage of endemic plants and animals. Sifakas live in groups of up to a dozen animals and defend their territories.

(A) *Ateles geoffroyi*(B) *Mandrillus sphinx*

33.32 Monkeys (A) The spider monkeys of Central America are typical of the New World monkeys, all of which are arboreal. Note the prehensile (gripping) tail. (B) Although many Old World monkeys are arboreal, none has a prehensile tail. Many Old World monkey species, like this mandrill, are thoroughly terrestrial.

Asian apes—gibbons and orangutans (**Figure 33.33A and B**)—descended from two of these ape lineages. Orangutans are the closest living sister group of the modern African apes: gorillas (**Figure 33.33C**), chimpanzees (**Figure 33.33D**), and humans.

Bipedal locomotion evolved in human ancestors

About 6 million years ago in Africa, a lineage split occurred that would lead to the chimpanzees on the one hand and to the **hominin** clade, which includes modern humans and their extinct close relatives, on the other.

The earliest protohominins, known as ar-dipithecines, had distinct morphological adaptations for **bipedal locomotion** (walking on two legs). Bipedal locomotion frees the forelimbs to manipulate objects and to carry them while walking. It also elevates the eyes, enabling the animal to see over tall vegetation to spot predators and prey. Bipedal locomotion is also energetically more economical than

(A) *Hylobates lar*(B) *Pongo pygmaeus*(C) *Gorilla gorilla*(D) *Pan troglodytes*

33.33 Apes (A) The several genera of gibbons are all smaller in size than the other apes. Gibbons are found throughout southeastern Asia. (B) Orangutans are also native to Asia, living in the forests of Sumatra and Borneo. (C) Gorillas—the largest apes—are restricted to humid African forests. This male is a lowland gorilla. (D) Chimpanzees, our closest relatives, are found in forested regions of Africa.

33.34 A Phylogenetic Tree of Hominins At times in the past, more than one hominin species lived on Earth at the same time. Originating in Africa, hominins spread to Europe and Asia multiple times. All

but one of those species are now extinct, but that one species, modern *Homo sapiens*, has colonized nearly every corner of the planet.

quadrupedal locomotion (walking on four legs). All three advantages were probably important for the ardipithecines and their descendants, the australopithecines (**Figure 33.34**).

The first australopithecine skull was found in South Africa in 1924. Since then australopithecine fossils have been found at many sites in Africa. The most complete fossil skeleton yet found was discovered in Ethiopia in 1974. The skeleton, approximately 3.5 million years old, was that of a young female who has since become known to the world as “Lucy.” Lucy was assigned to the species *Australopithecus afarensis*. Fossil remains of more than 100 *A. afarensis* individuals have since been discovered, and there have been recent discoveries of fossils of other australopithecine species that lived in Africa 4 to 5 million years ago.

Experts disagree over how many species are represented by australopithecine fossils, but it is clear that multiple species of hominins lived together over much of eastern Africa several million years ago. A lineage of larger species (weighing about 40 kilograms) is represented by *Paranthropus robustus* and *P. boisei*, both of which died out between 1 and 1.5 million years ago. A lineage of smaller australopithecines gave rise to the genus *Homo*.

Early members of the genus *Homo* lived contemporaneously with *Paranthropus* in Africa for about a million years. Some 2-million-year-old fossils of an extinct species called *H. habilis* were discovered in the Olduvai Gorge, Tanzania. Other fossils of *H. habilis* have been found in Kenya and Ethiopia. Associated with these fossils were tools that these early hominins used to obtain food.

Another extinct hominin species, *Homo erectus*, arose in Africa about 1.6 million years ago. Soon thereafter it had spread as far as eastern Asia, becoming the first hominin to leave Africa. Members of *H. erectus* were nearly as large as modern people, but their brains were smaller and they had comparatively thick skulls. The cranium, which had thick, bony walls, may have been an adaptation to protect the brain, ears, and eyes from impacts caused by a fall or a blow from a blunt object. What would have been the source of such blows? Fighting with other *H. erectus* individuals is a possible answer.

Homo erectus used fire for cooking and for hunting large animals, and made characteristic stone tools that have been found in many parts of Africa and Asia. Populations of *H. erectus* survived until at least 250,000 years ago, although more recent fossils may also be attributable to this species. In 2004 some 18,000-year-old fossil remains of a small *Homo* were found on

33.35 Neoteny in the Evolution of Humans

The skulls and heads of juvenile chimpanzees and humans start out relatively similar in shape. The grid over the skulls shows how the various bony elements change in their relative proportions over the course of maturation. The adult human skull retains a shape closer to its juvenile shape, resulting in a brain that is much larger relative to other parts of the skull (notably the jaw).

The skulls of juvenile chimpanzees and humans are quite similar to each other.

Pan

Homo

The chimp skull undergoes much more dramatic change in development than does the human skull.

the island of Flores in Indonesia. Since then, numerous additional fossils of this diminutive hominin have been found on Flores, dating from 95,000 to 17,000 years ago. Many anthropologists think that this small species, named *H. floresiensis*, was most closely related to *H. erectus*.

Human brains became larger as jaws became smaller

In another hominin lineage that diverged from *H. erectus* and *H. floresiensis*, the brain increased rapidly in size, and the jaw muscles, which were large and powerful in earlier hominins, dramatically decreased in size. These two changes were simultaneous, which suggests that they might have been developmentally linked. These changes are another example of evolution by neoteny (which, you may recall from our discussion of amphibians, is the retention of juvenile traits through delayed somatic development). Human and chimpanzee skulls are similar in shape at birth, but chimpanzee skulls undergo a dramatic change in shape as the animals mature (**Figure 33.35**). In particular, the jaw grows considerably in relation to the brain case. As human skulls grow, relative proportions much closer to those of the juvenile skull are retained, which results in a large brain case and small jaw compared with those of chimpanzees. A mutation in a regulatory gene that is expressed only in the head may have removed a barrier that had previously prevented this remodeling of the human cranium.

The striking enlargement of the brain relative to body size in the hominin lineage was probably favored by an increasingly complex social life. Any features that allowed group members to communicate more effectively with one another would have

been valuable in cooperative hunting and gathering as well as for improving one's status in the complex social interactions that must have characterized early human societies, just as they do ours today.

Several *Homo* species coexisted during the mid-Pleistocene, from about 1.5 million to about 250,000 years ago. All were skilled hunters of large mammals, but plants were important components of their diets as well. During this period another distinctly human trait emerged: rituals and a concept of life after death. Deceased individuals were buried with tools and clothing, supplies for their presumed existence in the next world.

One species, *Homo neanderthalensis*, was widespread in Europe and Asia between about 500,000 and 28,000 years ago. Neanderthals were short, stocky, and powerfully built. Their massive skull housed a brain somewhat larger than our own. They manufactured a variety of tools and hunted large mammals, which they probably ambushed and subdued in close combat. Early modern humans (*H. sapiens*) expanded out of Africa between 70,000 and 60,000 years ago. Then, about 35,000 years ago, *H. sapiens* moved into the range of *H. neanderthalensis* in Europe and western Asia, so the two species must have interacted with each other. Neanderthals abruptly disappeared about 28,000 years ago. Many anthropologists believe that Neanderthals were exterminated by those early modern humans. Scientists have been able to isolate large parts of the genome of *H. neanderthalensis* from recent fossils and compare it with our own. These studies suggest that there was some limited interbreeding between the two species while they occupied the same range. As a result, in humans with Eurasian ancestry, 1 to 4 percent of the genes in their genomes may be derived from Neanderthal ancestors.

Early modern humans made and used a variety of sophisticated tools. They created the remarkable paintings of large mammals, many of them showing scenes of hunting, found in European caves. The animals they depicted were characteristic of the cold steppes and grasslands that occupied much of Europe during periods of glacial expansion. Early modern humans also spread across Asia, reaching North America perhaps as early as 20,000 years ago, although the date of their arrival in the Americas is still uncertain. Within a few thousand years, they had spread southward through North America to the southern tip of South America.

Humans developed complex language and culture

As our ancestors evolved larger brains, their behavioral capabilities increased, especially the capacity for language. Most animal communication consists of a limited number of signals, which refer mostly to immediate circumstances and are associated with charged emotional states induced by those circumstances. Human language is far richer in its symbolic character than other animal vocalizations. Our words can refer to past and future times and to distant places. We are capable of learning thousands of words, many of them referring to abstract concepts. We can rearrange words to form sentences with complex meanings.

The expanded mental abilities of humans enabled the development of a complex culture, in which knowledge and traditions are passed along from one generation to the next by teaching and observation. Cultures can change rapidly because

genetic changes are not necessary for a cultural trait to spread through a population. Cultural norms, however, are not transferred automatically and must be deliberately taught to each generation.

Go to Media Clip 33.8

Humans Develop Complex Social Behaviors

Life10e.com/mc33.8

Cultural transmission greatly facilitated the domestication of plants and animals and the resultant conversion of most human societies from ones in which food was obtained by hunting and gathering to ones in which pastoralism (herding large animals) and agriculture provided most of the food. The development of agriculture led to an increasingly sedentary life, the growth of cities, greatly expanded food supplies, rapid increases in the human population, and the appearance of occupational specializations, such as artisans, shamans, and teachers.

RECAP 33.5

Grasping limbs with opposable digits distinguish primates from other mammals. Bipedal locomotion and large brains evolved in the primate ancestors that led to humans.

- Describe the differences between Old World and New World monkeys. **See p. 701 and Figures 33.32 and 33.33**
- Explain how neoteny resulted in the development of humans with relatively large brains and small jaws. **See p. 704 and Figure 33.35**

How has the evolution of complex behaviors affected the diversification of some major groups of deuterostomes?

ANSWER

Speciation in many groups of vertebrates is closely associated with the diversification of behaviors that are used for mate recognition or mate selection. These behavioral displays can be visual, olfactory, or auditory. Many vertebrate species have elaborate and stereotypical courtship displays, usually performed by males. In some cases these displays involve male-to-male combat, and the winning male mates with any attending females. In other cases a female may watch the displays of several different males and select a mate based on her perception of the quality of the display.

Some vertebrates, including most mammals, rely on olfactory cues to determine mate receptivity and to select mates. Humans have greatly reduced olfactory senses compared with most other mammals, although research has shown that we use more olfactory cues than we realize in selecting potential mates. This is the basis for the \$27.5-billion-per-year perfume industry, which

attempts to create smells that other humans will find sexually attractive.

In other vertebrate groups, such as frogs, mating calls play a primary role in mate selection. The calls are species-specific, but there is often some within-species variation in the calls as well. In many frog species, females can use the pitch of the calls to select larger, older males as mates. Males that are older have demonstrated that they have successful combinations of genes that have allowed them to survive and thrive in the local environment.

Whether mate selection is based on auditory, visual, or olfactory cues, divergence in the signaling system can lead to rapid speciation. Closely related species of frogs may look very similar but have distinctly different calls. Since the females use the calls to select appropriate mates of their own species, evolution of call differences among different populations can lead to rapid reproductive isolation and speciation.

33.1 What Is a Deuterostome?

- Deuterostomes vary greatly in adult form, but based on the distinctive patterns of early development they share and on phylogenetic analyses of their gene sequences, they are judged to be monophyletic.
- There are far fewer species of deuterostomes than of protostomes, but many deuterostomes are large and ecologically important.
- The deuterostomes comprise three major clades: the **echinoderms**, **hemichordates**, and **chordates**. **Review Figure 33.1, ACTIVITY 33.1, ANIMATED TUTORIAL 33.1**

33.2 What Features Distinguish the Echinoderms, Hemichordates, and Their Relatives?

- Echinoderms and hemichordates, together called **ambulacrarians**, have bilaterally symmetrical, ciliated larvae. Adult echinoderms have **pentaradial symmetry** and an **oral-aboral** body orientation. **Review Figure 33.3**
- The **xenoturbellids** and **acoels** are reduced, soft-bodied worm-like marine animals with few distinct organ systems. Their relationships are uncertain, but recent analyses suggest that they may be the sister group of the ambulacrarians.
- Echinoderms have an **internal skeleton** of calcified plates and a unique **water vascular system** connected to extensions called **tube feet**. **Review Figure 33.3**
- Hemichordates are bilaterally symmetrical and have a three-part body divided into a proboscis, collar, and trunk. **Review Figure 33.6**

33.3 What New Features Evolved in the Chordates?

- Chordates fall into three principal clades: **lancelets**, **tunicates**, and **vertebrates**.
- At some stage in their development, all chordates have a dorsal hollow nerve cord, a post-anal tail, and a **notochord**. Lancelets have all three key chordate features as adults. Tunicates have these features as larvae but lose them as adults. **Review Figure 33.7**
- The vertebrate body is characterized by an internal skeleton, which is supported by a **vertebral column** that replaces the notochord. It is also characterized by internal organs suspended in a coelom, a ventral heart, and an anterior skull enclosing a large brain. **Review Figure 33.9**
- From estuarine ancestors, vertebrates diversified into many lineages of marine and freshwater fishes. One of these lineages, the lobe-limbed vertebrates, later radiated into terrestrial environments. **Review Figure 33.10**
- In the **gnathostomes**, jaws evolved from gill arches. Jaws enabled these vertebrates to grasp large prey and, together with teeth, allowed them to cut food into small pieces. **Review Figure 33.12**

- **Chondrichthyans** have skeletons of cartilage; almost all species are marine. The skeletons of **ray-finned fishes** are made of bone; these fishes have colonized all aquatic environments.

33.4 How Did Vertebrates Colonize the Land?

- Lungs and jointed appendages enabled one lineage of **lobe-limbed vertebrates** to colonize the land. This lineage gave rise to the **tetrapods**. **Review Figure 33.16**
- The earliest split in the tetrapod tree is between the **amphibians** and the **amniotes** (**reptiles** and **mammals**).
- Most modern amphibians are confined to moist environments because their bodies and their eggs lose water rapidly. **Review Figure 33.17, ANIMATED TUTORIAL 33.2**
- An impermeable skin, efficient kidneys, and an **amniote egg** that could resist desiccation evolved in the amniotes. **Review Figure 33.19, ACTIVITY 33.2**
- The major living reptile groups are the **lepidosaurs** (**tuataras**, along with the **squamates**, which include lizards, snakes, and amphisbaenians), the **turtles**, and the **archosaurs** (**crocodilians** and **birds**). **Review Figure 33.20**
- Birds evolved from a group of active, predatory dinosaurs known as theropods. Feathers arose among the theropods, originally for insulation and to enhance coloration, but eventually developed into adaptations for flight in birds. **Review Figures 33.23, 33.24**
- Mammals are unique among animals in supplying their young with a nutritive fluid (milk) secreted by mammary glands. There are two primary mammalian clades: the **prototherians** (of which there are only five species) and the species-rich **therians**. The therian clade is further subdivided into the **marsupials** and the **eutherians**. **Review Table 33.1**
- Mammalian phylogeny is strongly associated with the breakup of the major continents during the Mesozoic. Major lineages of eutherians diversified in Laurasia, Africa, and South America. **Review Figure 33.28**

33.5 What Traits Characterize the Primates?

- Grasping limbs with opposable digits distinguish **primates** from other mammals. The **prosimian** clade includes the lemurs, lorises, and galagos; the **anthropoid** clade includes tarsiers, monkeys, and apes. **Review Figure 33.30**
- The ancestors of **hominins** were terrestrial apes that developed efficient **bipedal locomotion**. **Review Figure 33.34**
- In the lineage leading to *Homo*, brains became larger as jaws became smaller; the two events appear to be developmentally linked and are an example of evolution via **neoteny**. **Review Figure 33.35**

See **ACTIVITY 33.3** for a concept review of this chapter.

CHAPTER REVIEW

REMEMBERING

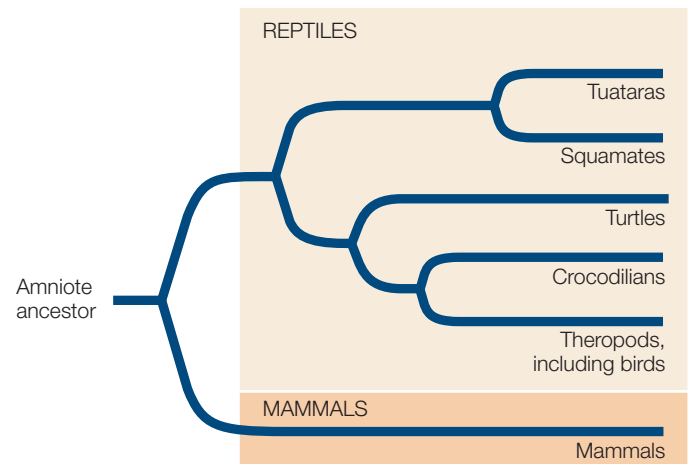

- Which of the following are *not* deuterostomes?
 - Acorn worms
 - Sea stars
 - Tunicates
 - Brachiopods
 - Lancelets
- The structure used by adult tunicates to capture food is a
 - pharyngeal basket.
 - proboscis.
 - lophophore.
 - mucus net.
 - radula.
- In most ray-finned fishes, lunglike sacs evolved into
 - pharyngeal gill slits.
 - true lungs.
 - coelomic cavities.
 - swim bladders.
 - none of the above
- The horny scales that cover the skin of reptiles prevent them from
 - using their skin as an organ of gas exchange.
 - sustaining high levels of metabolic activity.
 - laying their eggs in water.
 - flying.
 - crawling into small spaces.
- Which statement about bird feathers is *not* true?
 - They are highly modified reptilian scales.
 - They provide insulation for the body.
 - They exist in two layers.
 - They help birds fly.
 - They are important sites of gas exchange.
- The relatively large brain case and small jaw of humans relative to chimpanzees is an example of
 - genetic drift.
 - neoteny.
 - concerted evolution.
 - cultural transfer.
 - none of the above

UNDERSTANDING & APPLYING

- The body plan of most vertebrates is based on four appendages. What are the varied forms that these appendages take, and how are they used? In which lineages have two or more of these appendages been lost?
- Amphibians have survived and prospered for millions of years, but today many species are disappearing, and populations of others are declining seriously. What features of their life histories might make amphibians especially vulnerable to the kinds of environmental changes now happening on Earth?
- In the not-too-distant past, the idea that birds were reptiles met with skepticism. Explain how fossils, morphology, and molecular evidence now support the position of birds among the reptiles.

ANALYZING & EVALUATING

- On the phylogenetic tree of amniotes (below), map the evolutionary origin of the following traits: endothermy, hair, and feathers. Which of these traits appears to have evolved convergently in more than one lineage? What is a likely functional relationship among these traits? What are some reasons why many paleontologists think many extinct theropods were endothermic?

The Plant Body

CHAPTER OUTLINE

- 34.1** What Is the Basic Body Plan of Plants?
- 34.2** What Are the Major Tissues of Plants?
- 34.3** How Do Meristems Build a Continuously Growing Plant?
- 34.4** How Has Domestication Altered Plant Form?

TO NORTH AMERICANS AND EUROPEANS, it is tapioca. To Central and South Americans, it is yuca. To Africans, it is manioc or bananku. The roots of the cassava plant, *Manihot esculenta*, are important in the diets of more than 800 million people. Cassava is grown mostly by family farmers for their own consumption. The root of the plant is a store of starch, which can be hydrolyzed and used by the plant as the stems and leaves grow. Other crop plants such as rice and wheat apportion about 35 percent of the total carbon fixed in photosynthesis into their storage organs (the grains), whereas cassava is a “starch factory,” apportioning an astounding 80 percent of the plant’s total photosynthate into the root. For humans, this is a convenient and concentrated source of food energy. Indeed, cassava has been nicknamed the “bread of the tropics” because, just as wheat bread is the major starchy food in the Western world, cassava supplies the starch in tropical areas.

Most cassava plants are clones. The plants have wide adaptability and grow well in dry soils, in both hot and cool climates. Typically, the farmer breaks off some pieces of stem and plants them. Some of the stem cells dedifferentiate and form roots, while others become growing shoots. A whole new plant develops, and the roots are ready to eat 6 months to 2 years later. It’s a fairly easy process, much simpler than the work needed to grow rice, for example. As we pointed out in Chapter 19, totipotency is a remarkable property of plant cells, one that distinguishes them from animal cells.

There are countless recipes for preparing cassava as food. Cassava does not, however, offer complete nutrition. Although rich in carbohydrates, cassava is a

Cassava The roots of this plant supply food energy to hundreds of millions of people.

relatively poor source of protein, a requirement for the human diet. A diet based on cassava presents other difficulties as well. Cassava roots and leaves contain cyanogenic compounds, which are converted to cyanide by digestive enzymes and gut flora. Cyanide is highly toxic and potentially lethal because it blocks electron transport in the mitochondria. Therefore it is essential to soak, cook, or ferment cassava, to break down the cyanogenic compounds and eliminate the cyanide, before it can be eaten safely. In all probability, the plant uses cyanide production as a protection against predators that eat it.

We open with the topic of cassava because it offers a preview of a wide range of studies embraced by the discipline of plant physiology. Plant physiology is a broad subject, covering photosynthesis, transport, plant nutrition, regulation of growth and development, reproduction, and the interactions between plants and their environments.

How might plant physiologists improve the cassava plant for human use?

See answer on p. 724.

34.1 What Is the Basic Body Plan of Plants?

Plants live by harvesting energy from sunlight and by collecting water and mineral nutrients from the atmosphere and the soil. Because these resources are sometimes limited, plants must collect them from large areas, both above and below ground. The plant is further challenged by its inability to move; a plant cannot, for example, relocate from a dry, shady location to one that is wet and sunny.

The plant body plan allows plants to respond to these challenges:

- Stems, leaves, and roots enable a plant anchored to one spot to capture scarce resources effectively, both above and below the ground.
- Plants can grow throughout their lifetimes, enabling them to respond to environmental cues. A plant can redirect its growth to exploit opportunities in its immediate environment; for example, it can extend its roots toward a water supply.

In Chapters 28 and 29 we saw how modern plants arose from aquatic ancestors, giving rise to simple land plants and then to vascular plants. Despite their obvious differences in size and form, all vascular plants have essentially the same simple structural organization. This chapter describes the basic architecture of the largest group of vascular plants, the angiosperms (flowering plants), and shows how so much diversity can literally grow out of such a simple, basic form.

As we saw in Figure 29.1, angiosperms first appeared about 145 million years ago. They radiated explosively over a period of about 60 million years and eventually became the dominant form of plant life on Earth. Today there are more than 250,000 angiosperm species. Flowers are the main distinguishing feature of angiosperms; they consist of modified leaves and stems and carry the organs for sexual reproduction. We will examine the structures and functions of flowers in detail in Section 38.1. In this chapter we'll focus on the three kinds of vegetative (nonsexual) organs that angiosperms possess: roots, stems, and leaves. Each of these vegetative organs can be understood in terms of its structure. By structure we mean both the overall form of the organ (its morphology) and the arrangement of its cells and tissues (its anatomy).

Plant organs are organized into two systems (Figure 34.1):

- The **root system** anchors the plant in place, absorbs water and dissolved minerals, and stores the products of photosynthesis from the shoot system. The extreme branching of plant roots and their high surface area-to-volume ratios allow them to absorb water and mineral nutrients from the soil efficiently.
- The **shoot system** of a plant consists of the stems, leaves, and flowers. Broadly speaking, the **leaves** are the chief organs of photosynthesis. The **stems** hold and display the leaves to the sun and provide connections for the transport of materials between roots and leaves.

34.1 Vegetative Organs and Systems The basic plant body plan, with root and shoot systems, and the principal vegetative organs.

Shoots and roots are composed of repeating modules called **phytomers**. Each phytomer in the shoot consists of a **node** carrying one or more leaves; an **internode**, which is the interval of stem between two nodes; and one or more **axillary buds**, each of which forms in the angle (axil) where a leaf meets the stem. A **bud** is an undeveloped shoot that can develop further to produce another leaf, a phytomer, a flower, or a flowering stem. The axillary buds (also called lateral buds) are distinguished from the bud at the end of a stem or branch, which is called a **terminal bud**. If it becomes active, an axillary bud can develop into a new branch, or an extension of the shoot system. The arrangement of leaves along the stem (called the **phyllotaxy**) is characteristic of the plant species.

Plant roots also have a modular construction. In the roots, each phytomer consists of a root segment between two branches.

Most angiosperms are either monocots or eudicots

As we saw in Section 29.3, most angiosperms belong to one of two major clades. *Monocots* are generally narrow-leaved flowering plants such as grasses, lilies, orchids, and palms. *Eudicots* are broad-leaved flowering plants such as soybeans, roses, sunflowers, and maples. These two clades, which account for 97 percent of flowering plant species, differ in several basic characteristics:

- Monocots have one **cotyledon** (leaf in the embryo), whereas eudicots have two.

- In eudicots, the vascular bundles in the stem are arranged in concentric circles; in monocots they are scattered.
- In monocots, the major leaf veins are usually parallel; in eudicots they are reticulate, meaning they form a network.
- Eudicots usually have taproot systems; monocots have fibrous root systems.
- Monocot flowers have parts (petals and sepals) that occur in threes; eudicots have floral parts that occur in fours or fives.
- Monocot pollen grains each have one furrow or pore; eudicot pollen grains have three.

We will discuss some of these differences in more detail in Section 34.3.

Plants develop differently than animals

As we discussed in Chapter 19, the four processes that govern development in all multicellular organisms are **determination** (the commitment of cells to their ultimate fates); **differentiation** (cell specialization); **morphogenesis** (the organization of cells into tissues and organs); and **growth** (increase in body size). These processes govern plant development as well as animal development, but they are influenced by four unique properties of plants: apical meristems, totipotency, vacuoles, and cell walls.

APICAL MERISTEMS Animals have stem cells to replace tissues lost through damage or apoptosis. Plants have **meristems**: regions of undifferentiated cells where cell division occurs. **Apical meristems** are found at the tips of shoots and roots and allow plants to continue growing throughout their lives. We will discuss apical meristems in more detail below.

TOTIPOTENCY During normal animal development, only the early embryonic cells are totipotent: they can differentiate into any type of cell in the body (see Section 19.1). In contrast, some differentiated plant cells can dedifferentiate and become totipotent (see Figure 19.16). This means that a plant can readily repair damage wrought by the environment or herbivores.

VACUOLES Mature plant cells usually contain a single **central vacuole**, which may account for up to 90 percent of a cell's volume (see Figure 5.13). The vacuole is a watery sac containing a high concentration of solutes, including enzymes, amino acids, and sugars produced by photosynthesis. Many of these solutes are pumped into the vacuole by transporter proteins located in the **tonoplast**, the vacuolar membrane. This active accumulation of solutes provides the osmotic force for water uptake into the vacuole, as we will see in Section 35.1. As the vacuole expands, it exerts turgor pressure on the cell wall (see Chapter 6). Turgor pressure keeps plants upright and is essential for plant growth.

CELL WALLS Each plant cell is surrounded by a cell wall, which is interrupted by membrane-lined cytoplasmic channels called

34.2 Cytokinesis and morphogenesis The plane of cell division can determine the growth pattern of a plant's organs, as in this section of a shoot.

plasmodesmata (see Section 5.4). This rigid extracellular matrix makes it impossible for cells to move from place to place, as they do in animal development. Instead, plant morphogenesis is controlled by the planes of cell division, which determine the direction in which a piece of tissue will grow (**Figure 34.2**). In addition, unequal cell division can occur when the cytoplasm contains differentiation signals that are localized in one part of a cell (see Section 19.2). Plant cytokinesis (the division of the cytoplasm) occurs along a cell plate laid down by membranous vesicles produced by the Golgi apparatus (see Figure 11.13B). Unlike animal cells, in which the location of cytokinesis depends on the location of the middle of the mitotic spindle, the location of the plant cell plate is determined earlier—as early as mitotic prophase.

One of the major ways that plants grow is by cell expansion. Some cells can increase in volume by 100,000 to 1,000,000 times! As a growing plant cell takes up water, it exerts turgor pressure on the cell wall, which resists cell expansion. For the cell to expand, the wall must expand too. Proteins called **expansins** reside in the cell wall and help loosen it by disrupting the noncovalent bonds between cellulose microfibrils and other polysaccharides in the cell wall. This is followed by the assembly of new polysaccharides and microfibrils, allowing the cell wall to grow:

The wall of a growing plant cell is called the **primary cell wall**. When cell expansion stops, some types of plant cells

deposit one or more additional cellulosic layers to form a thick, rigid **secondary cell wall** that is internal to the primary cell wall:

Secondary cell walls cannot expand. Instead they provide the mechanical support that allows some plants to produce large stems. The secondary wall contains layers of ordered cellulose microfibrils embedded in a remarkable substance called **lignin**. Lignin is a major component of wood; it is a complex, carbon-containing polymer that forms a hydrophobic matrix. This matrix is strong, waterproof, and resistant to digestion by animals. After cellulose, lignin is the most abundant biological polymer on Earth, accounting for 20 to 35 percent of the dry weight of wood.

Apical–basal polarity and radial symmetry are characteristics of the plant body

Two basic patterns are established early in plant embryogenesis (embryo formation) (**Figure 34.3**):

- The *apical–basal axis*: the arrangement of cells and tissues along the main axis from root to shoot
- The *radial axis*: the concentric arrangement of the tissue systems. (which we will describe in Section 34.2)

Both axes are best understood in developmental terms. We will focus here on embryogenesis in *Arabidopsis thaliana*. As we have seen in previous chapters, *Arabidopsis* is a model eudicot

34.3 Two Patterns for Plant Morphogenesis (A) The apical–basal pattern is the arrangement of tissues along a main axis from root to shoot. (B) The radial pattern determines the concentric arrangement of tissues as organs grow in thickness.

that has been studied extensively by plant physiologists and geneticists.

The first step in the formation of an *Arabidopsis* embryo is a mitotic division of the zygote that gives rise to two daughter cells (**Figure 34.4, Step 1**). An asymmetrical plane of cell division results in an uneven distribution of cytoplasm between these two cells, and this determines their different fates. Signals in the smaller, upper daughter cell cause it to produce the embryo proper, and the other, larger daughter cell produces a supporting structure called the **suspensor** (**Figure 34.4, Step 2**). This division not only establishes the apical–basal axis of the new plant but also determines its polarity (which end is the tip, or apex, and which is the base). A long, thin suspensor and a more spherical or globular embryo are distinguishable after just four mitotic divisions (see Figure 19.1). The suspensor soon ceases to elongate.

In eudicots such as *Arabidopsis*, the initially globular embryo develops into the characteristic heart stage as the cotyledons start to grow (**Figure 34.4, Step 3**). Further elongation of the cotyledons and of the main axis of the embryo gives rise to the

34.4 Plant Embryogenesis

The basic body plan of the model eudicot *Arabidopsis thaliana* is established in several steps. By the heart stage, the three tissue systems are established: the dermal (gold), ground (light green), and vascular (blue) tissue systems.

torpedo stage, during which some of the internal tissues begin to differentiate (**Figure 34.4, Step 4**). Between the cotyledons is the **shoot apical meristem**; at the other end of the axis is the **root apical meristem**. Each of these meristems contains undifferentiated cells that will continue to divide to give rise to the organs that will develop during the life of the plant.

As shown in Step 2 of Figure 34.4, the plant embryo is first a sphere and later a cylinder. The root and stem retain this cylindrical shape throughout the plant's life. You can see this most easily in the trunk (mature stem) of a tree. By the end of embryogenesis, the radial symmetry of the plant has been established (see Figure 34.3). The embryonic plant contains three tissue systems, arranged concentrically, which will give rise to the tissues of the adult plant body. We will discuss these tissue systems in the next section.

RECAP 34.1

The vegetative plant body consists of a root system and a shoot system. The plant body is modular, made up of repeated units called phytomers. Plant cells are characterized by apical meristems, totipotency, vacuoles, and cell walls. Plants have apical–basal and radial patterns. Most angiosperms are either monocots or eudicots, which differ in several basic ways.

- How do plants explore their environment for resources even though they cannot move? **See p. 709**
- How does plant development differ from animal development? **See pp. 710–711**
- How do apical–basal and radial patterns develop? **See pp. 711–712 and Figures 34.3 and 34.4**

The dramatic differences between plant and animal body plans are not surprising given that the multicellular forms of plants and animals evolved independently from entirely distinct protist ancestors (see Figure 1.7). In the next two sections we will look more closely at the unique characteristics of the plant body, by following its development from a zygote into an adult.

34.2 What Are the Major Tissues of Plants?

By the end of embryogenesis, the radial axis of the plant has been established. Unlike complex animals that can have dozens of different tissues (for example, in humans there are three kinds of muscle tissue alone), plants have just three major tissue systems, each of which has specialized cells. These three tissue systems are arranged

concentrically in the embryo and give rise to the tissues of the adult plant body. In turn, these tissues form the major vegetative plant organs: roots, stems, and leaves.

The plant body is constructed from three tissue systems

A tissue is an organized group of cells that have features in common and that work together as a structural and functional unit. Plant tissues are grouped into three **tissue systems**: dermal, ground, and vascular. Established during embryogenesis, these three tissue systems ultimately extend throughout the plant body in a concentric arrangement (**Figure 34.5**). Each tissue system has distinct functions and is composed of different mixtures of cell types.

DERMAL TISSUE SYSTEM The **dermal tissue system** forms the **epidermis** (outer covering) of a plant and usually consists of a single cell layer. The stems and roots of woody plants develop a dermal tissue called **periderm**.

During plant development, the epidermis grows to cover the expanding plant body. The cells of the epidermis are initially small and round and usually have a small central vacuole or none at all. Once cell division ceases in the epidermis of an organ, the epidermal cells expand. Some epidermal cells differentiate to form one of three specialized structures:

- Stomatal guard cells, which form stomata (pores) for gas exchange in leaves

34.5 Three Tissue Systems Extend throughout the Plant Body

The arrangement shown here is typical of eudicots, but the three tissue systems are continuous in the bodies of all vascular plants.

(A) Parenchyma cells

(B) Collenchyma cells

(C) Fibers

(D) Sclereids

34.6 Ground Tissue Cell Types (A) Parenchyma cells in the petiole of *Coleus*. Note the thin, uniform cell walls. (B) Collenchyma cells make up the outer cell layers of this spinach leaf vein. Their walls are thick at the corners of the cells and thin elsewhere. (C) Sclerenchyma: fibers in a sunflower stem (*Helianthus*). The thick

secondary walls are stained red. (D) Sclerenchyma: sclereids. The extremely thick secondary walls of sclereids are laid down in layers. They provide support and a hard texture to structures such as nuts and seeds.

- Trichomes, or leaf hairs, which provide protection against insects and damaging solar radiation
- Root hairs, which greatly increase root surface area, thus providing more surface for the uptake of water and mineral nutrients

The aboveground epidermal cells secrete a protective extracellular layer called a **cuticle**. The cuticle is made up of cutin (a polymer composed of long chains of fatty acids), a complex mixture of waxes, and cell wall polysaccharides. The cuticle limits water loss, reflects potentially damaging solar radiation, and serves as a barrier against pathogens.

GROUND TISSUE SYSTEM Virtually all the tissue lying between the dermal tissue and the vascular tissue in both shoots and roots is part of the **ground tissue system**. Therefore the ground tissues make up most of the plant body. The ground tissues function primarily in storage, support, and photosynthesis. To fulfill these diverse functions, ground tissues contain three cell types that are classified according to their cell wall structure: parenchyma, collenchyma, and sclerenchyma.

The most common cell type in plants is the **parenchyma** cell (Figure 34.6A). Parenchyma cells have large vacuoles and thin

walls consisting only of a primary wall and the shared middle lamella. The **middle lamella** is a layer of pectin that cements adjacent plant cells together (see Figure 5.21). Parenchyma cells play important roles in photosynthesis (mainly in the leaves); proteins, starch, fats, or oils may be stored in parenchyma cells of the seeds and/or roots. Many retain the capacity to divide and give rise to new cells, as when a wound results in cell proliferation.

Collenchyma cells resemble parenchyma cells that have been modified to provide flexible support. They are generally elongated, and their primary walls are characteristically thick at the corners of the cells (Figure 34.6B). In these cells the primary wall thickens in part because of the deposition of pectins, but no secondary wall forms. Collenchyma cells provide support to leaf petioles, nonwoody stems, and growing organs. Tissue made of collenchyma cells is flexible, permitting stems and petioles to sway in the wind without snapping. The familiar “strings” in celery consist primarily of collenchyma cells.

Sclerenchyma cells have thickened secondary walls that enable the cells to perform their major function: support. Many sclerenchyma cells undergo programmed cell death (apoptosis; see

(A) Tracheids

(B) Vessel elements

(C) Sieve tube elements

34.7 Vascular Tissue Cell Types (A, B) Tracheary elements: (A) Tracheids in pinewood. The thick secondary walls are stained dark red. (B) Vessel elements in the stem of a squash. The secondary walls

are stained red; note the different patterns of thickening, including rings and spirals. (C) Sieve tube elements and companion cells in the stem of a cucumber.

Section 11.6) after developing the lignified secondary walls, and thus perform their supporting function when dead. There are two types of sclerenchyma cells: elongated **fibers** and variously shaped **sclereids**. Fibers are often organized into bundles and provide relatively rigid support to wood, bark, and other parts of the plant (Figure 34.6C). Sclereids may pack together densely, as in a nut's shell or in some seed coats (Figure 34.6D). Isolated clumps of sclereids, called stone cells, occur in pears and some other fruits and give them their characteristic gritty texture.

VASCULAR TISSUE SYSTEM The **vascular tissue system** is the plant's plumbing, or transport system—the distinguishing feature of vascular plants. Its two constituent tissues, the xylem and phloem, distribute materials throughout the plant. The **xylem** distributes water and mineral ions taken up by the roots to all the cells of the stems and leaves. **Phloem** performs a variety of functions, including transport, support, and storage. All the living cells of the plant body require a source of energy and chemical building blocks. The phloem meets these needs by transporting carbohydrates away from the sites of production, which are called **sources** (primarily leaves). The carbohydrates are transported to sites of utilization or storage, called **sinks**. Sinks include growing tissues, storage organs, and developing flowers.

Let's take a closer look at the structures of the diverse cell types that make up these vascular tissues. In Chapter 35 we will see how they transport water and materials throughout the plant body.

Cells of the xylem transport water and dissolved minerals

Xylem tissue contains conducting cells called **tracheary elements** that have secondary cell walls and undergo apoptosis before assuming their function of transporting water and dissolved minerals. There are two types of tracheary elements:

tracheids and vessel elements. The spindle-shaped **tracheids** (Figure 34.7A) are evolutionarily more ancient than vessel elements and are the major cell type in the wood of gymnosperms (see Section 29.2). When tracheids die, their internal components disintegrate and pits remain between the cells. Pits are cavities in the secondary cell walls spanned by porous structures that allow water and minerals to move between tracheids and thus through the xylem tissue.

Flowering plants have evolved a water-conducting system made up of vessels, which are formed from individual cells called **vessel elements**. These cells are laid down end-to-end. Like tracheids, vessel elements have pits in their cell walls, but their pits are generally larger in diameter than those of tracheids. Before they undergo apoptosis, the end walls of vessel elements partially break down, forming a continuous hollow tube that functions as an open pipeline for water conduction (Figure 34.7B). In the course of angiosperm evolution, vessel elements have become shorter and wider, and their end walls have become less oblique and less obstructed. These adaptations have presumably increased the efficiency of water transport through the vessels. The xylem of many angiosperms includes both tracheids and vessels.

Cells of the phloem transport the products of photosynthesis

The transport cells of the phloem, unlike those of the mature xylem, are living cells. In flowering plants the characteristic cells of the phloem are called **sieve tube elements** (Figure 34.7C). Like vessel elements, these cells meet end-to-end. They form long sieve tubes, which transport carbohydrates and many other materials from their sources (usually leaves) to tissues that consume or store them (for example, roots).

Unlike in vessel elements, which break down their end walls, the end walls of sieve tube elements contain plasmodesmata, which enlarge to form pores. The end walls look and function

like sieves and are thus called sieve plates. Although the sieve tube elements remain alive, some of their components, including the nucleus, ribosomes, and vacuole, break down during development. The sieve tube elements are, however, closely connected via plasmodesmata to **companion cells**—specialized parenchyma cells that retain all their organelles and function as “life support systems” for the sieve tube elements.

RECAP 34.2

The three concentric tissue systems of the plant embryo—dermal, ground, and vascular—give rise to the tissues and organs of the adult plant. These tissue systems have unique combinations of specialized cells that carry out the various functions necessary for plant life.

- What distinguishes the three tissue systems in terms of their location and functions? **See pp. 712–714 and Figure 34.5**
- What structural differences make tissues consisting of collenchyma cells more flexible than those consisting primarily of sclerenchyma cells? **See pp. 713–714**
- Outline the differences between tracheids and vessel elements. **See p. 714 and Figures 34.6 and 34.7**

After the plant embryo has formed, it is encased in a seed coat and is ready to germinate. We will discuss aspects of seed germination in the chapters that follow. For now, let’s consider the processes by which the embryo grows into a mature plant.

34.3 How Do Meristems Build a Continuously Growing Plant?

As noted at the beginning of this chapter, plants and animals develop and function differently. While animals use their mobility to forage for food, plants are sessile (rooted in one place) and grow toward scarce resources, both above and below the ground. Therefore plants grow in two directions: the shoots grow toward sunlight, and the roots grow toward water and dissolved minerals in the soil.

In most animals, growth is **determinate**: it ceases when the adult state is reached. Determinate growth is also characteristic of some plant organs, such as leaves, flowers, and fruits. The growth of shoots and roots, however, is a lifelong process. Such open-ended growth is **indeterminate**.

Plants increase in size through primary and secondary growth

Plant growth can occur in either of two ways:

- **Primary growth** is characterized by cell division followed by cell enlargement. It results in the proliferation and lengthening of shoots and roots. All seed plants have a primary plant body, which consists of all the nonwoody parts of the plant. Many herbaceous plants consist entirely of a primary plant body.
- **Secondary growth** increases plant thickness. Woody plants, such as trees and shrubs, have a secondary plant body

consisting of wood and bark. As the tissues of the secondary plant body are laid down, the stems and roots thicken.

A hierarchy of meristems generates the plant body

As we have already mentioned, meristems are localized regions of undifferentiated cells that are the sources of all new growth in the adult plant. Even before seed germination, the plant embryo has two meristems: a shoot apical meristem near the end of the embryonic shoot, and a root apical meristem at the end of the embryonic root (see Figure 34.4).

Meristematic cells are small and closely packed, with very small vacuoles and thin primary cell walls. They are undifferentiated and retain the ability to produce new cells indefinitely. The cells that perpetuate the meristems, called **initials**, are comparable to animal stem cells (discussed in Section 19.1). When the initials divide, some of the daughter cells develop into new initials, and some differentiate into more specialized cells.

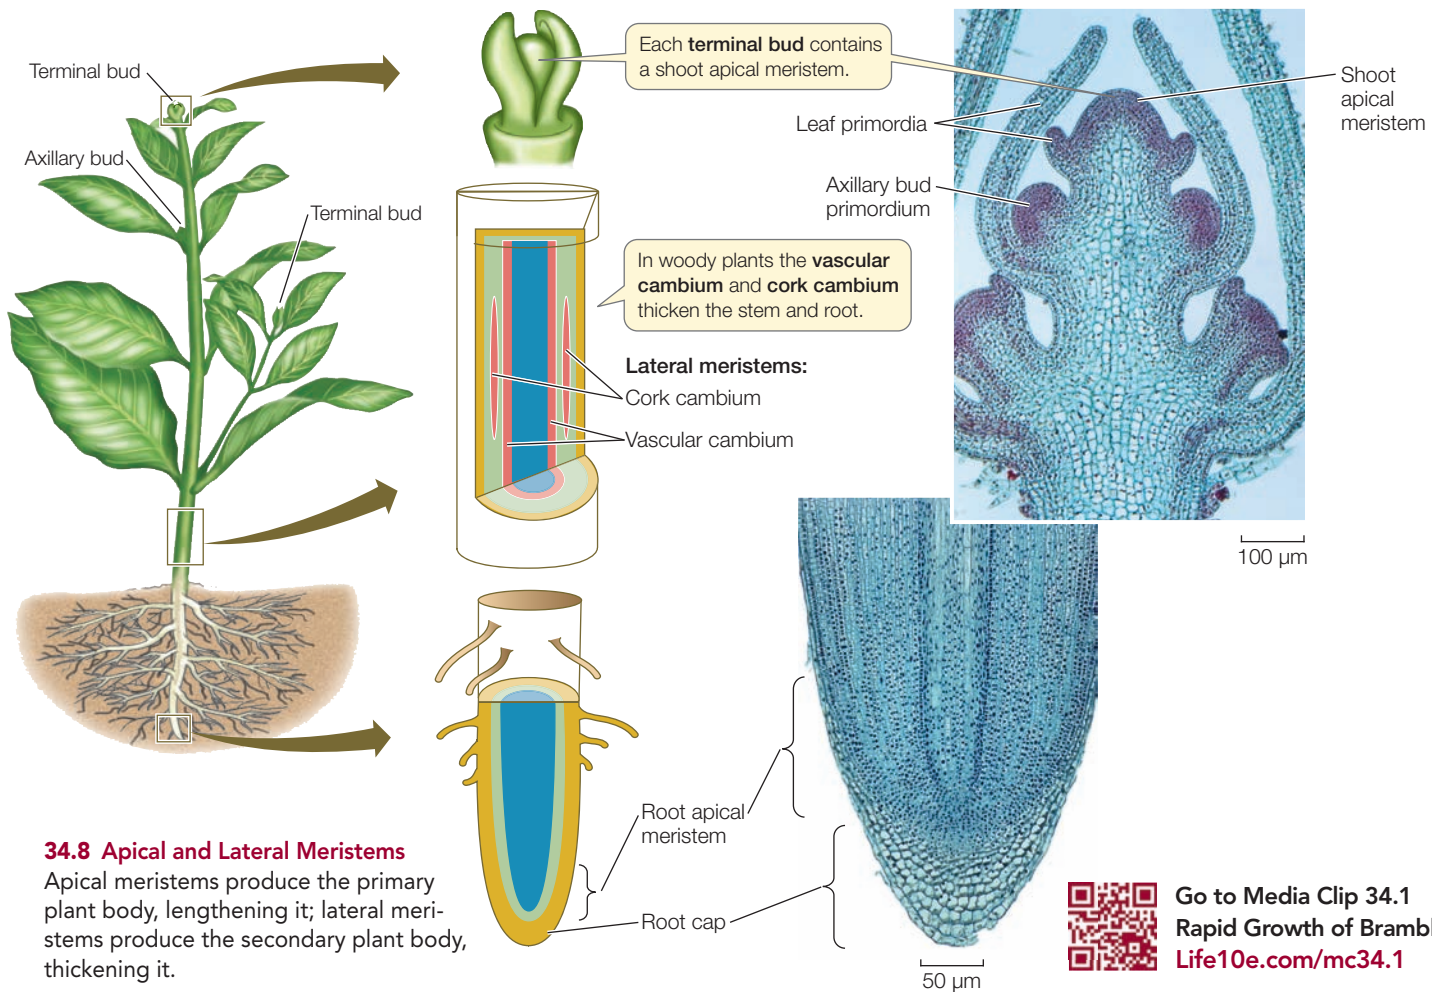

Several types of meristem contribute to the growth and development of the adult plant:

- **Apical meristems** in the root and shoot (**Figure 34.8**) orchestrate primary growth, ultimately giving rise to every cell in the primary plant body.
- When the initials of apical meristems divide, some of their daughter cells differentiate and become the **primary meristems**. Three kinds of primary meristem (see below) give rise to the three major tissue systems (dermal, ground, and vascular) described in Section 34.2.
- **Lateral meristems** (also called secondary meristems) orchestrate secondary growth (see Figure 34.8). Two lateral meristems, vascular cambium and cork cambium, contribute to the secondary plant body.

Indeterminate primary growth originates in apical meristems

Because apical meristems can perpetuate themselves indefinitely, a shoot or root can continue to lengthen and grow indefinitely; in other words, growth of the shoot or root is indeterminate. All plant organs arise ultimately from cell divisions in apical meristems, followed by cell expansion and differentiation. Several types of apical meristems play roles in organ formation:

- Shoot apical meristems supply the cells for new leaves and stems. In addition to the main stem of the plant, each branch has its own shoot apical meristem. Shoot apical meristems are also called **vegetative meristems**, because they give rise to vegetative tissues (leaves, stems, and roots).
- When the plant is ready to flower, one or more of its shoot apical meristems are transformed into **inflorescence meristems**, and these in turn develop **floral meristems**. See Section 38.2 for more on floral development.
- Root apical meristems supply the cells that extend roots, enabling the plant to penetrate and explore the soil for water and minerals. Each type of root (i.e., the taproot, a lateral root, or an adventitious root; see below) has its own root apical meristem.

34.8 Apical and Lateral Meristems

Apical meristems produce the primary plant body, lengthening it; lateral meristems produce the secondary plant body, thickening it.

Apical meristems in both the shoot and the root give rise to a set of **primary meristems**, which produce the tissues of the primary plant body. From the outside to the inside of the shoot or root, the primary meristems are the **protoderm**, the **ground meristem**, and the **procambium** (see Figure 34.8). These meristems, in turn, give rise to the three tissue systems:

Apical meristems	→	Primary meristems	→	Tissue systems
Root or shoot apical meristem	↘	Protoderm	→	Dermal tissue system
		Ground meristem	→	Ground tissue system
		Procambium	→	Vascular tissue system

Because meristems can continue to produce new organs throughout the lifetime of the plant, the plant body is much more variable in form than the animal body, which produces each organ only once.

Let's look more closely at how the root apical meristem produces the root system.

The root apical meristem gives rise to the root cap and the root primary meristems

The root apical meristem produces all the cells that contribute to the growth and development of the root (Figure 34.9A). Some of the daughter cells from the apical (tip) end of the root apical meristem contribute to a **root cap**, which protects the delicate growing region of the root as it pushes

through the soil. The root cap secretes a mucopolysaccharide (slime) that acts as a lubricant. Even so, the cells of the root cap are often damaged or scraped away and must therefore be replaced constantly. The root cap is also the structure that detects the pull of gravity and thus controls the downward growth of roots.

In the middle of the root apical meristem is a quiescent center, in which cell divisions are rare. The quiescent center can become more active when needed—following injury, for example. The daughter cells produced above the quiescent center (that is, away from the root cap) become the three primary meristems.

The apical and primary meristems constitute the **zone of cell division**, the source of all the cells of the root's primary tissues. Just above this zone is the **zone of cell elongation**, where the newly formed cells are elongating and thus pushing the root farther into the soil. Above that zone is the **zone of maturation**, where the cells are differentiating, taking on specialized forms and functions. These three zones grade imperceptibly into one another; there is no abrupt line of demarcation.

The products of the root's primary meristems become root tissues

The products of the three primary meristems (the protoderm, ground meristem, and procambium) are the tissue systems of the mature root. The differing arrangement of the three tissue

systems in the roots of eudicots and monocots is one of the ways in which the two clades are distinguished (**Figure 34.10**).

The protoderm gives rise to the epidermis, the outer layer of cells that is adapted for protection of the root and absorption of mineral ions and water. Many of the epidermal cells produce long, delicate **root hairs**, which vastly increase the surface area of the root (**Figure 34.9B**). Root hairs grow out among the soil particles, probing nooks and crannies and taking up water and minerals.

Internal to the epidermis, the ground meristem gives rise to a region of ground tissue that is many cells thick, called the **cortex**. The cells of the cortex are relatively unspecialized and often serve as storage depots. The innermost layer of the cortex is the **endodermis**. Unlike other cortical cells, the endodermal cells contain a waterproof substance called **suberin** in their primary cell walls. The suberin forms a cylindrical ring around the inside of the endodermis, which allows the endodermal cells to control the movement of water and dissolved mineral ions into and out of the vascular tissue system.

Within the endodermis is the vascular cylinder, or **stele**, produced by the procambium. The stele consists of three tissues: pericycle, xylem, and phloem. The **pericycle** consists of one or more layers of relatively undifferentiated cells. It has three important functions:

- It is the tissue within which lateral roots arise (**Figure 34.11**).
- It can contribute to secondary growth by giving rise to lateral meristems that thicken the root.
- Its cells contain membrane transport proteins that export nutrient ions into the cells of the xylem.

At the very center of the root of a eudicot lies the xylem. Seen in cross section, it typically has the shape of a star with a variable number of points (see **Figure 34.10A**). Between the points are bundles of phloem.

34.10 Products of the Root's Primary Meristems The protoderm gives rise to the outermost layer (epidermis). The ground meristem produces the cortex, the innermost layer of which is the endodermis. The primary vascular tissues of the root are found in the stele, which is the product of the procambium. The arrangement of tissues in the stele differs in the roots of (A) eudicots and (B) monocots. The photomicrographs show cross sections of the stele of a representative eudicot (the buttercup, *Ranunculus*) and a representative monocot (corn, *Zea mays*), showing the arrangement of the primary root tissues.

Go to Activity 34.2 Monocot Root [Life10e.com/ac34.2](https://www.life10e.com/ac34.2)

34.11 Lateral Root Anatomy Cross section through the tip of a lateral root in a willow tree. Cells in the pericycle divide and the products differentiate, forming the tissues of a lateral root.

In monocots, a region of parenchyma cells called the **pith** typically lies in the center of the root, surrounded by xylem and phloem (see Figure 34.10B). Pith, which often stores carbohydrate reserves, is also found in the stems of both eudicots and monocots.

The root system anchors the plant and takes up water and dissolved minerals

Water and minerals enter most plants through the root system, which is located in the soil. Because light does not penetrate the soil, roots typically lack the capacity for photosynthesis. Although hidden from view, the root system is often larger than the visible shoot system. For example, the root system of a 4-month-old winter rye plant (*Secale cereale*) was found to be 130 times longer in total than the shoot system,

with almost 13 million branches that had a cumulative length of more than 500 kilometers!

Angiosperm root systems develop from the embryonic root, called the **radicle**. From this common starting point, the root systems of monocots and eudicots develop differently. Following seed germination, the radicle of most eudicots develops as a primary root called the **taproot**, which extends downward by tip growth and outward by initiating **lateral roots**. The taproot and the lateral roots form a **taproot system**, which can take a variety of forms. For example, the taproot itself often functions as a nutrient storage organ, as in carrots (*Daucus carota*), sugar beets (*Beta vulgaris*), and sweet potato (*Ipomoea batatas*) (Figure 34.12A).

In contrast, the primary root of monocots (and some eudicots) is short-lived. Because they originate from the stem at ground level or just below, the roots of a typical monocot are called **adventitious** (“arriving from outside”) **roots**, and they form a **fibrous root system** composed of numerous thin roots that are all roughly equal in diameter (Figure 34.12B). Many fibrous root systems have large surface areas for the absorption of water and minerals. A fibrous root system clings to soil very well. The fibrous root systems of grasses, for example, may protect steep hillsides where runoff from rain would otherwise cause erosion.

In some plants—corn, banyan, and pandanus trees, for example—adventitious roots grow down from above the ground and function as props to help support the shoot system (Figure 34.12C). These **prop roots** have evolved for different reasons in different species. For example, some monocots may develop prop roots because they are unable to support aboveground growth through the thickening of their stems. Pandanus trees often grow near coastal beaches, where their prop roots help provide support in very sandy soils. Banyans begin life as epiphytes (plants that grow on other plants) and then develop woody prop roots, which enable them to grow into huge trees.

(C) Prop roots

34.12 Root Systems of Eudicots and Monocots (A) The taproot systems of eudicots, such as carrots, sugar beets, and sweet potato, contrast with (B) the fibrous root system of a leek and (C) the adventitious prop roots of corn.

34.13 Vascular Bundles in Stems

(A) In herbaceous eudicot stems, the vascular bundles are arranged in a cylinder, with pith in the center and the cortex outside the cylinder. (B) A scattered arrangement of vascular bundles is typical of monocot stems.

Go to Activity 34.4 Monocot Stem
Life10e.com/ac34.4

The products of the stem's primary meristems become stem tissues

Recall that shoots and roots are composed of repeating modules called phytomers. A phytomer in the shoot system consists of a node with its attached leaf or leaves, the internode below the node, and axillary buds, each of which forms in the angle between a leaf and the stem (see Figure 34.1). Shoots grow by adding new phytomers. Initially these form only on the primary stem of the plant, but if an axillary bud develops into a branch, it does so by producing new phytomers. The new phytomers originate from cells in the shoot apical meristems, which are present in the terminal buds of each branch and the main stem.

The shoot apical meristem, like the root apical meristem, forms three primary meristems: protoderm, ground meristem, and procambium. These primary meristems, in turn, give rise to the three shoot tissue systems.

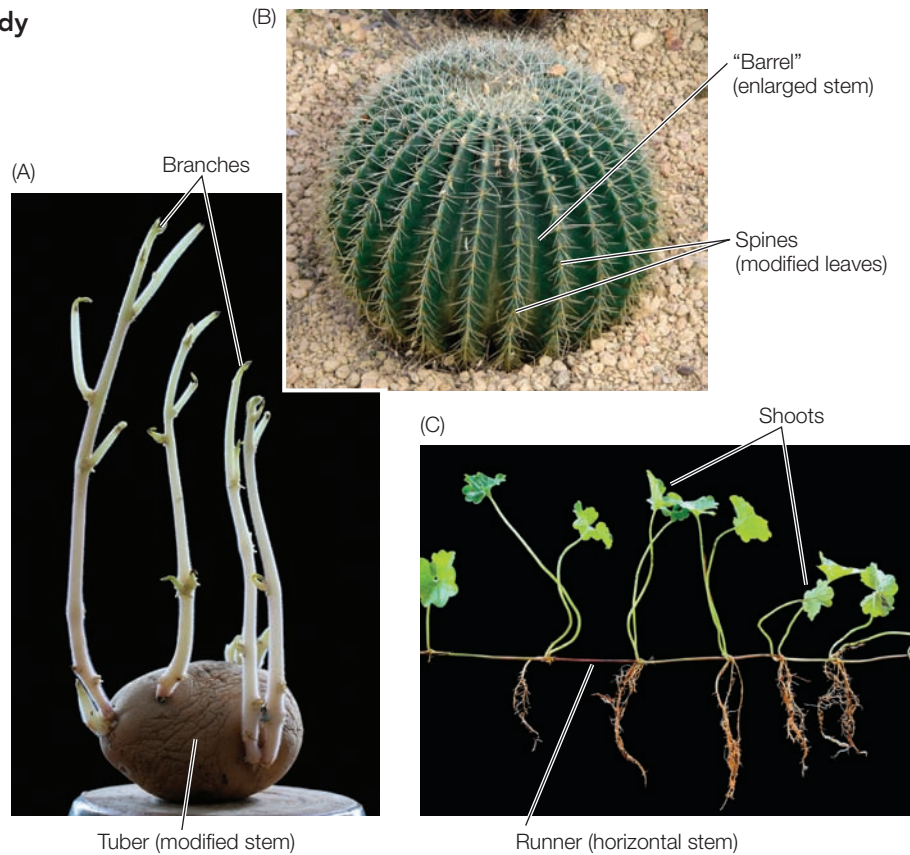

As the shoot grows and extends, bulges called **leaf primordia** develop on the sides of the shoot apical meristem at regular intervals. These primordia are made up of primary meristematic tissues, which go on to develop into the mature tissues of the leaf. In addition, bud primordia form at the bases of the

leaf primordia. These have the potential to become new apical meristems and initiate new shoots. The sites where leaf primordia form become nodes on the developing stem. The regions between the nodes (the internodes) lengthen initially via cell division in the primary meristematic tissues, and later by cell elongation in the mature stem tissues. The growing stem has no protective structure analogous to the root cap, but the leaf primordia can act as a protective covering for the shoot apical meristem.

The vascular systems of stems differ from those of roots. In a root, the vascular tissue lies deep in the interior, with the xylem at or near the center (see Figure 34.10). The vascular tissue of a young stem, however, is divided into discrete **vascular bundles** (Figure 34.13). Each vascular bundle contains both xylem and phloem. In eudicots the vascular bundles generally form a cylinder, whereas in monocots they are scattered throughout the stem.

In addition to the vascular tissues, the stem contains other important storage and supportive tissues. In eudicots the pith lies inside the ring of vascular bundles and also extends between them, forming regions called pith rays. To the outside lies the cortex, which may contain supportive collenchyma

34.14 Modified Stems (A) A potato is a modified stem called a tuber; the sprouts that grow from its “eyes” are shoots, not roots. (B) The stem of this barrel cactus is enlarged to store water. Its highly modified leaves serve as thorny spines. Most of this plant’s photosynthesis occurs in the stem. (C) The runners of ground ivy are horizontal stems that produce roots and shoots at intervals. Rooted portions of the plant can live independently if the runner is cut.

cells with thickened walls. The pith and cortex constitute the ground tissue system of the stem. The outermost cell layer of the young stem is the epidermis.

The stem supports leaves and flowers

The central function of stems is to elevate and support the photosynthetic organs (leaves) as well as the reproductive organs (flowers). Various modifications of stems are seen in nature. The tuber of a potato, for example—the part of the plant eaten by humans—is not a root but rather an underground stem. The “eyes” of a potato are depressions containing axillary buds—in other words, a sprouting potato is just a branching stem (**Figure 34.14A**). Many desert plants have enlarged, water-retaining stems (**Figure 34.14B**). The runners of strawberry plants are horizontal stems that develop adventitious roots some distance from the main stem (**Figure 34.14C**); if the links between the rooted portions are broken, independent plants can develop on each side of the break—a form of vegetative (asexual) reproduction (see Section 38.3).

Leaves are determinate organs produced by shoot apical meristems

For most of its life, a plant produces leaves from apical meristems. As we mentioned earlier, apical meristems that produce leaves are called vegetative meristems. Leaves originate from the edges of the apical meristem as initial cells that differentiate into leaf primordia. A highly simplified way to think of the development of a leaf from a leaf primordium is to imagine leaves as flattened stems. However, there are two important differences:

- Unlike the growth of the stem, which is indeterminate, the growth of a leaf is determinate.

- Whereas the tissues of the stem are arranged in a radial pattern, the leaf, as a flat organ, has a distinct top side and bottom side.

Leaf anatomy is beautifully adapted to carry out photosynthesis, and to support that process by exchanging the gases O_2 and CO_2 with the environment, while at the same time limiting evaporative water loss. Its extensive vascular system supplies the leaf with water and mineral nutrients and exports the products of photosynthesis to the rest of the plant. **Figure 34.15A** shows a section of a typical eudicot leaf in three dimensions.

The photosynthetic parenchyma tissue in leaves is called the **mesophyll** (which means “middle of the leaf”). Most eudicot leaves have two zones of mesophyll: an upper layer of elongated cells called the palisade mesophyll, and a lower layer of irregularly shaped cells called the spongy mesophyll. Within the mesophyll is a great deal of air space through which CO_2 can diffuse to photosynthesizing cells.

Vascular tissue branches extensively throughout the leaf, forming a network of veins (**Figure 34.15B**). Typically, monocot leaves have a parallel pattern of major veins; for example, look at the grass blades on a nearby lawn. Dicot leaves, in contrast, have major veins in a netlike pattern, as in a maple or oak leaf. Veins extend to within a few cell diameters of all the cells of the leaf, ensuring that the mesophyll cells are well supplied with water and minerals. The products of photosynthesis are loaded into the veins for export to the rest of the plant.

The epidermis covers the entire surface of the leaf and is made up of nonphotosynthetic cells. The epidermal cells secrete a waxy cuticle that is impermeable to water. Although this impermeability prevents excessive water loss, it also poses

34.15 The Eudicot Leaf (A) This three-dimensional diagram shows a section of a eudicot leaf. (B) The network of fine veins in this maple leaf carries water to the mesophyll cells and carries photosynthetic products away from them. (C) Carbon dioxide enters the leaf through stomata like this one on the epidermis of a eudicot leaf.

Go to Activity 34.5 Eudicot Leaf Life10e.com/ac34.5

a problem: while the epidermis keeps water in the leaf, it also keeps out CO_2 —the other raw material of photosynthesis.

The problem of balancing water retention and carbon dioxide availability is solved by an elegant regulatory system that will be discussed in more detail in Section 35.3. Stomatal guard cells are modified epidermal cells that can change their shape, thereby opening or closing pores called **stomata** (singular *stoma*). The stomata serve as passageways between the environment and the leaf's interior (**Figure 34.15C**). When the stomata are open, carbon dioxide can enter and oxygen can leave, but water can also be lost.

Many eudicot stems and roots undergo secondary growth

As we have seen, the roots and stems of some eudicots develop a secondary plant body, the tissues of which we commonly refer to as wood and bark. These tissues are derived by secondary growth from the two lateral meristems, the vascular cambium and the cork cambium.

The **vascular cambium** is a cylindrical layer of tissue consisting predominantly of elongated cells that divide frequently. It supplies the cells of the secondary xylem and secondary phloem, which eventually become wood and bark. The **cork cambium** produces mainly waxy-walled protective cells. It supplies some of the cells that become bark.

Each year, deciduous trees lose their leaves and have bare branches and twigs over the winter (**Figure 34.16**). The apical meristems of the

34.16 A Woody Twig Has Both Primary and Secondary Growth The apical meristems in this dormant twig will produce primary growth in spring. Lateral meristems are responsible for secondary growth.

34.17 Vascular Cambium Thickens Stems and Roots Stems and roots grow thicker because a thin layer of cells, the vascular cambium, remains meristematic. These highly diagrammatic images emphasize the pattern of deposition of secondary xylem and phloem by the vascular cambium.

Go to Animated Tutorial 34.1

Secondary Growth: The Vascular Cambium

Life10e.com/at34.1

twigs are enclosed in buds protected by bud scales. When the buds begin to grow in spring, the scales fall away, leaving scars that show where the bud was. These scars allow us to identify the parts of the twig from each year's growth. The dormant twig shown in Figure 34.16 is the product of both primary and secondary growth. Only the buds consist entirely of primary tissues.

The vascular cambium is initially a single layer of cells lying between the primary xylem and the primary phloem within the vascular bundles. The root or stem increases in diameter when the cells of the vascular cambium divide, producing secondary xylem cells toward the inside of the root or stem and producing secondary phloem cells toward the outside (Figure 34.17). In the stem, cells in the pith rays between the vascular bundles also divide, forming a continuous cylinder of vascular cambium running the length of the stem. This cylinder, in turn, gives rise to complete cylinders of secondary xylem (the **wood**) and secondary phloem, which contributes to the bark. It also produces vascular rays for lateral transport, a structure not found in primary xylem and phloem. Therefore the vascular cambium produces vessel elements, tracheids, and supportive fibers in the secondary xylem; and sieve tube elements, companion cells, fibers, and parenchyma cells in the secondary phloem.

As secondary growth of stems or roots continues, the expanding vascular tissue stretches and breaks the epidermis and the outer layers of the cortex, which ultimately flake away. Before these dermal tissues are broken away, cells lying near the surface of the secondary phloem begin to divide, forming a cork cambium. This meristematic tissue produces layers of cork, a protective tissue composed of cells with thick walls waterproofed with suberin. The cork soon becomes the outermost tissue of the stem or root (see Figure 34.16). Without the activity of the cork cambium, the sloughing off of the outer primary

tissues would expose the plant to potential damage, such as excessive water loss or invasion by microorganisms. Sometimes the cork cambium produces cells toward the inside as well as the outside; these cells constitute a tissue known as the phelloderm.

The cork cambium, cork, and phelloderm constitute the secondary dermal tissue called periderm. As the vascular cambium continues to produce secondary vascular tissue, these corky layers are lost, but the continuous formation of new cork cambia in the underlying secondary phloem gives rise to new corky layers. The periderm and the secondary phloem—that is, all the tissues external to the vascular cambium—constitute the **bark**.

When periderm forms on stems or roots, the underlying tissues still need to release carbon dioxide and take up oxygen for cellular respiration. Spongy regions in the periderm called lenticels allow such gas exchange (Figure 34.18).

Cross sections of most trunks (mature stems) of trees in temperate-zone forests show annual rings of wood (Figure 34.19), which result from seasonal environmental conditions.

34.18 Lenticels Allow Gas Exchange through the Periderm The region of periderm that appears to be broken open is a lenticel in a year-old elderberry (*Sambucus*) twig; note the spongy tissue that constitutes the lenticel.

34.19 Annual Rings Rings of secondary xylem are the most noticeable feature of this cross section from a tree trunk.

In spring, when water is relatively plentiful, the tracheids or vessel elements produced by the vascular cambium tend to be large in diameter and thin-walled. Such wood is well adapted for transporting water and minerals. As water becomes less available during the summer, narrower cells with thicker walls are produced, making this summer wood darker and perhaps more dense than the wood formed in spring. Thus each growing season is usually recorded in a tree trunk by a clearly visible annual ring. Trees in the moist tropics do not undergo seasonal growth, so they do not lay down such obvious regular rings. Variations in temperature or water supply can lead to the formation of more than one ring in a single year, but most commonly a single annual ring is formed.

Only eudicots and other non-monocot angiosperms, along with many gymnosperms, have a vascular cambium and a cork cambium and thus undergo secondary growth. The few monocots that form thickened stems—palms, for example—do so without secondary growth. Palms have a very wide apical meristem that produces a wide stem, and dead leaf bases add to the diameter of the stem. All monocots grow in essentially this way, as do other angiosperms that lack secondary growth.

RECAP 34.3

Meristems are localized regions of cell division that are the sources of all new organs in the adult plant. Apical meristems are responsible for primary growth, which is associated with the lengthening and branching of shoots and roots. Lateral meristems increase plant thickness and form wood and bark in many eudicots.

- Explain how an apical meristem can be maintained for years while continuing to form leaves. **See p. 715 and Figure 34.8**
- What cells are derived from the root apical meristem, and what is the general process of root growth? **See pp. 716–717 and Figures 34.9 and 34.10**
- How does the vascular cambium give rise to thicker stems and roots? **See pp. 721–722 and Figures 34.16 and 34.17**

34.4 How Has Domestication Altered Plant Form?

The building of the plant body by meristems allows a plant to respond to its environment by redirecting its growth. Thus individual plants of the same species can vary greatly in form. What underlies this variation, and how have we humans used it to our advantage?

We have seen in this chapter that a very simple, modular plant body plan underlies the remarkable diversity of the flowering plants that cover our planet. Differences in plant form among species are not surprising, given the high levels of genetic diversity among plant species. However, members of the same species can also show remarkable diversity in form. From a genetic perspective, this suggests that minor differences in gene content or gene regulation can underlie dramatic differences in plant form.

It is hard to believe that modern corn was domesticated from the wild grass teosinte, which still grows in the hills of Mexico (**Figure 34.20**). One of the most conspicuous differences is that teosinte, like other wild grasses, is highly branched, whereas domesticated corn has a single shoot. This morphological difference is due in large part to the activity of a single gene called *teosinte branched 1* (*tb1*). The protein product of *tb1* regulates the growth of axillary buds (see Figure 34.1). The allele of *tb1* in domesticated corn represses branching, whereas the allele in teosinte permits branching.

34.20 Modern Corn Was Domesticated from the Wild Grass Teosinte

Each teosinte plant has multiple branches. Beginning more than 8,000 years ago in Mexico, farmers favored plants with minimal branching. Reducing the number of branches results in fewer ears per plant but allows each ear to grow larger and produce more seeds.

Even harder to believe is that a single species, *Brassica oleracea* (wild mustard), is the ancestor of many familiar and morphologically diverse crops, including kale, broccoli, Brussels sprouts, and cabbage (see Figure 21.4). But each of these familiar vegetable crops has the same basic body plan. Starting with morphologically diverse populations of the wild ancestor, humans selected and planted the seeds of variants with traits they found desirable. For example, Brussels sprout plants were selected for their enlarged axillary buds, cabbage plants were selected for their enlarged terminal buds and short internodes, and broccoli and cauliflower plants were selected for their large clusters of flower buds. Many generations of such artificial selection produced the crops that fill the produce section of the supermarket or the stands of the farmers' market.

Just as they were for ancient farmers, the genomes of plants are priceless resources today. The genetic variation in crop plants and their wild relatives can be used to improve our crop

plants or adapt them to changing conditions. The improvement of crop plants is a work in progress that is being carried out in plant breeding programs worldwide. In fact, these programs are more important than ever. Increased human activity is dramatically changing our planet and leading to the extinction of more and more plant species. For this reason, various organizations around the world have developed seed banks, where seeds of diverse species, and variants within species, are stored.

RECAP 34.4

Crop domestication involves artificial selection of certain desirable traits found in wild plant populations. By understanding the basic body plan of plants, one can more easily understand the morphological relationship between a crop plant and its wild relatives.

- Why are the seeds from wild relatives of crop plants valuable? See p. 725

How might plant physiologists improve the cassava plant for human use?

ANSWER

Many people depend on cassava roots for food. Unfortunately, however, the varieties that are traditionally grown have inadequate levels of protein, iron, and β -carotene. (The human body converts β -carotene into vitamin A.) Furthermore, cassava plants have high levels of cyanogens that are converted to toxic cyanide when eaten. BioCassava Plus is an international consortium of scientists who are using biotechnology to develop cassava varieties with improved nutritional contents. Another team has

developed cassava plants that contain reduced levels of cyanogens. The anatomy of the plant is also being changed. Cassava has been crossed with a treelike relative, *Manihot glaziovii*, and the resulting plants produce roots that are not only fleshy and edible but that grow deep into the soil, where they can tap into water supplies far below the surface in dry climates. This crop is being investigated for use in sub-Saharan Africa.

CHAPTER SUMMARY 34

34.1 What Is the Basic Body Plan of Plants?

- The vegetative organs of flowering plants are roots, which form a **root system**, and stems and leaves, which form a **shoot system**. Review Figure 34.1
- Plant development differs from animal development in that plants have apical meristems, cell walls, vacuoles, and in some cases, totipotent cells.
- Plants have apical-basal and radial axes of symmetry. Review Figures 34.3, 34.4

34.2 What Are the Major Tissues of Plants?

- Three **tissue systems**, arranged concentrically, extend throughout the plant body: the vascular tissue, dermal tissue, and ground tissue systems. Review Figure 34.5
- The **dermal tissue system** protects the plant body surface. Dermal cells form the **epidermis** and, in woody plants, the **periderm**.
- The **ground tissue system** contains cells of three types. Some **parenchyma** cells carry out photosynthesis; others store starch. **Collenchyma** cells provide flexible support. **Sclerenchyma** cells include **fibers** and **sclereids** that provide strength and mechanical support. Review Figures 34.6, 34.7

- The **vascular tissue system** includes **xylem**, which conducts water and minerals absorbed by the roots, and **phloem**, which conducts the products of photosynthesis throughout the plant body.
- **Tracheary elements** include **tracheids** and **vessel elements**, which are the conducting cells of the xylem. **Sieve tube elements** are the conducting cells of the phloem.

34.3 How Do Meristems Build a Continuously Growing Plant?

- All seed plants possess a primary plant body consisting of non-woody tissues. Woody plants also possess a secondary plant body consisting of wood and bark. **Apical meristems** generate the primary plant body, and **lateral meristems** generate the secondary plant body. Review Figure 34.8
- Apical meristems are responsible for **primary growth** (lengthening of roots and shoots). Apical meristems at the tips of stems and roots give rise to three **primary meristems** (**protoderm**, **ground meristem**, and **procambium**), which in turn produce the three tissue systems of the primary plant body.
- The root apical meristem gives rise to the **root cap** and to three primary meristems. Root tips have overlapping **zones of cell division**, **cell elongation**, and **cell maturation**. Review Figure 34.9

continued

- The vascular tissue of roots is contained within the **stele**. It is arranged differently in eudicot and monocot roots. **Review Figures 34.10, 34.11, ACTIVITIES 34.1, 34.2**
- In nonwoody stems, the vascular tissue is divided into **vascular bundles**, each containing both xylem and phloem. **Review Figure 34.13, ACTIVITIES 34.3, 34.4**
- Eudicot leaves have two zones of photosynthetic **mesophyll** that are supplied by veins with water and minerals. Veins also carry the products of photosynthesis to other parts of the plant body. A waxy **cuticle** limits water loss from the leaf. Guard cells control openings called **stomata** in the leaf that allow CO₂ to enter, but also allow some water to escape. **Review Figure 34.15, ACTIVITY 34.5**
- Two lateral meristems, the **vascular cambium** and **cork cambium**, are responsible for secondary growth. The vascular cambium produces secondary xylem (wood) and secondary phloem. The

cork cambium produces a protective tissue called cork. **Review Figures 34.16, 34.17, ANIMATED TUTORAL 34.1**

34.4 How Has Domestication Altered Plant Form?

- The plant body plan is simple, yet it can be changed dramatically by minor differences in genes, as evidenced by the natural diversity of wild plants.
- Crop domestication involves artificial selection of certain desirable traits found in wild populations. **Review Figure 34.20**

CHAPTERREVIEW

REMEMBERING

- Roots
 - always form a fibrous root system that holds the soil.
 - possess a root cap at their tip.
 - form branches from axillary buds.
 - are commonly photosynthetic.
 - do not show secondary growth.
- Which statement about parenchyma cells is *not* true?
 - They are alive when they perform their functions.
 - They typically lack a secondary wall.
 - They often function as storage depots.
 - They are the most common cell type in the plant body.
 - They are found only in stems and roots.
- Which statement about meristems is *not* true?
 - They are formed during embryogenesis.
 - They have secondary cell walls.
 - Their cells have small central vacuoles.
 - They are clusters of undifferentiated cells.
 - They retain the ability to produce new cells indefinitely.
- The pericycle
 - is the innermost layer of the cortex.
 - is the tissue within which lateral roots arise.
 - consists of highly differentiated cells.
 - forms a star-shaped structure at the very center of the root.
 - is waterproofed by suberin.
- Which statement about leaf anatomy is *not* true?
 - Opening of stomata is controlled by guard cells.
 - The cuticle is secreted by the epidermis.
 - The veins contain xylem and phloem.
 - The cells of the mesophyll are packed together, minimizing air space.
 - The spines of cacti are actually modified leaves.

UNDERSTANDING & APPLYING

- Which of these statements is true of secondary growth but *not* of primary growth?
 - It occurs in eudicots and monocots.
 - It involves the proliferation of roots and shoots through branching.
 - It derives from the vascular cambium and the cork cambium.
 - It occurs in palms.
 - It derives from the shoot apical meristem.
- Which of the following is a difference between monocots and eudicots?
 - Only eudicots have phytomers.
 - Only monocots have shoot and root apical meristems.
 - Monocot stems do not undergo secondary growth.
 - The vascular bundles of monocot stems are commonly arranged as a cylinder.
 - Eudicot embryos commonly have one cotyledon.
- Compare sclerenchyma cells and collenchyma cells in terms of structure and function.
- Compare primary and secondary growth. Do all angiosperms undergo secondary growth? Explain.

ANALYZING & EVALUATING

- When a young oak was 5 meters tall, a thoughtless person carved his initials in its trunk at a height of 1.5 meters above the ground. Today that tree is 10 meters tall. How high above the ground are those initials? Explain your answer in terms of plant growth.
- Take a walk through a farmers' market or the produce section of a supermarket. Use your knowledge of plant growth and form to figure out what desirable trait was selected to produce some of your favorite salad vegetables.

CHAPTER OUTLINE

- 35.1** How Do Plants Take Up Water and Solutes?
- 35.2** How Are Water and Minerals Transported in the Xylem?
- 35.3** How Do Stomata Control the Loss of Water and the Uptake of CO_2 ?
- 35.4** How Are Substances Translocated in the Phloem?

EVERYONE KNOWS THAT PLANTS NEED WATER to grow. However, it may come as a surprise that the cultivation of crop plants consumes far more water than all other human activities combined. The worldwide demand for fresh water is increasing at a greater rate than the supply. This situation makes it imperative that we understand how plants use water so that we can select or breed plants that use it more efficiently. Much of the mass that plants acquire as they grow is due to their net fixation of atmospheric CO_2 into carbohydrates through photosynthesis. But plants need to take up a lot of water to grow. The ratio of net photosynthetic carbon fixation to water uptake is known as a plant's water-use efficiency.

Droughts and dwindling water supplies are challenging farmers all over the world. One of the least water-efficient of all crop plants is, unfortunately, one of our most important: rice. Rice plants use up to three times more water per unit of growth than crops such as wheat and corn. The precariousness of heavily water-dependent rice farming was dramatically demonstrated in eastern India between 1997 and 2003, when drought reduced rice production by more than 5 million tons—some farmers lost up to 50 percent of their crops.

A strain of rice requiring less water yet producing the same amount of grain would both make the world supply of rice less vulnerable to drought and help conserve water for other uses. A team of molecular biologists, plant physiologists, and crop scientists led by Andrew Pereira at Virginia Polytechnic began a quest for such a strain of rice by studying an entirely different plant—the model organism *Arabidopsis thaliana* (thale cress). They searched for genetic variants of *Arabidopsis* that had superior water-use efficiency. One variant they studied

Thirsty Rice Cultivation of rice, the most important food crop in Asia, requires large quantities of water.

was particularly hard to pull out of the ground because of its extensive root system (indicating higher capacity for water uptake) and had thick leaves with abundant photosynthetic tissue (indicating prolific photosynthesis). Molecular and physiological characterization of this *Arabidopsis* strain showed that its improved water usage was linked to a mutation in a single gene that codes for a transcription factor. When this gene (called *HARDY*) was isolated and put into rice plants using recombinant DNA technology, the transformed rice plants not only had higher water-use efficiency than wild-type rice plants but were more tolerant of dry soil as well.

Many laboratories around the world are using *Arabidopsis* to isolate genes involved in water usage and other important physiological processes. The knowledge gained from these studies may lead to various improvements of crop plants.

What other methods are used to reduce water loss in agriculture?

See answer on p. 738.

35.1 The Pathways of Water and Solutes in a Plant

Water travels from the soil to the atmosphere, with only a small fraction used within the plant.

35.1

How Do Plants Take Up Water and Solutes?

Terrestrial plants must obtain both water and mineral nutrients from the soil, usually through their roots. The roots, in turn, obtain carbohydrates and other important materials from the leaves (Figure 35.1). Water is required for photosynthesis in the leaves (see Section 10.1), for transporting solutes between plant organs, for cooling the plant, and for developing the internal pressure that supports the plant body.

The minerals that a plant needs are transported along with the water. Several steps in water and mineral transport will be considered in this chapter. In this section we will focus on the first part of the journey—the uptake of water and minerals into the roots and their transport into the xylem.

Water potential differences govern the direction of water movement

To enter a root cell, a solution must pass through the cell's plasma membrane. In Section 6.3 we described osmosis, the movement of water through a selectively permeable membrane from a region of lower solute concentration (higher water potential) to a region of higher solute concentration (lower water potential). Plant biologists define **water potential (Ψ , psi)** as the tendency of a solution (water plus solutes) to take up water from pure water across a membrane. By definition, the water potential of pure water is zero. Any solution that has a water

potential less than zero has a tendency to take up water from pure water. The lower (more negative) the water potential, the greater the driving force for water movement across the membrane.

Water potential has two major components:

- **Solute potential (Ψ_s):** Solutes affect the osmotic behavior of a solution. The solute potential of pure water is zero, so any solution will create a negative solute potential. The greater the concentration of solutes, the lower the water potential, and the lower (more negative) the solute potential.
- **Pressure potential (Ψ_p):** As plant cells take up water, they tend to swell. However, the presence of the cell wall provides resistance to swelling (see Figure 6.9). The result is an increase in pressure inside the cell (**turgor pressure**), which decreases the tendency of the cell to take up more water. Therefore the pressure potential within a plant cell is usually positive.

A solution's water potential is the sum of its (negative) solute potential (Ψ_s) and its (usually positive) pressure potential (Ψ_p):

$$\Psi = \Psi_s + \Psi_p$$

We measure solute potential, pressure potential, and water potential in megapascals (MPa), a unit of pressure. Atmospheric pressure, "one atmosphere," is about 0.1 MPa, or 14.7 pounds per square inch; a typical pressure in an automobile tire is about 0.2 MPa.

Whenever water moves by osmosis, the following important rule applies: *water always moves across a selectively permeable membrane toward the region of lower (more negative) water potential.* In the left-hand tube in Figure 35.2A, the solution has a negative solute potential and a pressure potential of zero (relative to the atmosphere), so water moves across the membrane into the solution. In the right-hand tube, a piston is used to increase the pressure potential in the solution. When the negative solute potential is balanced by the positive pressure potential there is no net movement of water across the membrane.

In a plant cell immersed in pure water (Figure 35.2B), turgor pressure is comparable to the pressure potential exerted by the piston in Figure 35.2A. Water enters the cell by osmosis until the pressure potential exactly balances the solute potential and the water potential is zero. At this point the cell is **turgid**—that is, it has a significantly positive pressure potential. The cells in a plant are not surrounded by pure water, and their water potential is dependent on the water potential in the soil. But because turgid cells have a positive pressure potential, there is no net movement of water into them. The physical structures of many plants are maintained by the positive pressure potential of the water in their cells. If the pressure potential drops (for example, if the plant does not have enough water), the plant wilts (Figure 35.3).

Within living plant tissues, the movement of water from cell to cell follows a gradient of water potential. Over long distances, in unobstructed tubes such as xylem vessels and phloem sieve tubes, the flow of water and dissolved solutes is driven by a *gradient of pressure potential*, not a gradient of water potential. The movement of a solution from a region of higher pressure

35.2 Water Potential, Solute Potential, and Pressure Potential

A theoretical illustration of water potential. (B) The effect of differences in water potential on a plant cell.

Water Uptake in Plants

Life10e.com/at35.1

potential to a region of lower pressure potential is called **bulk flow**. As we will see later in this chapter, bulk flow in the xylem is between regions of differing *negative* pressure potentials (tension). By contrast, bulk flow in the phloem is between regions of differing *positive* pressure potentials (turgor pressure).

Water and ions move across the root cell plasma membrane

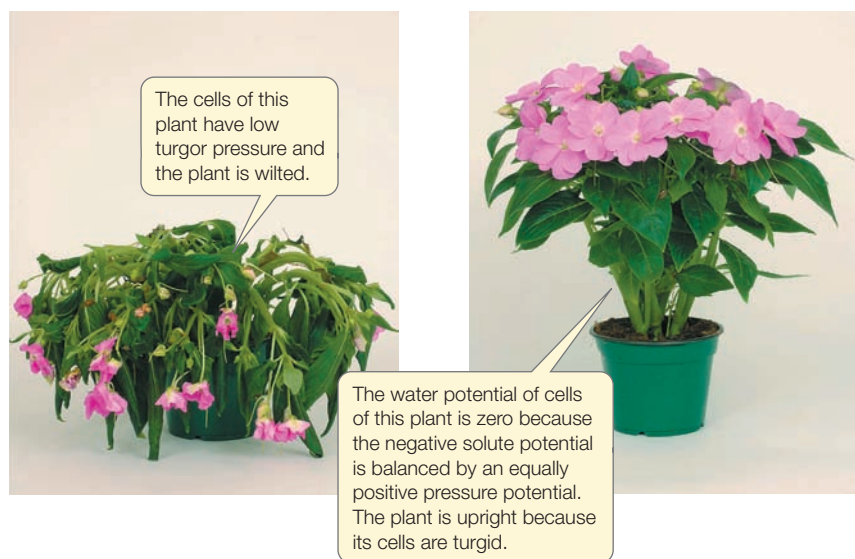

The movement of water and mineral ions across a root cell plasma membrane can be impeded for two reasons:

- The membrane is hydrophobic, whereas water and mineral ions are polar.
- Some mineral ions must be moved against their concentration gradients.

However, as we saw in Chapter 6, membrane proteins assist with the movement of materials across membranes:

- **Aquaporins.** Aquaporins (see Figure 6.11) are located in both the plasma membrane and the tonoplast (vacuolar membrane) of a plant cell. Aquaporins allow water to diffuse rapidly across these membranes. The abundance of aquaporins in a particular cell depends on that cell's need to

obtain and retain water, and can vary with environmental conditions. The permeability of some aquaporins also can be regulated. Alterations in aquaporin abundance and permeability change the *rate* of osmosis across the membrane. Note that water movement through aquaporins is always

35.3 A Wilted Plant A plant wilts when the pressure potential in its cells (the turgor pressure) is low.

35.4 The Proton Pump in Transport of K^+ and Cl^-

The active transport of hydrogen ions (H^+) out of the cell by the proton pump (1) drives the movement of both cations (2) and anions (3) into the cell.

inside of the cell is more negative than the outside, cations (positively charged ions) such as potassium (K^+) can move into the cell by facilitated diffusion through specific membrane channels (**Figure 35.4, step 2**). In addition, the proton concentration gradient can be harnessed to drive secondary active transport, in which anions (negatively charged ions) such as chloride (Cl^-) are moved into the cell. These ions can move against the electrochemical gradient because symport proteins couple their movement with that of H^+ (**Figure 35.4, step 3**).

Water and ions pass to the xylem by way of the apoplast and symplast

The journey from the soil through the roots to the xylem occurs primarily by one of two pathways, either separately or simultaneously: the fast lane (called the apoplast) and the slow(er) lane (called the symplast) (**Figure 35.5**):

- The **apoplast** (Greek *apo*, “away from”; *plast*, “living material”) consists of the cell walls, which lie outside the plasma membranes, and the intercellular spaces (spaces between cells) that are common in many plant tissues. The apoplast is a continuous meshwork through which water and dissolved substances can flow without ever having to cross a membrane. Movement of materials through the apoplast is thus unregulated and rapid.
- The **symplast** (Greek *sym*, “together with”) is the continuous cytoplasm of the living cells, which are connected by plasmodesmata (see Figure 7.19). The selectively permeable plasma membranes of the root cells control access to the symplast, so movement of water and dissolved substances into the symplast is tightly regulated.

Water and minerals that pass from the soil solution through the apoplast can travel as far as the endodermis, the innermost

passive: from a region of higher water potential to one of lower water potential.

- **Ion channels and pumps.** When the concentration of a charged ion in the soil is greater than that in the plant, transport proteins can move the ions into the plant by facilitated diffusion, which is a passive process (see Section 6.3). The concentrations of most ions in the soil solution, however, are lower than those inside the plant. In these cases the plant must actively take up ions *against* their concentration gradients—a process that requires energy (Section 6.4).

Electric charge differences also play a role in the uptake of mineral ions. For example, a negatively charged ion that moves into a negatively charged compartment is moving against an *electrical gradient*, and this requires energy. Concentration and electrical gradients combine to form an electrochemical gradient (see Section 45.2). Uptake against an electrochemical gradient involves active transport, which requires energy and specific transport proteins.

Unlike animals, plants do not have a sodium–potassium pump (see Section 6.4) to drive active transport. Rather, plants have a **proton pump**, which uses energy obtained from ATP to move protons out of the cell against a proton concentration gradient (**Figure 35.4, step 1**). Because protons (H^+) are positively charged, their accumulation outside the cell has two results:

- An electrical gradient is created, with the region outside the cell more positively charged than the inside.
- A proton concentration gradient develops, with more protons outside the cell than inside.

Both the electrical gradient and the concentration gradient assist with the movement of other ions into the cell. Because the

35.5 Apoplast and Symplast Plant cell walls and intercellular spaces constitute the apoplast. The symplast comprises the living cells, which are connected by plasmodesmata. To enter the symplast, water and solutes must pass through a plasma membrane. No such selective barrier limits movement through the apoplast.

35.6 Pathways to the Root Xylem Water and solutes can move into the root through the symplast or the apoplast until they reach the endodermis (shown in dark green); there the water and solutes must enter the symplast to bypass the Casparian strip (red), a region of the endodermal cell wall that is impregnated with the water-repelling substance suberin. Inside the stele, the water and solutes enter the xylem (blue).

Go to Activity 35.1 Apoplast and Symplast of the Root
Life10e.com/ac35.1

layer of the root cortex (**Figure 35.6**; see Section 34.3). The endodermis is distinguished from the rest of the ground tissue by the presence of the **Casparian strip**. This waxy, suberin-impregnated region of the endodermal cell wall forms a hydrophobic belt around each endodermal cell where it is in contact with other endodermal cells. The Casparian strip acts as a seal that prevents water and ions from moving through apoplastic spaces between the endodermal cells (see **Figure 35.6**). Therefore all water and ions must enter the symplast in order to cross the endodermis into the stele, which contains the vascular tissues of the root. The materials pass from the endodermal cells to cells in the stele via plasmodesmata.

Once they have passed the endodermal barrier, water and minerals remain in the symplast until they reach parenchyma cells in the pericycle or xylem. These cells then actively export mineral ions into the apoplast of the stele. As the concentrations of mineral ions in the apoplast increase, its water potential becomes more negative. Consequently, water moves out of the cells and into the apoplast by osmosis. In other words, ions are transported actively, and water follows passively. The end result is that water and minerals end up in the xylem, where they constitute the **xylem sap**.

RECAP 35.1

Differences in water potential govern the osmotic flow of water from the soil into the plant stele; this is a passive process. Uptake of minerals from the soil that occurs along an electrochemical gradient is an active process requiring energy and membrane transport proteins. Water and minerals can move into the root through either the apoplast or the symplast, but must enter and leave via the symplast to reach the xylem.

- What distinguishes water potential, solute potential, and pressure potential? **See p. 727 and Figure 35.2**
- Why is the cell wall important in determining the direction of water movement and plant form? **See pp. 727–728**
- What are aquaporins, and why are they needed? **See p. 728**
- What are the differences between the apoplast and the symplast? **See p. 729 and Figures 35.5 and 35.6**

So far we've described the movement of water and minerals into plant roots and their entry into the root xylem. How does the xylem sap move once it is in the xylem?

35.2 How Are Water and Minerals Transported in the Xylem?

Water has arrived in the xylem—and must travel “uphill” from there. Before considering the ascent of water and minerals to the leaves, acquaint yourself with the cells that make up the xylem: the tracheids and vessel elements (see **Figure 34.7A and B**). Recall that these xylem cells are dead and lack all cell contents. When fused end to end, they form long tubular “straws” of lignified cell walls called **xylem vessels**. These vessels provide both structural support and the rigidity needed to maintain a gradient of pressure.

Consider the magnitude of what the xylem accomplishes when it transports large amounts of water over great distances within a plant. A single maple tree 15 meters tall was estimated to have some 177,000 leaves, with a total leaf surface area of 675 square meters—about one and a half times the area of a basketball court. During a summer day, that tree loses 220 liters of water *per hour* to the atmosphere by evaporation from the leaves. So to prevent wilting, the xylem needs to transport 220 liters of water up to 15 meters from the roots to the leaves every hour. (By comparison, a 50-gallon drum holds 189 liters.)

Until the twentieth century, scientists proposed two possible mechanisms for moving water through the xylem: upward pressure by living cells, and capillary action. Both of these possibilities were largely ruled out by experiments:

- A simple experiment in 1893 ruled out the hypothesis that root cells might initiate a *pumping mechanism* to propel water upward. A tree was cut at its base and the sawed-off part was placed in a vat containing a solution of poison that killed living cells. The poison rose up the trunk, killing any living cells it encountered along the way. The experiment demonstrated that a living pump in the root is not necessary to push the xylem sap up a tree. Because the roots were absent, it was clear that they are not involved

in xylem movement. Furthermore, when the poison sap reached the leaves, they died and all upward movement of the solution stopped, showing that living leaves are necessary for water to move in the xylem.

- Because of its surface tension (see Section 2.4) and adhesive forces between water and its container, water will move up a narrow column by a mechanism called *capillary action*. Capillary action was ruled out as a primary mechanism for upward xylem sap transport when calculations showed that xylem vessels (at 100 micrometers in diameter) are too wide to get water to the top of a 15-meter tree in this fashion. In fact, the maximum height for a water column raised by capillary action alone in a 100-micrometer tube would be only 0.15 meters.

The transpiration–cohesion–tension mechanism accounts for xylem transport

The current model of xylem transport involves three processes (**Figure 35.7**):

- *Transpiration* of water molecules from the leaves by evaporation
- *Tension* in the xylem sap resulting from transpiration from the leaves

- *Cohesion* of water molecules in the xylem sap, from the leaves to the roots

The relative amount of water vapor in the atmosphere is lower than that in the leaf. Because of this difference, water vapor diffuses from the intercellular spaces of the leaf to the outside air, in a process called **transpiration**. Within the leaf blade, water evaporates from the moist walls of the mesophyll cells and enters the intercellular spaces. As water evaporates from the aqueous film coating each cell, the film shrinks back into tiny spaces in the cell walls, increasing the curvature of the water surface and thus increasing its surface tension. This increased *tension* (negative pressure potential) in the surface film draws more water into the walls from the cells, replacing that which was lost. The resulting tension in the mesophyll draws water from the xylem of the nearest vein into the apoplast surrounding the mesophyll cells. The removal of water from the veins, in turn, establishes tension on the entire column of water contained in the xylem. *Cohesion* between water molecules in the column prevents the column from breaking. So these three forces—transpiration, tension, and cohesion—operate together to draw water up the xylem, all the way from the roots to the leaves.

Each part of this theory is supported by evidence:

- The difference in water potential between the soil solution and the air is huge, on the order of -100 MPa. This difference should generate more than enough tension to pull a water column up a tree.
- There is a continuous column of water in the xylem, which is caused by cohesion.
- Actual measurements of xylem pressures in cut stems show negative pressure potentials, indicating considerable tension in the xylem (**Figure 35.8**).

The transpiration–cohesion–tension mechanism accounts for the movement of water through the xylem. Dissolved mineral ions are carried along with the water to all of the plant's living tissues, where the ions are used for various cellular processes (see Chapter 36 for more on plant nutrition). In addition to promoting the transport of minerals, transpiration has an added benefit of cooling a plant's leaves. The evaporation of water from mesophyll cells consumes heat, thereby decreasing the leaf temperature. A farmer can hold a leaf between thumb and forefinger to estimate its temperature; if the leaf doesn't feel cool, that means transpiration is not occurring and it must be time to water.

RECAP 35.2

The transpiration–cohesion–tension mechanism explains the ascent of xylem sap. Transpiration draws water out of leaves, resulting in tension that pulls water from the xylem. Because of cohesion between water molecules, water is pulled passively through the xylem vessels in continuous columns, always toward a region with lower pressure potential.

- What are the roles of transpiration, cohesion, and tension in xylem transport? **See pp. 731–732 and Figure 35.7**
- What experiment rules out the role of pressure from the roots in the upward flow of water in xylem? **See p. 731**

RESEARCH TOOLS

35.8 Measuring the Pressure of Xylem Sap with a Pressure Chamber

Xylem sap pulls away from a cut stem because the pressure in the intact xylem is lower than that of the atmosphere. The negative pressure potential originally present in the plant can be measured in a pressure chamber in which the pressure can be raised. The cut surface remains outside the chamber. As gas pressure increases, the xylem sap is pushed back to the cut surface. When the sap first becomes visible again at the cut surface, the pressure in the chamber is recorded. This pressure is equal in magnitude but opposite in sign to the tension (negative pressure potential) originally present in the xylem.

Although transpiration provides the driving force for the transport of water and minerals in the xylem, it also results in the loss of tremendous quantities of water from the plant. How plants control this loss will be the subject of the next section.

35.3 How Do Stomata Control the Loss of Water and the Uptake of CO₂?

The epidermis of leaves and stems secretes a waxy cuticle, which is impermeable to water and thus helps minimize the loss of water from transpiration. However, the cuticle is also impermeable to carbon dioxide. The cuticle poses a dilemma: how can the plant balance its need to retain water with its need to obtain CO₂ for photosynthesis?

An elegant compromise has evolved in plants in the form of pores called **stomata** (singular *stoma*) in the epidermis of their leaves. A pair of specialized epidermal cells, called **guard cells**, controls the opening and closing of each stoma (**Figure 35.9A**). When the stomata are open, CO₂ can enter the leaf by diffusion—but water vapor diffuses out of the leaf at the same time. Closed stomata prevent water loss but also exclude CO₂ from the leaf.

Most plants open their stomata only when the light intensity is sufficient to maintain a moderate rate of photosynthesis. At

night, when darkness precludes photosynthesis, their stomata are closed; no CO₂ is needed, and water is conserved. Even during the day, the stomata close if water is being lost at too rapid a rate.

Stomata are ancient structures; they have been found in plant fossils that are more than 400 million years old. For this reason they are thought to predate the evolution of leaves. Stomata are found in all vascular plants and in many non-vascular plants, including mosses (but not liverworts; see Chapter 28).

The stoma and guard cells seen in Figure 35.9A are typical of eudicots. Monocots typically have specialized epidermal cells associated with their guard cells. However, the principle of operation, which we will now describe in more detail, is the same for both monocot and eudicot stomata.

The guard cells control the size of the stomatal opening

The opening and closing of stomata are regulated by several environmental factors, including light, CO₂ levels, temperature, and water availability. For example, light causes the stomata of most plants to open, admitting CO₂ for photosynthesis. A low level of CO₂ in the intercellular spaces of the leaf will trigger the opening of the stomata as well, allowing the uptake of more CO₂. However, to conserve water, plants will close their stomata on hot days and when water availability is limited.

Stomata can respond to these environmental stimuli in a matter of minutes. How does this important biological process happen so rapidly? Stomata open and close rapidly in response to changes in turgor pressure in the guard cells. These changes in turgor pressure arise in response to changes in K⁺ concentrations in the guard cells. These concentration changes are triggered by environmental cues.

In sunlight, a pigment in the guard cell membrane absorbs blue light, which activates a proton pump that actively transports H⁺ out of the guard cells and into the apoplast of the surrounding epidermis. The resulting electrochemical gradient drives K⁺ into the guard cells, making the water potential of the guard cells more negative (Figure 35.9B). Negatively charged chloride ions and organic ions move into and out of the guard cells along with the potassium ions, functioning to maintain the electrical balance and contributing to the change in the solute potential of the guard cells. Water enters by osmosis (guard cell membranes are particularly rich in aquaporin protein channels), which increases the pressure potential of the guard cells. The cellulose microfibrils in the guard cell walls are arranged so that the shape of the cells changes in response to the increase in pressure potential, and a gap—the stoma—appears between them.

In the absence of sunlight, the stomata of most plants close. Lacking blue light, the proton pump becomes less active, potassium and chloride ions diffuse passively out of the guard cells, and water follows by osmosis (see Figure 35.9B, step 3). These changes lower the pressure potential in the guard cells so that they sag together, closing the stoma.

35.9 Stomata (A) Scanning electron micrograph of an open stoma formed by two sausage-shaped guard cells. (B) Potassium ion concentrations affect the water potential of the guard cells, controlling the opening and closing of stomata. Negatively charged ions (e.g., Cl⁻) that accompany K⁺ maintain electrical balance and contribute to the changes in water potential that open and close the stomata.

Stomata respond not only to light but to water availability. Water stress is a common problem for plants, especially on hot, windy days. On hot, dry days plants will close their stomata even when the sun is shining. The water potential of the mesophyll cells is the cue for this protective response. If the mesophyll is too dehydrated—that is, if its water potential is too negative—its cells release a plant hormone called abscisic acid. Abscisic acid causes the guard cells to close the stomata and prevent further drying of the leaf. Although this protective response reduces the rate of photosynthesis, it protects the plant from wilting.

Not all plants respond to environmental cues in the same way. CAM plants such as cacti (see Section 10.4) are often found in the desert. To avoid excess water loss, these plants close their stomata during the day and open them at night. They have a metabolic adaptation that allows them to accumulate CO_2 at night when their stomata are open, then release the CO_2 inside the plant for photosynthesis during the day.

Plants can control their total numbers of stomata

Individual stomata are tiny, yet plants can lose large amounts of water. A single corn plant can lose 2 quarts of water per day. Plant water loss can be great because there can be a huge numbers of stomata on every leaf: up to 250,000 per square inch of leaf surface! Plants limit water loss by controlling stomata in two very different ways:

- By regulating stomatal opening and closing (described above)
- By controlling the total number of stomata

Whereas the process of opening and closing stomata can occur in minutes, as we saw above, the process of controlling the total number of stomata occurs over days or weeks. Trees can reduce their total number of stomata by shedding some of their leaves. Other plants reduce the numbers of stomata on new leaves that develop during a drought.

CO_2 levels can also trigger changes in stomatal density. If the model plant *Arabidopsis* is exposed to high CO_2 levels, its new leaves have fewer stomata than they would have under normal conditions. Why do you think this might be advantageous?

RECAP 35.3

CO_2 , which is needed for photosynthesis, enters leaves via tiny pores called stomata. Stomata also permit the loss of water by transpiration. Guard cells open or close stomata in response to a variety of environmental cues. Plants control their total numbers of stomata by shedding leaves or by altering the density of stomata on new leaves.

- What is the role of K^+ ions in the functioning of guard cells?
See p. 733 and Figure 35.9
- Describe how environmental cues (such as CO_2 level and water availability) can affect stomatal function and density during the life of a plant. See p. 734

Stomata are normally open during daylight hours, allowing photosynthesis—the production of carbohydrates from CO_2

and water. In the next section we'll see how the products of photosynthesis are delivered to other parts of the plant, supporting plant growth.

35.4 How Are Substances Translocated in the Phloem?

Photosynthesis occurs primarily in the leaf (see Figure 10.1). The carbohydrate products of photosynthesis (mainly sucrose) diffuse to the nearest small vein (composed of xylem and phloem), where they are actively transported into sieve tube elements of the phloem. The movement of carbohydrates and other solutes through the phloem is called **translocation**. The products of photosynthesis are called **photosynthates**, and the content of the phloem is called the **phloem sap**.

The photosynthates and other substances are translocated from sources to sinks.

- A **source** is an organ (such as a mature leaf or a storage root) that *produces*, by photosynthesis or by digestion of stored reserves, more sugars than it requires.
- A **sink** is an organ (such as a root, flower, developing fruit, or immature leaf) that *consumes* sugars for its own growth and storage needs of the plant.

A given organ can be a sink at some times and a source at others. An example is the roots of maple trees, which store sugars sent down from the leaves during one growing season, then send sugars back upward to support the emergence of new leaves the following spring.

Sucrose and other solutes are carried in the phloem

Evidence that the phloem carries sucrose and other solutes was first obtained in the 1600s when the Italian scientist Marcello Malpighi removed a ring of bark from the trunk of a tree—that is, he “girdled” the tree. The bark contained the phloem, while the xylem in the underlying wood remained intact. Over time, the bark in the region above the girdle swelled:

Malpighi correctly concluded that a solution coming from the leaves above the girdle was trapped in the bark. Later the bark below the girdle died, presumably because it no longer received nutrients from the leaves. Eventually the roots, and then

35.10 Sieve Tubes Individual sieve tube elements join together to form long tubes that transport carbohydrates and other nutrient molecules throughout the plant body in the phloem. Sieve plates form at the ends of each sieve tube element, and phloem sap passes through the pores in the sieve plate.

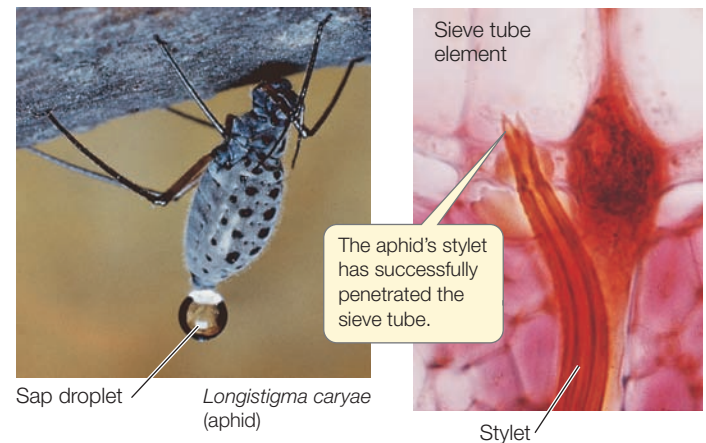

the entire tree, died—suggesting that sugar transport might occur in the phloem.

The cells that make up the phloem's conducting tubes are sieve tube elements (see Figure 34.7C). Like the vessel elements in the xylem, sieve tube elements meet end to end. However, unlike vessel elements, whose end walls are broken down as they mature, sieve tube elements retain their end walls. Communication between sieve tube elements is achieved by plasmodesmata in their end walls. During sieve tube development, the diameter of these plasmodesmata increases 10- to 100-fold, resulting in pores that allow the flow of phloem sap between neighboring cells. Because the end walls of sieve tube elements look and function like sieves, they are called **sieve plates** (Figure 35.10).

What happens next is truly remarkable and makes sieve tube elements among the most unusual cell types in nature. As the holes in the sieve plates expand, most of the cell contents are lost, including the nucleus, Golgi apparatus, and most of the ribosomes and cytoskeleton. Despite this, sieve tube elements live for an entire growing season in deciduous trees, and for decades in some other plants. How can sieve tube elements live for so long with no nucleus? The answer is that each

sieve tube element has one or more **companion cells** (see Figure 35.10). Companion cells are produced as daughter cells along with the sieve tube elements when parent cells divide. Numerous plasmodesmata link a companion cell with its neighboring sieve tube element. Companion cells retain all their organelles and provide all the components needed to maintain the sieve tube elements—they may be thought of as the “life support systems” of the sieve tube elements.

Plant biologists in the twentieth century used aphids to precisely analyze the contents of the phloem. Aphids are insects that feed on plants by drilling into sieve tube elements with a specialized organ, the stylet. The pressure potential in the sieve tube is higher than that outside the plant, so the phloem contents are forced through the stylet into the aphid's digestive tract. So great is the pressure that some of the liquid is forced through the insect's body and out its anus. If an aphid is frozen in the act of feeding, its body can be chopped off the plant stem, leaving the stylet intact. Phloem sap continues to flow from the stylet for hours, and can be collected for analysis.

These and other experiments led to several important observations:

- Sucrose makes up 90 percent of the phloem sap solutes. The phloem sap also contains hormones, small molecules such as amino acids, mineral nutrients, and viruses.
- The flow rate can be very high, as much as 100 centimeters per hour.
- Different sieve tube elements conduct their contents in different directions—for example, up or down the stem. Therefore the overall movement in the phloem is bidirectional.
- The movement of phloem sap requires living cells, in contrast to movement in the xylem.

The pressure flow model appears to account for translocation in the phloem

As noted above, phloem sap flows under positive pressure through the sieve tubes. It moves by bulk flow (i.e., from a region of higher pressure potential to a region of lower pressure potential) from one sieve tube element to the next. We need to

35.11 The Pressure Flow Model Water potential differences produce a pressure gradient and bulk flow of phloem sap from sources to sinks.

Go to Animated Tutorial 35.3
The Pressure Flow Model
Life10e.com/at35.3

understand how this pressure is generated in order to understand translocation in the phloem.

Two steps in translocation require metabolic energy:

- Transport of sucrose and other solutes from sources into the sieve tubes; called **loading**
- Removal of the solutes from the sieve tubes into sinks; called **unloading**

According to the **pressure flow model** of translocation in the phloem, sucrose is actively transported into sieve tube elements at a source, giving those cells a greater sucrose concentration than the surrounding cells. Therefore the cells develop a lower solute potential—a more negative Ψ_s —at which point water enters the sieve tube elements from xylem vessels by osmosis. The entry of this water causes a greater pressure potential (turgor pressure) at the source end of the sieve tube, so that the entire fluid content of the sieve tube is pushed toward the sink end of the tube—in other words, the sap moves by bulk flow in response to a pressure gradient (**Figure 35.11**). In the sink, the sucrose is unloaded both passively and by active transport, and water moves back to the xylem vessels. In this way the gradients of solute potential and pressure potential, which are needed for movement of the phloem sap, are maintained.

Sugars and other solutes move from the mesophyll cells in the leaf to the phloem by two general routes: apoplastic and symplastic. The exact details of these routes vary widely among plant species. In many plants, sugars and other solutes follow the **apoplastic pathway**: solutes move out of the mesophyll cells and then diffuse through the apoplast to the sieve tubes. Specific sugars and amino acids are then actively transported into the sieve tube elements. Active transport across membranes (see Section 6.4) allows plants to regulate which specific substances enter the phloem. In contrast, in the **symplastic pathway**, solutes remain within the symplast and pass through plasmodesmata all the way from the mesophyll cells to the sieve tube cells. Because no membranes are crossed in the symplastic pathway, the solutes are loaded into the phloem by mechanisms other than active membrane transport.

The pressure flow model of translocation in the phloem is contrasted with the transpiration–cohesion–tension model of xylem transport in **Table 35.1**.

Upon arriving in sink regions, solutes are actively transported *out* of the sieve tube elements and into the surrounding tissues. This unloading serves several purposes: it helps maintain the gradient of solute potential and hence of pressure potential in the sieve tubes; it supplies carbohydrates and amino acids to developing organs, where they are used for growth; and it helps build up high concentrations of proteins and

carbohydrates in storage organs such as storage roots, fruits, and seeds. The demand for fixed carbon can be very large in some tissues, such as a rapidly growing stem or a developing potato tuber. These tissues receive a lot of phloem sap, while a slowly growing organ receives less.

An experiment by Lothar Willmitzer and colleagues at the Max Planck Institute in Germany demonstrated the importance of sink strength in potato tubers (**Figure 35.12**). Sink strength is the relative ability of an organ to attract photosynthates. A potato tuber is formed from an underground stem that changes its function from transport to synthesis and storage of starch. Because the source of glucose to make this starch is sucrose from the phloem, there is a high demand for phloem unloading into the developing potato tuber. The enzyme invertase catalyzes the hydrolysis of sucrose to glucose and fructose, and the fructose is quickly converted to glucose. Willmitzer and colleagues transformed potato plants by introducing a gene that caused invertase to accumulate in the apoplast of the tuber tissue, where the enzyme accumulated to high levels. In these plants, the sucrose that was transported out of the phloem into the apoplast was rapidly hydrolyzed. The resulting glucose was taken up by the tuber cells and converted to starch. The action of the invertase in the apoplast lowered the sucrose concentration in the potato tissue and led to a high rate of phloem unloading (see **Figure 35.11**). As a result, the potato tubers

TABLE 35.1 Mechanisms of Sap Flow in Plant Vascular Tissues

	Xylem	Phloem
Driving force for bulk flow	Transpiration from leaves	Active transport of sucrose at source and sink
Site of bulk flow	Nonliving vessel elements and tracheids	Living sieve tube elements
Pressure potential in sap	Negative (pull from top; tension)	Positive (push from source; pressure)

INVESTIGATINGLIFE

35.12 Manipulating Sucrose Transport from the Phloem

Does a change in the concentration of sucrose in a sink tissue affect the unloading of sucrose from the phloem? Lothar Willmitzer and colleagues genetically modified potato plants so that sucrose in the developing tubers was immediately hydrolyzed. This lowered the effective sucrose concentration in the “sink” for phloem unloading. The researchers then tested whether this affected tuber development, a reflection of sucrose unloading from phloem.^a

HYPOTHESIS Reducing the sucrose concentration in a sink organ will increase the transport and unloading of sucrose from the phloem.

Method Plants were transformed with a gene for invertase, an enzyme that hydrolyzes sucrose.

The potato plant has underground tubers, modified stems that store starch.

**Results**

Wild-type plants

The wild-type plants had a high level of sucrose in developing tubers. The tubers were normal in size and number.

Transgenic plants

The genetically modified plants had a low level of sucrose in developing tubers and produced fewer but much larger potatoes.

CONCLUSION Increasing sink strength increases sucrose transport into developing tissues.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

^aSonnewald, U. et al. 1997. *Nature Biotechnology* 15: 794–797.

that developed on the transformed plants were larger than those of wild-type plants. This experiment demonstrated that transport into the apoplast is an efficient way for phloem cells to unload sucrose, and that the sucrose concentration gradient between the phloem and the apoplast influences the rate of unloading.

WORKING WITHDATA:

Manipulating Sucrose Transport from the Phloem**Original Paper**

Sonnewald, U., N.-R. Hajirezaei, J. Kossmann, A. Heyer, R. Tretheway, and L. Willmitzer. 1997. Increased potato tuber size from apoplastic expression of yeast invertase. *Nature Biotechnology* 15: 794–797.

Analyze the Data

Plant tissues can be exporters (sources) or importers (sinks) of carbohydrates, mainly in the form of sucrose. Many of the foods grown for human consumption are sink tissues; we eat the crops' carbohydrates, mostly as starch. As a potato tuber develops from an underground stem, or stolon, it requires a lot of carbohydrate, which it obtains as sucrose from the phloem. Lothar Willmitzer and colleagues at the Max Planck Institute in Germany hypothesized that the rate of sucrose unloading from phloem to tuber is affected by the sucrose concentration difference (gradient) between the phloem and the developing tuber. To test their hypothesis, they used genetic engineering to express the gene for yeast invertase in developing tuber cells (see Figure 35.12).

Normal potato plants have invertase but do not express it at high levels in tubers. The yeast invertase gene used to transform the plants was coupled to a plant promoter that caused high expression of the enzyme in the developing tubers. Invertase hydrolyzes sucrose, so the researchers predicted that the concentration of sucrose would be lower in the tubers of transgenic plants (and the gradient steeper) than in wild-type plants. Experiments performed on the transgenic plants confirmed that increasing the sucrose concentration difference between the phloem and the tubers led to increased sucrose unloading from the phloem.

QUESTION 1

To test whether the introduced yeast invertase was having the predicted effects on sucrose levels, the researchers measured invertase activity and sugars in tubers of wild-type and transgenic plants. The results are in the first three rows of the table (mean \pm standard deviation). Which group of plants had higher invertase activity? Carry out a statistical test to evaluate your conclusion (see Appendix B). How do the sugar content measurements relate to invertase activity?

QUESTION 2

The researchers estimated sucrose unloading from phloem by comparing the sizes of the tubers that developed on normal and transgenic plants, assuming that larger tubers must have unloaded more sucrose from the phloem. The tuber yields are shown in the last two rows of the table (mean \pm standard deviation). What can you conclude about the distribution of sucrose to developing tubers?

	Wild type	Transgenic
Invertase activity (units/mg protein)	9 \pm 4	598 \pm 73
Sucrose (mg/g tuber weight)	15.8 \pm 0.7	1.2 \pm 0.2
Glucose (mg/g tuber weight)	2.1 \pm 0.4	38.0 \pm 4.3
Tubers per plant	6.4 \pm 0.4	2.6 \pm 0.1
Tuber weight (g/tuber)	18	57.3

The control of phloem sap travel from source to sink has great importance for humans. The parts of plants that we use for food, such as seeds (e.g., the rice in the opening story), fruits, and storage organs, are mostly sinks. Increasing the flow of sucrose into these organs as they develop can increase food production in crop plants. The experiment on potatoes, described above, is an important step toward understanding and manipulating phloem transport.

RECAP 35.4

Carbohydrates produced by photosynthesis are translocated from source to sink through the phloem by a pressure flow mechanism.

- Explain the difference between a source and a sink. **See p. 734**
- How does loading of sucrose at the source result in bulk flow toward the sink? **See pp. 735–736 and Figure 35.11**

What other methods are used to reduce water loss in agriculture?

ANSWER

Optimal plant growth depends on the presence of an appropriate amount of soil water near the roots during a plant's life cycle. In addition to using plants that are more water-efficient, plant growers can manipulate the environment to reduce water losses that are due to evaporation and soil runoff. Simply putting a pan out in the field and measuring the rate of evaporation can be a guide as to when to increase irrigation. Cheap sensors in the soil can measure water content and alert the grower to deficits or excess. Farmers can use laser technology to grade (shape) fields to reduce water runoff during irrigation.

35.1 How Do Plants Take Up Water and Solutes?

- Water moves through biological membranes by osmosis, always moving toward regions with a more negative water potential. The **water potential (Ψ)** of a cell or solution is the sum of the **solute potential (Ψ_s)** and the **pressure potential (Ψ_p)**. **Review Figure 35.2, ANIMATED TUTORIAL 35.1**
- **Turgid** plant cells have significant positive pressure potential because the rigid cell wall limits expansion of the cell. This positive pressure (**turgor pressure**) maintains the physical structure of many plant cells; if the pressure potential drops, the plant wilts.
- The movement of a solution due to a difference in pressure potential between two parts of a plant is called **bulk flow**.
- Aquaporins are channel proteins that facilitate movement of water molecules through biological membranes.
- Mineral uptake requires transport proteins. Some minerals enter the plant passively by facilitated diffusion; others enter by active transport. A **proton pump** provides energy for the active transport of many mineral ions across membranes in plants. **Review Figure 35.4**
- Water and minerals pass from the soil into the root by way of the **apoplast** and **symplast**, but must pass through the symplast to cross the endodermis and enter the xylem. The **Casparian strip** in the endodermis blocks movement of water and minerals through the apoplast. **Review Figures 35.5, 35.6, ACTIVITY 35.1**

35.2 How Are Water and Minerals Transported in the Xylem?

- Experiments proved that neither a root pump nor capillary action can alone account for the ascent of xylem sap in trees.
- Water transport in the xylem results from the combined effects of **transpiration**, cohesion, and tension—the transpiration-cohesion-tension mechanism. Evaporation from the leaf produces tension in the mesophyll cells, which pulls a column of water—held together by cohesion—up through the xylem from the root. **Review Figure 35.7, ANIMATED TUTORIAL 35.2**

CHAPTER SUMMARY 35

- Transport in the xylem is passive. It does not require the expenditure of energy by the plant.

35.3 How Do Stomata Control the Loss of Water and the Uptake of CO_2 ?

- The waxy cuticle of plant epidermis is impermeable to both water and carbon dioxide. **Stomata** allow for carbon dioxide uptake (when open) while minimizing transpirational water loss (when closed).
- A pair of **guard cells** controls the size of the stomatal opening. A light-activated proton pump moves protons out of the guard cells to the walls of surrounding epidermal cells, setting up an electrochemical gradient that drives the transport of potassium ions into the guard cells. Water follows osmotically, swelling the guard cells and opening the stomata. **Review Figure 35.9**
- When threatened by dehydration, mesophyll cells release abscisic acid, which causes guard cells to close the stomata, even in the light.

35.4 How Are Substances Translocated in the Phloem?

- Products of photosynthesis, as well as some minerals, are translocated through sieve tubes in the phloem by way of living sieve tube elements. **Review Figure 35.10**
- **Translocation** in the phloem can proceed in both directions in the stem. Translocation requires a supply of ATP.
- Translocation in the phloem is explained by the **pressure flow model**: the difference in solute concentration between **sources** and **sinks** creates a difference in (positive) pressure potential along the sieve tubes, resulting in bulk flow. **Review Figure 35.11, Table 35.1, ANIMATED TUTORIAL 35.3**

CHAPTER REVIEW

REMEMBERING

- Osmosis
 - requires ATP.
 - results in the bursting of plant cells placed in pure water.
 - can cause a cell to become turgid.
 - is independent of solute concentrations.
 - continues until the pressure potential equals the water potential.
- Water potential
 - is the difference between the solute potential and the pressure potential.
 - is analogous to the air pressure in an automobile tire.
 - is the movement of water through a membrane.
 - determines the direction of water movement between cells.
 - is defined as 1.0 MPa for pure water under no applied pressure.
- Which statement about proton pumping across the plasma membrane of plants is *not* true?
 - It requires ATP.
 - The region inside the membrane becomes positively charged with respect to the region outside.
 - It enhances the movement of K^+ ions into the cell.
 - It moves protons out of the cell against a proton concentration gradient.
 - It can drive the secondary active transport of negatively charged ions.
- Which statement is *not* true?
 - The symplast consists of the interconnected cytoplasm of living cells.
 - Water can enter the stele without entering the symplast.
 - The Casparian strips prevent water from moving through the apoplast between endodermal cells.
 - The endodermis is a cell layer in the cortex.
 - Water can move freely in the apoplast without entering cells.
- Which of the following is *not* part of the transpiration-cohesion-tension mechanism?
 - Water evaporates from the walls of mesophyll cells.
 - Removal of water from the xylem exerts a pull on the water column.
 - Water is remarkably cohesive.
 - The wider the tube, the greater the tension its water column can withstand.
 - At each step, water moves to a region with a more strongly negative water potential.
- Which statement about phloem transport is *not* true?
 - It takes place in sieve tubes.
 - It depends on mechanisms for loading solutes into the phloem at sources.

- It stops if the phloem is killed by heat.
- A high pressure potential is maintained in the sieve tubes.
- At sinks, solutes are actively transported into sieve tube elements.

UNDERSTANDING & APPLYING

- Shoot epidermal cells protect against excess water loss. How do they perform this function? What differences might you expect to find in the structure of the epidermis in stems, roots, and leaves?
- Compare sources to sinks. Give examples of each. How might the distribution of sources and sinks change in the course of a year?
- What is the minimum number of plasma membranes a water molecule would have to cross in order to get from the soil solution to the atmosphere by way of the stele? To get from the soil solution to a mesophyll cell in a leaf?

ANALYZING & EVALUATING

- In the story that opened this chapter we saw that a mutation in the *HARDY* gene resulted in *Arabidopsis* plants with a more extensive root system and thicker leaves than wild-type plants. When the *HARDY* gene was isolated, it was found to encode a transcription factor that stimulates expression of genes for increased water-use efficiency. What phenotype due to a mutation in the *HARDY* gene would cause *Arabidopsis* plants to use water more efficiently? How would you investigate the effect of the *HARDY* mutation on stomata? What results would you expect?
- Here are measurements of water potential (Ψ) in a 100-meter-tall tree and its surroundings:

Region	Ψ (MPa)
Soil water	-0.3
Xylem of root	-0.6
Xylem of trunk	-1.2
Inside of leaf	-2.0
Outside air	-58.5

Gravity exerts a force of -0.01 MPa per meter of height above ground.

- Is the water potential in the leaf sufficiently low to draw water to the top of the tree?
- Would transpiration continue if soil water potential decreased to -1.0?
- What would you expect to happen to the xylem water potential if all of the stomata closed?

CHAPTER OUTLINE

- 36.1** What Nutrients Do Plants Require?
- 36.2** How Do Plants Acquire Nutrients?
- 36.3** How Does Soil Structure Affect Plants?
- 36.4** How Do Fungi and Bacteria Increase Nutrient Uptake by Plant Roots?
- 36.5** How Do Carnivorous and Parasitic Plants Obtain a Balanced Diet?

CROPS SUCH AS RICE, WHEAT, AND CORN supply more than half of the human diet. But like other organisms, the plants themselves require good nutrition in order to grow and produce our food. One of the nutrients most often in short supply in soils is nitrogen. Fertilizer or manure can be used to overcome this deficiency, producing a spectacular effect on plant growth and grain production. The production yield of many crops increased significantly in the past century, in part because of the application of more fertilizer.

But nitrogen fertilizer is expensive in two ways. First, the century-old process of manufacturing ammonium from hydrogen and nitrogen gases is very energy-intensive; when the price of oil goes up, the price of fertilizer also rises. In 2012 it cost farmers in the U.S. about \$8 billion a year to spread nitrogen fertilizer on 90 million acres of cornfields. This was three times as much as it cost in 2000. Imagine what this means if you are a poor farmer without the money to pay the higher price for fertilizer needed for your crop to grow.

Nitrogen fertilizer is also environmentally expensive. When it rains excessively, nitrogen fertilizer can be lost from farm fields and end up in lakes, rivers, or groundwater. When nitrogen-laden rivers enter the sea, excessive growth of marine algae is likely to result. Eventually the algae die, and the organisms that decompose the algae use up so much oxygen that there is not enough left to support animal life. Nitrogen fertilizer runoff has thus resulted in vast “dead zones” in waters near the mouths of major rivers, including the Mississippi River Delta in the Gulf of Mexico. An additional

Nitrogen Sipper Corn plants, such as those being fertilized here, extract a lot of nitrogen compounds from the soil. Excess nitrogen the corn plants do not take up gets left behind in the soil, where it can be a pollutant.

environmental cost is the conversion of some nitrogen fertilizer to nitrous oxide gas (N_2O), which contributes to global warming.

Scientists are working on several strategies by which nitrogen fertilizer might be used efficiently. One strategy is to improve farming practices, to apply optimal rates of nitrogen to crops while reducing losses to the environment. The other strategy is to alter the genetics of crop plants to improve their uptake and assimilation of nitrogen.

Several companies in the U.S. are working to modify corn genetics to increase the nitrogen use efficiency. Many processes are involved in a plant's use of nitrogen from the soil, such as uptake into the roots, transport to other organs in the vascular system, and incorporation of nitrogen into molecules such as amino acids and nucleotides. Each process involves many genes, and so inheritance is complex. An understanding of these processes, however, will yield improvements in nitrogen use efficiency.

What progress has been made in improving the nitrogen use efficiency of corn?

See answer on p. 753.

36.1 What Nutrients Do Plants Require?

Every living thing—and a plant is no exception—must obtain raw materials from its environment. These **nutrients** include the major ingredients of macromolecules: carbon, hydrogen, oxygen, and nitrogen. Plants are autotrophs, and obtain both carbon and oxygen from atmospheric carbon dioxide through the reactions of photosynthesis (see Chapter 10). Hydrogen comes mainly from water, so it is plentiful when there is an adequate water supply. Nitrogen, as you will see later in this chapter, enters most plants from the soil. The activities of microorganisms are important in converting organic nitrogen and nitrogen gas into inorganic forms that are usable by plants.

In addition to nitrogen, organisms require other **mineral nutrients**: inorganic elements that are used for various cellular processes. For example, proteins contain sulfur (S), nucleic acids contain phosphorus (P), chlorophyll contains magnesium (Mg), cytochromes contain iron (Fe), and cellular signaling can involve calcium (Ca). Most plants obtain these nutrients from

the soil. Within the soil, minerals dissolve in water as ions, forming a solution—called the **soil solution**—that contacts the roots of plants.

All plants require specific macronutrients and micronutrients

A plant nutrient is called an **essential element** if the plant fails to complete its life cycle or grows abnormally when the element is absent or insufficient. In addition to needing the non-mineral elements carbon, oxygen, and hydrogen, plants require many mineral nutrients (**Table 36.1**). Essential elements fall roughly into two categories—macronutrients and micronutrients—based on the amounts required by plants.

- A plant needs **macronutrients** in concentrations of at least 1 gram per kilogram of the plant's dry matter.
- A plant needs **micronutrients** in concentrations of less than 100 milligrams per kilogram of the plant's dry matter.

How do we know if a plant is getting enough of a particular nutrient?

TABLE 36.1 Mineral Elements Required by Plants

Element (Abbreviation; Absorbed Form)	Typical Amount in Plant (g/kg)	Major Functions	Deficiency Symptoms
MACRONUTRIENTS			
Nitrogen (N; NO_3^- and NH_4^+)	15	In proteins, nucleic acids	Oldest leaves turn yellow and die prematurely; plant is stunted
Phosphorus (P; H_2PO_4^- and HPO_4^{2-})	2	In nucleic acids, ATP, phospholipids	Plant is dark green with purple veins and is stunted
Potassium (K; K^+)	10	Enzyme activation; water balance; ion balance; stomatal opening	Older leaves have dead edges
Sulfur (S; SO_4^{4-})	1	In proteins and coenzymes	Young leaves are yellow to white with yellow veins
Calcium (Ca; Ca^{2+})	5	Affects the cytoskeleton, membranes, and many enzymes; second messenger	Growing points die back; young leaves are yellow and crinkly
Magnesium (Mg; Mg^{2+})	2	In chlorophyll; required by many enzymes; stabilizes ribosomes	Older leaves have yellow stripes between veins
MICRONUTRIENTS			
Iron (Fe; Fe^{2+} and Fe^{3+})	0.1	In active site of many redox enzymes and electron carriers; chlorophyll synthesis	Young leaves are white or yellow
Chlorine (Cl; Cl^-)	0.1	Photosynthesis; ion balance	Leaf tips wilt; leaves turn yellow and die
Manganese (Mn; Mn^{2+})	0.05	Activation of many enzymes	Younger leaves are pale with green veins
Boron [B; $\text{B}(\text{OH})_3$]	0.02	Required for proper cell wall formation and expansion	Poor growth of leaves and roots
Zinc (Zn; Zn^{2+})	0.02	Enzyme activation; auxin synthesis	Young leaves are abnormally small; older leaves have many dead spots
Copper (Cu; Cu^{2+})	0.006	In active site of many redox enzymes and electron carriers	New leaves are dark green, may have dead spots
Nickel (Ni; Ni^{2+})	0.00005	Activation of the enzyme urease	Leaf tips die; deficiency is rare
Molybdenum (Mo; MoO_4^{2-})	0.0001	Nitrate reduction	Leaves turn yellow between veins; older leaves die

36.1 Mineral Nutrient Deficiency Symptoms The plants on the left were grown with a full complement of essential nutrients. The center plants were deprived of iron, whereas the plants on the right were deprived of nitrogen.

Go to Animated Tutorial 36.1
Nitrogen and Iron Deficiencies
Life10e.com/at36.1

Deficiency symptoms reveal inadequate nutrition

When a plant is deficient in an essential element, it displays characteristic **deficiency symptoms**. Table 36.1 lists some of these symptoms, and plants deficient in iron and nitrogen are also shown in **Figure 36.1**. Such symptoms help growers diagnose mineral nutrient deficiencies in plants. With proper diagnosis, the missing nutrient(s) can be provided in the form of a **fertilizer** (an added source of mineral nutrients).

We know that the elements listed in Table 36.1 are essential to the life of all plants. How did biologists discover which elements are essential?

Hydroponic experiments identified essential elements

The essential elements for plants were identified by growing plants **hydroponically**—that is, with their roots suspended in nutrient solutions instead of soil. Growing plants in this manner allows for greater control of nutrient availability than is possible in a complex medium such as soil.

INVESTIGATINGLIFE

36.2 Is Nickel an Essential Element for Plant Growth?

Using highly purified salts in growth media, Patrick Brown and his colleagues tested whether barley can complete its life cycle in the absence of nickel.^a Other investigators showed that no other element could substitute for nickel.

HYPOTHESIS Nickel is an essential element for a plant to complete its life cycle.

Method

1. Grow barley plants for 3 generations in nutrient solutions containing 0, 0.6, and 1.0 μM NiSO_4 .
2. Harvest seeds from 5–6 third-generation plants in each of the groups.
3. Determine the nickel concentration in seeds from each plant.
4. Germinate other seeds from the same plants on nickel-free medium and plot the success of germination against nickel concentration.

Results

There was a positive correlation between seed germination and seed nickel concentration. There was significantly less germination at the lowest nickel concentrations.

CONCLUSION Barley seeds require nickel in order to survive and germinate, and therefore nickel is an essential element for plant nutrition.

^aBrown, P. H., R. M. Welch, and E. E. Cary. 1987. *Plant Physiology* 85: 801–803.

In the first experiments of this type, performed a century and a half ago, plants seemed to grow normally in solutions containing only calcium nitrate [$\text{Ca}(\text{NO}_3)_2$], magnesium sulfate (MgSO_4), and potassium phosphate (KH_2PO_4). A solution missing any of these compounds could not support normal growth. Tests with other compounds that included various combinations of these elements soon established the existence of six essential elements: calcium, nitrogen, magnesium, sulfur, potassium, and phosphorus. These are now known as the essential mineral macronutrients.

Iron was the first micronutrient to be clearly established as essential, in the 1840s. The last micronutrient to be listed as essential was nickel, in 1983. That experiment is described in **Figure 36.2**. Identifying essential micronutrients proved to be more difficult than identifying macronutrients because of the small amounts involved. Sufficient amounts of micronutrients can be present in the environment used to grow plants or in the plants themselves. A seed may contain enough of a micronutrient to supply the embryo and the entire plant throughout its lifetime. There might even be enough left over to pass on to third-generation

WORKING WITH DATA:

Is Nickel an Essential Element for Plant Growth?**Original Paper**

Brown, P. H., R. M. Welch, and E. E. Cary. 1987. Nickel: A micronutrient essential for higher plants. *Plant Physiology* 85: 801–803.

Analyze the Data

For an element to be classified as an essential nutrient in plants, two criteria must be satisfied. Specifically, one must demonstrate that a plant cannot complete its life cycle in the absence of the element, and that no other element can substitute for the test element. To determine if nickel is an essential element for plants, Patrick Brown and colleagues tested whether barley could complete its life cycle in the absence of nickel. The researchers grew barley plants for three generations in nutrient solutions containing either 0, 0.6, or 1.0 μM NiSO_4 , then tested the seeds for nickel content and germination. The results indicated a positive correlation between seed germination and nickel concentration (see Figure 36.2). Importantly, no germination was observed at the lowest nickel concentration. Together with results from another study showing that no other element could substitute for nickel, the investigators concluded that nickel is an essential micronutrient.

As shown in Figure 36.2, Ni depletion reduced the germination of barley grains. This could be caused by a reduced ability of the parental plant to produce grains, or, alternatively, a reduced germination ability of the grain itself. To investigate these two possibilities, Brown and colleagues measured grain production by twenty plants for each nickel treatment. The results are shown in **TABLE A**.

QUESTION 1

Did Ni depletion reduce the ability of the parental plants to produce grain? What data support your answer?

QUESTION 2

The data are expressed as mean \pm standard deviation. What statistical test would you perform to determine whether the means are significantly different? Are they? (Refer to Appendix B if needed.)

QUESTION 3

To determine whether the reduced germination ability could be corrected by adding Ni, dry seeds from the three groups in the table were soaked in water with or without added 1.0 μM NiSO_4 . The results are shown in **TABLE B**. Did adding Ni solution to dry seeds affect germination?

QUESTION 4

Plant biologists define the critical value as that concentration of a mineral nutrient in plant tissue that results in a 15 percent reduction in the optimum yield of the plant. Using maximum germination percentage in the graph in Figure 36.2 as the optimum yield, what is the critical value for nickel?

TABLE A

Ni in nutrient solution (μM)	Total grain weight (g)	Grain number (per plant)
0	7.3 ± 1.3	175 ± 26
0.6	7.5 ± 0.9	179 ± 35
1.0	8.4 ± 1.5	195 ± 41

TABLE B

Ni supplied to maternal plant (μM)	Germination after soaking seed with or without nickel (%)	
	0 μM NiSO_4	1 μM NiSO_4
0	9.1 ± 10	11.5 ± 10.3
0.6	55.2 ± 17	51.2 ± 20.3
1.0	98.2 ± 6.7	97.1 ± 9.1

Go to **BioPortal** for all **WORKING WITH DATA** exercises

plants. Because of such difficulties, nutrition experiments must be performed in tightly controlled laboratories with special air filters that exclude microscopic salt particles in the air, and must use only the purest available chemicals.

RECAP 36.1

Plants are autotrophs that obtain carbon and oxygen by photosynthesis, and mineral nutrients and water from the soil. Nutrients required by plants are classified as either macronutrients or micronutrients depending on the amount needed. Micronutrients are often needed in such minute amounts that only sophisticated chemical experiments can determine their essentiality.

- What are some specific mineral deficiency symptoms seen in plants? **See pp. 741–742 and Table 36.1**
- Why do plants need phosphorus? Why do they need nitrogen? **See p. 741**
- Outline an experimental method for determining whether an element is essential to a plant. **See Figure 36.2**

As we have seen, all plants require a specific set of nutrients for growth. Unlike many other organisms, however, plants can't move around to find nutrients. Let's look at how a plant finds and takes up nutrients from its environment.

36.2 How Do Plants Acquire Nutrients?

Many organisms can move from place to place to find the nutrients they need. But a plant cannot change its location (it is sessile), and so must obtain nutrients from its immediate environment. With the exception of the carbon and oxygen in CO_2 , a plant's supply of nutrients is strictly local, and a plant may use up the water and mineral nutrients in its local environment as it grows. How does a plant cope with the problem of scarce nutrient supplies?

Plants rely on growth to find nutrients

As discussed in Chapter 34, plants differ fundamentally from animals in that they grow throughout their lifetimes. In fact,

36.3 Plants Regulate Their Nutrition Plant roots branch and grow toward nutrients. Nutrients are taken up by transport proteins in the epidermal cell membrane. The number of transporters for a given nutrient can be regulated in response to nutrient availability.

growth is a plant's version of movement. For example, roots obtain most of the mineral nutrients plants need. By growing through the soil, roots mine it for new sources of mineral nutrients and water. The growth of stems and leaves helps a plant secure light and carbon dioxide, which in turn allows the roots to continue their growth through the soil. Deficiencies in water or specific mineral nutrients can stimulate plants to grow more roots, to improve the plants' chances of finding the nutrients they need.

As it grows, a plant—or even a single root—must deal with a variable environment. Animal droppings create high local concentrations of nitrogen. A particle of calcium carbonate may make a tiny area of the soil alkaline, while dead organic matter may make a nearby area acidic. Such microenvironments encourage or discourage the proliferation of a root system and help direct its growth. A major effort is underway to identify the signals in the soil and signaling pathways in the root that result in growth toward a source of nutrients (**Figure 36.3**).

Nutrient uptake and assimilation are regulated

Nutrients must cross the plasma membranes of cells in order to be used or assimilated into larger molecules. Polar molecules, including mineral ions, cross the membrane via specialized transport systems. In Chapter 35 we discussed the movement of water and ions into plant roots by way of the apoplast

(through cell walls and intercellular spaces) or symplast (directly through cells). The Casparian strip prevents water and ions from entering the xylem tissues of the roots (see Section 35.1); therefore these nutrients must enter the symplast before they can be transported to other tissues. In most cases, ions are actively transported across the plasma membrane of epidermal cells into the symplast because their concentrations in the soil solution are generally lower than their concentrations inside cells (see Figure 35.4).

Plants have specialized transport systems for the uptake of specific ions (see Figure 36.3). For example, *Arabidopsis thaliana* has more than 50 genes that encode nitrate (NO_3^-) transporters, 6 genes encoding ammonium (NH_4^+) transporters, and at least 4 genes for phosphate (PO_4^{3-}) transporters. Nutrient uptake is highly regulated because the levels of ions inside cells must be maintained at constant levels. The genes for ion transporters are regulated at the transcriptional level by the amounts of each nutrient inside cells: low nutrient levels stimulate transcription, whereas high levels repress transcription. In addition, the transporter proteins themselves are regulated (for example, by phosphorylation) to control their ion transport activity.

The assimilation of nutrients into more complex molecules is also regulated according to the plant's needs. The enzymes involved in assimilating nitrate and ammonium into amino acids are regulated at the transcriptional and posttranscriptional levels to increase assimilation when available nitrogen is abundant. The uptake and assimilation of nitrogen are also stimulated by photosynthesis, and this ensures that the nitrogen status in the plant is coordinated with its carbon status.

RECAP 36.2

Both the uptake and assimilation of nutrients are regulated according to a plant's needs.

- How does the ability to grow throughout their lifetime allow plants to seek out nutrients? **See p. 744**
- Describe how plants control the uptake and assimilation of mineral nutrients. **See Figure 36.3**

Plants acquire many essential elements from the soil. As we will see in the next section, soils have complex structures that affect the availability of nutrients for plants.

36.3 How Does Soil Structure Affect Plants?

Most terrestrial plants grow in soil. Soils provide:

- Mechanical support
- Mineral nutrients and water from the soil solution
- O_2 for root respiration

Soils also harbor many bacteria and other organisms; some of these are beneficial to plant life, but others are harmful. Some

soils contain toxic levels of metal ions such as cadmium, chromium, and lead (see Section 39.4).

Soils are modified by natural phenomena such as rain, temperature extremes, and the activities of plants and animals. They are also modified by the activities of humans, particularly in agriculture. In this section we will examine the composition, structure, and formation of soils, as well as their role in plant nutrition.

Soils are complex in structure

Soils have living and nonliving components (**Figure 36.4**). The living components include plant roots as well as populations of bacteria, fungi, protists, and animals such as earthworms and insects. The nonliving portion of the soil includes rock fragments ranging in size from large stones to sand to silt, and finally to tiny particles of clay that are 2 micrometers (μm) or less in diameter. Soil also contains water and dissolved mineral nutrients, air spaces, and dead organic matter. The air spaces in soil contain O_2 .

Although soils vary greatly, almost all of them have a soil profile consisting of several recognizable horizontal layers, called **horizons**, lying on top of one another. Soil scientists recognize three major horizons—termed A, B, and C—in the profile of a typical soil (**Figure 36.5**).

- The **A horizon** is the **topsoil** that supports the plant's nutrient needs. It contains most of the soil's living and dead organic matter.
- The **B horizon** is the **subsoil**, which accumulates materials from the topsoil above it and from the parent rock below.
- The **C horizon** is the **parent rock**, also called bedrock, that is in the process of breaking down to form soil.

Soil fertility is a soil's ability to support plant growth. A topsoil's fertility is determined by several factors. Topsoils vary

36.5 A Soil Profile The A, B, and C horizons can sometimes be seen at construction sites such as this one in Massachusetts. The upper layer (the A horizon) is home to most of the living organisms in the soil.

greatly in their proportions of sand, silt, and clay, and this influences their ability to support plant growth. For example, mineral nutrients tend to be **leached** from the upper soil horizons—dissolved in rain or irrigation water and carried to deeper horizons, where they are unavailable to plant roots. Dissolved minerals are readily leached from sandy soil because sand particles are relatively large and cannot hold water. Clay, by contrast, binds more water than sand does, and the charged surfaces of clay particles bind mineral ions that plant roots ultimately take up. But clay particles are tiny and pack tightly together, leaving little space for air. A **loam** is a soil that is an optimal mixture of sand, silt, and clay, and thus has sufficient levels of air, water, and available nutrients for plants. Loams also usually contain organic matter. Most of the best topsoils for agriculture are loams.

In addition to mineral particles, soils contain dead organic matter, largely from plants. Soil organisms break down dead leaves and other plant organs on the ground into a substance called **humus**. This material is used as a food source by microbes that break down complex organic molecules and release simpler molecules into the soil solution. Humus also provides air spaces that increase O_2 availability to plant roots.

Soils form through the weathering of rock

Rocks are broken down into soil particles—**weathered**—in two ways. First there is *mechanical weathering*, which is the physical breakdown of materials by wetting, drying, and freezing. Second there is *chemical weathering*, the alteration of the chemistry of the materials in the rocks. Several

36.4 The Complexity of Soil Soils favorable for plant growth contain both clay and larger mineral particles, as well as water, air, and organic matter. Other organisms are also present.

types of chemical weathering occur, all of which influence the availability of mineral nutrients:

- Oxidation by atmospheric oxygen
- Hydrolysis (reaction with water)
- Reaction with acids (particularly carbonic acid)

The parent rock and the weathering it undergoes determine the basic structure and chemical composition of a soil. However, a key soil characteristic for plants is the availability of nutrients, which must be dissolved in the soil solution for uptake by the plant. Chemical weathering often results in clay particles that are covered with negatively charged chemical groups, which bind positively charged mineral nutrients. How might roots obtain these mineral nutrients?

Soils are the source of plant nutrition

Humus and clay particles often carry negative charges. These particles form ionic attractions (see Section 2.2) with the positively charged ions (cations) of many minerals that are important for plant nutrition, such as potassium (K^+), magnesium (Mg^{2+}), and calcium (Ca^{2+}). To become available to plants or other organisms, these cations must be detached from the clay particles.

Recall that the root surface is covered with root hair cells (see Figure 34.8). Transporters in the plasma membranes of these cells actively pump protons (H^+) out of the cell. In addition, cellular respiration in the roots releases CO_2 , which dissolves in the soil water and reacts with it to form carbonic acid. This acid ionizes to form bicarbonate and free protons:

Proton-pumping by the root and ionization of carbonic acid both act to increase the proton concentration (lower the pH) in the soil surrounding the root. The protons bind more strongly to clay particles than do mineral cations; in essence, they trade

places with the cations in a process called **cation exchange** (Figure 36.6). Cation exchange releases important cations into the soil solution, where they are available to be taken up by the roots. Soil fertility is determined in part by the soil's ability to provide nutrients in this manner.

Some soil particles, such as ones containing oxides of iron or aluminium, are positively charged under acid conditions and can exchange anions in a process similar to cation exchange. However, soil pH is rarely low enough for anion exchange to occur. As a result, important anions such as nitrate (NO_3^-) and sulfate (SO_4^{2-})—direct sources of nitrogen and sulfur, respectively—may leach rapidly from the A horizon.

As we have just seen, soil fertility is affected by soil pH. The proton concentration affects the binding of cations and anions to soil particles, and can affect the solubility of other nutrients, such as iron. In addition, soil pH affects the absorption of nutrients by plant roots. The pH level of a soil depends on its mineral and organic contents and can be altered by various factors, including rainfall, weathering, plant growth, and fertilizer applications. The optimal soil pH for most plants is in the range 6 to 7.5, but some plants, such as blueberries and cranberries, prefer pH levels of 4.5 to 5.

Fertilizers can be used to add nutrients to soil

Leaching and the harvesting of crops can deplete a soil of its nutrients, so that new crops grow poorly on that soil. Soil fertility can be restored or increased in various ways, including shifting agriculture to another location or applying organic or chemical fertilizers.

SHIFTING AGRICULTURE In the past, when the soil could no longer support a level of plant growth sufficient for agricultural purposes, people simply moved to another location. The nutrients in the soil of a field allowed to lie fallow will be replenished gradually through the addition of organic matter from

the growth and death of plants naturally present, and by the weathering of the parent rock. Both processes take a long time, which is not a problem as long as a lot of land is available. Today, however, the food needs of a large human population are too great to allow land to be left vacant for a long time, and people are disinclined to move away from settled homesteads. As a consequence, chemical fertilizers are now commonly used to improve soil fertility.

ORGANIC FERTILIZERS Microorganisms in the soil break down organic molecules into smaller, simpler molecules. These simpler molecules can dissolve in soil water and enter plant roots. For example, soil bacteria break down the proteins in dead leaves and produce ammonium ions (NH_4^+), which in turn are converted into nitrate (NO_3^-). Both ammonium and nitrate can be taken up and used by plants:

36.6 Cation Exchange Plants obtain mineral nutrients from the soil primarily in the form of positive ions; potassium (K^+) is the example shown here.

Farmers can increase the nutrient content of soil by adding organic materials such as compost (partially decomposed plant materials) or manure (waste from farm animals). Manure is a particularly good source of nitrogen. In either case, the addition of these **organic fertilizers** adds nutrients to the soil much more rapidly than weathering or the gradual addition of organic matter from natural vegetation. Organic fertilizers allow for a slow release of ions as the materials decompose.

INORGANIC FERTILIZERS Organic fertilizers may act too slowly to restore fertility if a soil is to be used every year. **Inorganic fertilizers** supply mineral nutrients in forms that can be taken up immediately by plants or that are rapidly converted to usable forms in the soil. Inorganic fertilizers are easily transported and handled, and allow farmers to control the amount of a particular nutrient that is supplied to each crop. Particular fertilizers are used in varying amounts, depending on the needs of the crop and the type of soil. For example, much higher amounts of nitrogen are applied to cornfields than to soybean fields. Inorganic fertilizers come in many forms. Common ones include ammonia (NH_3), urea ($\text{NH}_2\text{-CO-NH}_2$), and salts formed from positive and negative ions such as ammonium (NH_4^+), potassium (K^+), nitrate (NO_3^-), phosphate (PO_4^{3-}), and sulfate (SO_4^{2-}).

The use of inorganic fertilizers became widespread in many countries during the twentieth century. This contributed (along with improved genetic strains and other technological advances) to the “green revolution”—a massive increase in world food production during the second half of the century. However, as we saw in the opening story, excessive fertilizer use has led to environmental problems. Agricultural scientists are developing methods for determining the exact amount of a particular nutrient that a crop requires, and for applying fertilizer at an optimal time to maximize yield while reducing losses to the environment.

RECAP 36.3

Land plants live anchored in the soil and obtain water and mineral nutrients from it. Soils are complex in structure and vary in fertility. Farmers can add fertilizers to improve the nutrient contents of soils.

- Explain how mechanical and chemical weathering form soil from rock. [See pp. 745–746](#)
- How is soil fertility enhanced by the process of cation exchange? [See p. 746 and Figure 36.6](#)
- What are the differences between organic and inorganic fertilizers in terms of plant nutrition? [See pp. 746–747](#)

Thus far we have focused on the uptake of nutrients in the soil by plant roots. An understanding of how plants acquire nutrients from the soil would be incomplete, however, without taking into account the involvement of soil microbes, including fungi and bacteria. In the next section we will focus on the intimate interactions of plants with these organisms, which are essential to the success of most terrestrial plants.

36.4 How Do Fungi and Bacteria Increase Nutrient Uptake by Plant Roots?

One gram of soil can contain 6,000 to 50,000 bacterial *species* and up to 200 *meters* of fungal hyphae (the long branching cells of fungi), although both are largely invisible to the naked eye. In Chapter 39 we will describe the strategies plants use to prevent infection by harmful soil microbes. But plants actively encourage a few species of fungi and bacteria to infect their roots and even invade root cells. In this section we will describe the mutually beneficial relationships in which products are exchanged between the plants and these special soil microbes.

Plants send signals for colonization

In Chapter 30 we described mycorrhizae, the association of fungi with plant roots—an interaction that occurs in more than 90 percent of terrestrial plants. Our example in Chapter 30 was ectomycorrhizal fungi, which wrap themselves around a plant root (see Figure 30.9). In this chapter we will examine arbuscular mycorrhizae, in which fungal hyphae penetrate root cells. We will also describe here the close association between the roots of some plants and rhizobia, a group of nitrogen-fixing bacteria (bacteria that convert atmospheric N_2 into a more biologically useful form). We will see that mycorrhizal and rhizobial associations are both initiated by signals sent by plant roots that attract the soil organisms, and that the development of these associations involves similar genes and cellular pathways.

FORMATION OF MYCORRHIZAL ASSOCIATIONS The events in the formation of arbuscular mycorrhizae are shown in **Figure 36.7A**. Plant roots produce compounds called **strigolactones** that stimulate rapid growth of fungal hyphae toward the root. In response, the fungi produce signals that stimulate expression of plant symbiosis-related genes. The products of some of these genes give rise to the prepenetration apparatus (PPA), which guides the growth of the fungal hyphae into the root cortex. The sites of nutrient exchange between fungus and plant are the arbuscules, which form within root cortical cells. Despite the intimacy of this association, the plant and fungal cytoplasms never mix—they are separated by two membranes, the fungal plasma membrane and the periarbuscular membrane (PAM), which is continuous with the plant plasma membrane.

FORMATION OF NITROGEN-FIXING NODULES A group of plants called legumes (members of the plant family Fabaceae) can form symbioses with soil bacteria in several genera collectively known as rhizobia. The legume roots release flavonoids and other chemical signals that attract the rhizobia to the vicinity of the roots (**Figure 36.7B**). The flavonoids also trigger the transcription of bacterial *nod* genes, the products of which synthesize Nod (nodulation) factors. These factors, when secreted by the bacteria, cause cells in the root cortex to divide, leading to the formation of a primary nodule meristem. This meristem gives rise to the plant tissue that constitutes the **root nodule**.

36.7 Roots Send Signals for Colonization Plant roots send chemical signals to arbuscular mycorrhizal fungi (A) and nitrogen-fixing bacteria (B) to stimulate colonization.

Bacteria enter the root via an infection thread, analogous to the PPA in mycorrhizal associations, and eventually reach cells inside the root nodule. There the bacteria are released into the cytoplasm of the nodule cells, enclosed in membrane vesicles similar to the PAM. Inside the vesicles, the bacteria differentiate into **bacteroids**—the form of the bacteria that can fix nitrogen.

A COMMON MECHANISM There is increasing evidence that nodule formation depends on some of the same genes and mechanisms that allow mycorrhizae to develop. For example,

both processes involve invagination of the plasma membrane to allow entry of the fungal hyphae or rhizobia. The similarities in the structures formed during the development of mycorrhizae and nodules are especially striking, considering that the symbioses involve members of two different kingdoms (fungi and bacteria) (**Figure 36.8**).

Mycorrhizae expand the root system

In many cases the roots of vascular plants cannot nutritionally support plant growth alone—they simply cannot reach all the

36.8 Intracellular Structures in Plant–Fungus and Plant–Rhizobium Symbioses Several steps in the development of mycorrhizae and nodules involve similar structures.

nutrients available in the soil. Mycorrhizae expand the root surface area 10-fold to 1,000-fold, increasing the amount of soil that can be mined for nutrients. In addition, because fungal hyphae are much finer than root hairs, they can get into pores in the soil that are inaccessible to roots. In this way, mycorrhizae probe a vast quantity of soil for nutrients and deliver them into root cortical cells.

The primary nutrient that the plant obtains from a mycorrhizal interaction is phosphorus. In exchange, the fungus obtains an energy source: the products of photosynthesis. In fact, up to 20 percent of the photosynthate of terrestrial plants is directed to and consumed by arbuscular mycorrhizal fungi. Such associations are excellent examples of mutualism, an interaction between two species in which both species benefit (further discussed in Chapter 56). Mutualism is a type of symbiosis, in which two different species live in close contact for a significant portion of their life cycles.

Soil bacteria are essential in getting nitrogen from air to plant cells

The essential mineral nutrient most commonly in short supply, in both natural and agricultural situations, is nitrogen. This is surprising because elemental nitrogen (N_2) makes up almost four-fifths of Earth's atmosphere. However, plants cannot use N_2 directly as a nutrient. The triple bond linking the two

nitrogen atoms is extremely stable, and a great deal of energy is required to break it; thus N_2 is a highly unreactive substance.

Some prokaryotes have an enzyme that enables them to convert N_2 into a more reactive and biologically useful form by a process called **nitrogen fixation**:

Nitrogen fixers, including those present in root nodules, fix approximately 170 million metric tons of nitrogen per year. Humans use industrial methods to fix about 80 million metric tons per year. In addition, about 20 million metric tons per year are fixed in the atmosphere by nonbiological means such as lightning, volcanic eruptions, and forest fires. Rain brings these atmospherically formed products to the ground.

Two types of organisms can fix nitrogen:

- Free-living organisms living in soil and water (e.g., *Azotobacter* bacteria and *Nostoc* cyanobacteria [sometimes called blue-green algae])
- Symbiotic organisms living in other organisms (e.g., rhizobia in roots of legumes, and *Anabaena* cyanobacteria in aquatic ferns)

Nitrogenase catalyzes nitrogen fixation

Nitrogen fixation is the reduction (see Section 9.1) of nitrogen gas. It proceeds by the stepwise addition of three pairs of

36.9 Nitrogenase Fixes Nitrogen Throughout the chemical reactions of nitrogen fixation, the reactants are bound to the enzyme nitrogenase. A reducing agent transfers hydrogen atoms to nitrogen,

and eventually the final product—ammonia—is released. This reaction requires a large input of energy: about 16 ATPs are consumed per reaction.

hydrogen atoms to N_2 (Figure 36.9). In addition to N_2 , these reactions require three things:

- A strong reducing agent to transfer hydrogen atoms (protons and electrons) to N_2 and to the intermediate products of the reaction
- A great deal of energy, which is supplied by ATP
- The enzyme **nitrogenase**, which catalyzes the reaction

Depending on the species of nitrogen fixer, either respiration or photosynthesis provides the necessary reducing agent and ATP.

Nitrogenase is strongly inhibited by oxygen, and many nitrogen fixers are anaerobes that live in environments with little or no O_2 . But rhizobia are aerobic and fix nitrogen in aerobic plant roots. How can nitrogenase function under these circumstances?

Plants typically house nitrogen-fixing bacteria in root nodules. Within a nodule, O_2 is maintained at a low level that is sufficient to support respiration, but not so high as to inactivate nitrogenase. This is possible because the cytoplasm of nodule cells contains a plant-produced protein called **leghemoglobin**, which is an O_2 carrier. Leghemoglobin is a close relative of hemoglobin, the red, oxygen-carrying pigment of animals, and is thus an evolutionarily ancient molecule. Some plant nodules contain enough of it to be bright pink inside. Leghemoglobin, with its iron-containing heme groups, transports enough oxygen to the nitrogen-fixing bacteria to support their respiration, while keeping free oxygen concentrations low enough to protect nitrogenase.

Biological nitrogen fixation does not always meet agricultural needs

Crop rotation systems have been used for hundreds or thousands of years by many human civilizations. In these systems, each field is used to grow different crops in different years, with legumes (such as alfalfa, clover, peas, and beans) included in the rotation. The rotation may also include periods of grazing by farm animals. Because of their association with nitrogen-fixing bacteria, legumes can replace all or some of the nitrogen removed by grain crops such as wheat and corn. Even with

these systems, however, bacterial nitrogen fixation is not always sufficient to support the needs of agriculture. Some traditional farmers used to plant dead fish along with corn; the decaying fish released nitrogen that the developing corn could use. Today farmers use inorganic nitrogen fertilizers produced through industrial nitrogen fixation to meet the food needs of a rapidly expanding human population.

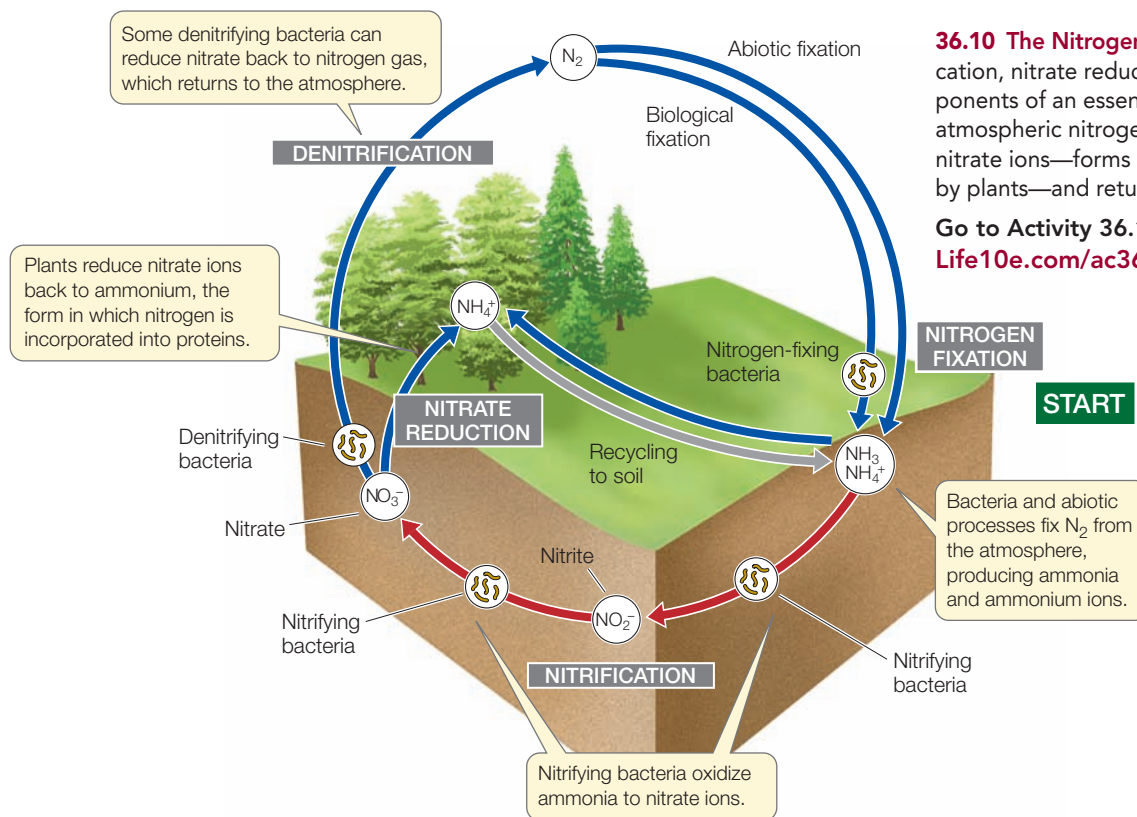

Most industrial nitrogen fixation is done by the Haber process, which produces ammonia (NH_3) from methane (CH_4) gas and molecular nitrogen (N_2). The Haber process requires a great deal of energy. (Biological nitrogen fixation also consumes lots of energy in the form of ATP—about 16 ATP per N fixed.) At present in the United States, the manufacture of nitrogen-containing fertilizer takes more energy—primarily natural gas and hydroelectric—than does any other aspect of crop production. The rising cost of energy sources raise serious questions about the sustainability of this approach to fertilizer production.

Plants and bacteria participate in the global nitrogen cycle

Nitrogen moves through the biosphere in a **global nitrogen cycle** (Figure 36.10), which includes four key steps:

1. *Fixation* of atmospheric N_2 to NH_3 and NH_4^+ by bacteria and by abiotic processes
2. *Nitrification* of these molecules to nitrate by bacteria
3. *Nitrate reduction* by plants
4. *Denitrification* of nitrate by bacteria back to N_2 , which is then released to the atmosphere to begin another cycle

Nitrogen fixation results in the formation of ammonia (NH_3), most of which is rapidly ionized to form ammonium (NH_4^+). The balance between ammonia and ammonium depends on pH; neutral and acidic pH levels favor the ionic form. Ammonia can be toxic to plants, but ammonium ions are taken up safely. Soil bacteria called **nitrifiers** oxidize ammonia to nitrate ions (NO_3^-)—another form that plants can take up—by the process of **nitrification**. Soil pH affects which form of nitrogen is taken up by plants: nitrate ions are taken up preferentially under more basic conditions, and ammonium

36.10 The Nitrogen Cycle Nitrogen fixation, nitrification, nitrate reduction, and denitrification are components of an essential chemical cycle that converts atmospheric nitrogen gas into ammonium ions and nitrate ions—forms of nitrogen that can be taken up by plants—and returns N_2 to the atmosphere.

Go to Activity 36.1 The Nitrogen Cycle
Life10e.com/ac36.1

ions under more acidic ones. To use nitrate, a plant must first reduce it to ammonium in a process called **nitrate reduction**, which occurs in two enzyme-catalyzed steps. First, nitrate is converted to nitrite (NO_2^-) in the cytoplasm, and then nitrite is converted to ammonium in the plastids. The plant uses the ammonium to manufacture amino acids, from which the plant's proteins and all its other nitrogen-containing compounds are formed. Animals cannot reduce nitrogen and so depend on plants to supply them with reduced nitrogenous compounds.

The nitrogen cycle is essential for life on Earth: nitrogen-containing compounds constitute 5 to 30 percent of a plant's total dry weight. The nitrogen content of animals is even higher, and all of it arrives there by way of the plant kingdom.

Let's turn now to some special mechanisms for obtaining nutrients that have evolved in plant species with unusual lifestyles.

36.5 How Do Carnivorous and Parasitic Plants Obtain a Balanced Diet?

Most plants obtain their mineral nutrients from the soil solution. Carnivorous and parasitic plants are examples of plants that obtain nutrients from other sources.

Carnivorous plants supplement their mineral nutrition

Some plants augment their nitrogen supply by capturing and digesting flies and other insects. There are about 500 of these **carnivorous plant** species, the best known of which are Venus flytraps (genus *Dionaea*; **Figure 36.11A**), sundews (genus *Drosera*; **Figure 36.11B**), and pitcher plants (genus *Sarracenia*).

Carnivorous plants are typically found in boggy habitats that are acidic and nutrient deficient. To obtain extra nitrogen, these plants capture animals, digest their proteins, and absorb the amino acids. Pitcher plants have pitcher-shaped leaves that collect small amounts of rainwater. Insects and even small rodents are lured into the pitchers by bright colors or attractive scents and are prevented from leaving by stiff, downward-pointing hairs. The animals eventually die and are digested by a combination of plant enzymes and bacteria in the water. Sundews have leaves covered with hairs that secrete a sticky, sugary liquid. Insects become stuck to these hairs, and more hairs curve over to further entrap them. Enzymes secreted by the plant digest the insects. Venus flytraps have specialized leaves with two halves that fold together. When an insect touches special hairs called trigger hairs on the

RECAP 36.4

Two mutualistic interactions with soil microbes are critical to the success of terrestrial plants. Fungi and plants form mycorrhizae, which greatly increase the soil volume that roots can scavenge for nutrients. Bacteria in soils and root nodules fix atmospheric nitrogen into forms that plants and ultimately animals can use. Denitrification returns nitrogen from dead organisms and animal waste back to the atmosphere, completing the global nitrogen cycle.

- How is the formation of a root nodule on a legume similar to the formation of an arbuscular mycorrhiza? **See p. 747–749 and Figures 36.7 and 36.8**
- What is exchanged between plants and fungi in mycorrhizae? **See p. 749**
- What, besides nitrogenase, is required to reduce nitrogen gas to a form plants can use? **See p. 750 and Figure 36.9**

36.11 Carnivorous Plants Some plants have adapted to nitrogen-poor environments by becoming carnivorous. (A) The Venus flytrap obtains nitrogen from the bodies of insects trapped inside the plant when its hinges snap shut. (B) Sundews trap insects on sticky hairs. Secreted enzymes will digest the carcass externally.

 **Go to Media Clip 36.1**
A Venus Flytrap “Snaps to It”
Life10e.com/mc36.1

leaf, its two halves snap together. The spiny margins interlock and imprison the insect before it can escape. The leaf then secretes enzymes that digest its prey.

The closing of the Venus flytrap’s leaf is one of the fastest movements in the plant world, requiring only 0.1 seconds. To find out how this happens, Dr. Lakshminarayanan Mahadevan and colleagues at Harvard University painted fluorescent dots on the surface of the flytrap’s leaf surface and used high-speed cameras to record the trap snapping shut when its trigger hairs were touched. They then used computer analysis of the recorded dot movements to generate a mathematical model to help explain the movement. The researchers found that the first step is the osmosis-driven elongation of cells on the outer surface of the leaf. The expansion of only one side of the leaf causes it to snap from a convex into a concave shape, much like a contact lens flipping inside out.

Carnivorous plants photosynthesize and extract soil nutrients just like other plants, but eating insects helps them grow faster in their natural habitats. They use the additional nitrogen from the insects to make more proteins, chlorophyll, and other nitrogen-containing compounds.

Parasitic plants take advantage of other plants

Approximately 1 percent of flowering plant species derive some or all of their water, mineral nutrients, and sometimes even photosynthate from other plants. These **parasitic plants** have evolved absorptive organs called **haustoria**, which invade the host and tap into the vascular tissues in the root or stem.

Parasitic plants are divided into two broad classes based on their nutritional interactions with their hosts. **Hemiparasites** can still photosynthesize but derive water and mineral nutrients from the living bodies of other plants. Perhaps the most familiar hemiparasites are the several genera of mistletoes. Mistletoes are green and carry on some photosynthesis, but they parasitize other plants for water and mineral nutrients and may derive photosynthetic products from them as well. Dwarf mistletoe (*Arceuthobium americanum*) is a serious parasite in forests of the western United States, destroying more than 3 billion board feet of lumber per year.

Holoparasites are completely parasitic and do not perform photosynthesis. They are taxonomically and morphologically

(A) *Dionaea muscipula*

(B) *Drosera rotundifolia*

diverse. Some, such as members of the dodder family, are plantlike in appearance, with small leaf remnants and flowers (**Figure 36.12**). Some holoparasites do not have leaves or stems because they spend most of their life cycle underground and only break the surface to flower.

Several parasitic plant species lack many of the genes normally present in the chloroplast genome (which in turn is only a remnant of the genome of the original endosymbiont from which the chloroplast evolved; see Sections 5.5 and 27.1). These genes, which are needed for photosynthesis, have been lost because there is no evolutionary pressure to retain them. Thus while the parasitic lifestyle can be viewed as a free ride, for

36.12 A Parasitic Plant Tendrils of dodder (genus *Cuscuta*) wrap around a goldenrod (genus *Solidago*). The parasitic dodder obtains water, sugars, and other nutrients through tiny, rootlike protuberances that penetrate the surface of the host plant.

some plants it is also a one-way ticket, with no possibility of return to self-sufficiency.

The plant–parasite relationship is similar to plant–fungus and plant–bacteria associations

Plant–bacteria and plant–fungus associations both involve reciprocal signaling between the two species (see Figure 36.7). Parasitic plants also need to detect signals from nearby plants so they can grow toward them and obtain their nutrients, but obviously this is to the disadvantage of the potential host plant. In one interesting case, a parasitic plant has evolved the ability to recognize the chemical signals produced by plants to attract beneficial fungi.

The holoparasite *Striga* (witchweed) is a serious pest of cereal crops in Africa. In Section 36.4 we saw that arbuscular fungi are attracted to plant roots by compounds called strigolactones. One of these same molecules induces the seed germination of some parasitic plants, including *Striga*. Scientists strongly suspect that this is no coincidence. The mycorrhizal interaction is ancient (more than 400 million years old) and predates the evolution of parasitic plants. For this reason scientists hypothesize that a mechanism evolved in the ancestors of modern *Striga* to recognize a compound that was already produced by plants to attract soil microbes.

In *Striga* we thus find an example of “opportunistic evolution”—that is, the repurposing of preexisting processes rather than the development of new processes. This is not the first time we have encountered this phenomenon in this chapter. Recall that the formation of nodules by rhizobia uses some of the same mechanisms used by arbuscular fungi to establish residence inside plant cells (see Figure 36.7). This implies an evolutionary connection between the two symbioses.

RECAP 36.5

Carnivorous plants supplement their nutrition by extracting materials from animals. Rapid reflexes have evolved in some of these plants for trapping their prey. Parasitic plants, by contrast, get some or all of their sustenance from other plants. Holoparasites cannot function as autotrophs, having lost chloroplast genes coding for photosynthetic machinery. At least one parasitic plant responds to the same signaling molecule that the host plant uses to attract beneficial fungi.

- Why do carnivorous plants eat animals? [See p. 752](#)
- How do the needs of holoparasitic plants differ from those of carnivorous plants? [See p. 752](#)
- What characteristics are shared among plant–parasite, plant–fungus, and plant–bacteria associations? [See p. 753](#)

What progress has been made in improving the nitrogen use efficiency of corn?

ANSWER

There has been significant progress in developing corn varieties with improved nitrogen use efficiency, using both conventional plant breeding (genetics) and biotechnology. The recent publication of the corn genome sequence will provide useful information about genes involved in nitrogen use. For example, the seed company Pioneer Hi-Bred is developing a strain of corn that produces a more efficient version of the enzyme glutamine synthetase (GS). GS adds ammonia to glutamate to form glutamine, and therefore plays an important role in nitrogen assimilation in plants. The new corn strain uses up to 20 percent less fertilizer to produce the same yields as other corn varieties.

36.1 What Nutrients Do Plants Require?

- Plants are photosynthetic autotrophs that can produce all their organic molecules from carbon dioxide, water, and minerals, including a nitrogen source.
- **Mineral nutrients** are obtained from the **soil solution**.
- Plants require 14 **essential elements**, 6 of which are **macronutrients** and 8 of which are **micronutrients**. **Deficiency symptoms** suggest what essential element a plant lacks. [Review Table 36.1, Figure 36.1, ANIMATED TUTORIAL 36.1](#)
- The essential elements were discovered by growing plants **hydroponically**, meaning in solutions that lacked individual elements. [Review Figure 36.2](#)

36.2 How Do Plants Acquire Nutrients?

- Root growth allows plants, which are sessile, to search for mineral resources.
- Plants can regulate the uptake of nutrients by increasing the number or activity of active transport proteins in root epidermal cells. [Review Figure 36.3](#)

36.3 How Does Soil Structure Affect Plants?

- **Soils** contain water, air, and inorganic and organic substances. Soils have living (biotic) and nonliving (abiotic) components. [Review Figure 36.4](#)
- A soil typically consists of two or three horizontal zones called **horizons**. **Topsoil** forms the uppermost or **A horizon**. Topsoil tends to lose mineral nutrients through **leaching**. **Loams** are excellent agricultural topsoils, with a good balance of sand, silt, clay, and organic matter. [Review Figure 36.5](#)
- Soils form by mechanical and chemical **weathering** of rock. Chemical weathering imparts mineral nutrients to clay particles. Plant litter and other organic matter decompose to form **humus**. Plants obtain some mineral nutrients through **cation exchange** between the soil solution and the surface of clay particles. [Review Figure 36.6](#)
- Farmers use **fertilizers** to make up for deficiencies in soil mineral nutrient content.

continued

CHAPTER SUMMARY 36

36.4 How Do Fungi and Bacteria Increase Nutrient Uptake by Plant Roots?

- Mycorrhizae are symbiotic root–fungus associations that greatly increase a plant’s absorption of water and minerals, especially phosphorus. They occur in more than 90 percent of terrestrial plant species.
- The arbuscules are the sites of nutrient exchange between the fungus and plant. **Review Figure 36.7**
- In the earliest stages of mycorrhiza formation, the hyphae of arbuscular fungi grow toward **strigolactones**, compounds that are produced by the plant roots.
- Some **nitrogen fixers** live free in soil or water; others live symbiotically as **bacteroids** within plant roots. The formation of a root nodule requires interaction between the root system of a legume and rhizobia. **Review Figure 36.7**
- Several steps in the formation of root nodules and arbuscules are similar and probably involve some of the same plant genes. **Review Figure 36.8**
- In **nitrogen fixation**, nitrogen gas (N_2) is reduced to ammonia (NH_3) or ammonium ions (NH_4^+) in a reaction catalyzed by **nitrogenase**. **Review Figure 36.9**

- Plants and bacteria interact in the **global nitrogen cycle**, which involves a series of reductions and oxidations of nitrogen-containing molecules. **Review Figure 36.10, ACTIVITY 36.1**

36.5 How Do Carnivorous and Parasitic Plants Obtain a Balanced Diet?

- **Carnivorous plants** are autotrophs that supplement a low nitrogen supply by feeding on insects or other small animals.
- **Parasitic plants** draw on other plants to meet their needs, which may include minerals, water, or the products of photosynthesis.
- **Hemiparasites**, such as mistletoes, can still photosynthesize. **Holoparasites** cannot function as autotrophs because they have lost chloroplast genes that code for components of the photosynthetic apparatus (which they no longer need).
- A strigolactone—a compound in the same category of compounds plants use to attract mycorrhizal fungi—also induces the germination of some parasitic plants, including *Striga*. Scientists hypothesize that a mechanism evolved in the ancestors of modern *Striga* to recognize a compound that was already produced by plants to attract arbuscular fungi.

CHAPTER REVIEW

REMEMBERING

1. Macronutrients
 - a. are so called because they are more essential than micronutrients.
 - b. include manganese, boron, and zinc, among others.
 - c. function as catalysts.
 - d. are required in concentrations of at least 1 gram per kilogram of plant dry matter.
 - e. are obtained by the process of photosynthesis.
2. Which of the following is *not* an essential mineral element for plants?
 - a. Potassium
 - b. Magnesium
 - c. Calcium
 - d. Lead
 - e. Phosphorus
3. Fertilizers
 - a. always have a defined chemical composition.
 - b. are not required if crops are removed frequently enough.
 - c. restore needed mineral nutrients to the soil.
 - d. are needed to provide carbon, hydrogen, and oxygen to plants.
 - e. are needed to destroy soil pests.
4. In a typical soil,
 - a. the topsoil tends to lose mineral nutrients by leaching.
 - b. there are four or more horizons.
 - c. the C horizon consists primarily of loam.
 - d. the dead and decaying organic matter gathers in the B horizon.
 - e. more clay means more air space and thus more oxygen for roots.
5. Nitrogen fixation is
 - a. performed only by plants.
 - b. the oxidation of nitrogen gas.
 - c. catalyzed by the enzyme nitrogenase.
 - d. a single-step chemical reaction.
 - e. possible because N_2 is a highly reactive substance.
6. Which of the following is true of the formation of *both* arbuscules and root nodules?
 - a. Invasion of a plant root by a fungus
 - b. Invasion of a plant root by a bacterium
 - c. Strigolactones produced by the root are recognized by the microbe
 - d. Root cells are invaded but there is no direct contact between plant and microbe cell contents
 - e. Root cells are invaded and there is direct contact between plant and microbe cell contents

UNDERSTANDING & APPLYING

7. Methods for determining whether a particular element is essential have been known for more than a century. Since these methods are so well established, why was the essentiality of some elements discovered only recently?
8. Soils are dynamic systems. What changes might result when land is subjected to heavy irrigation for agriculture after being relatively dry for many years? What changes in the soil might result when a virgin deciduous forest is cut down and replaced by crops that are harvested each year?
9. The biosphere of Earth as we know it depends on the existence of a few species of nitrogen-fixing prokaryotes. What do you think might happen if one of these species were to become extinct? If all of them were to disappear? (See also Figure 58.13.)

ANALYZING & EVALUATING

10. Some mutant *Arabidopsis* plants that are very bushy (their shoots are more highly branched than wild-type plants) cannot make strigolactones because of a mutation in a gene necessary for strigolactone biosynthesis. If an investigator applies strigolactones to the plants, they grow normally. What does this experiment suggest about the role of strigolactones in plant growth? How does this add to the story of strigolactones as signals for arbuscules and parasitic plants?
11. Holoparasitic plants have lost many of the morphological and genetic traits necessary for an autotrophic lifestyle. From an evolutionary point of view, how do you think this happened? (Hint: think about selection pressures.)

Regulation of Plant Growth

CHAPTER OUTLINE

- 37.1** How Does Plant Development Proceed?
- 37.2** What Do Gibberellins and Auxin Do?
- 37.3** What Are the Effects of Cytokinins, Ethylene, and Brassinosteroids?
- 37.4** How Do Photoreceptors Participate in Plant Growth Regulation?

AGRICULTURAL SCIENTISTS are constantly searching for ways to help farmers produce more food for a growing population. One way is to breed crop plants whose physiology allows them to produce more grain per plant (resulting in higher yields). The drawback of this approach is that the sheer weight of the load of seeds may cause the stem to bend over. The problem is made worse when fertilizer makes the plants grow taller. Harvesting seeds on the ground is very difficult; think of how hard it would be to pick up seeds one by one, when some have already sprouted.

During World War II, the island nation of Japan was blockaded and could not import food or other supplies. Food was rationed and many people were hungry, but there were no major famines in Japan during that period. How were the Japanese able to produce enough grain to feed their population? One answer to this question lay in the fields: the Japanese had bred genetic strains of rice and wheat with short, strong stems that could bear high yields of grain without bending over. An agricultural advisor to the occupying American army sent samples of the grains to the U.S.

A decade later, the American plant geneticist Norman Borlaug, who was working in Mexico at the time, began making genetic crosses between the Japanese wheat and other varieties that had genes conferring rapid growth, adaptability to varying climates, and resistance to fungal diseases. The results were "semi-dwarf" wheat varieties that gave record yields. The

Norman Borlaug Seen here in a field of semi-dwarf wheat, plant geneticist Norman Borlaug carried out a program of genetic crosses that led to high-yielding varieties and saved millions from starvation.

varieties were grown first in Mexico, and later in India and Pakistan during the 1960s. At about the same time and using a similar strategy, scientists in the Philippines developed semi-dwarf rice with equally spectacular results. People who had lived on the edge of starvation now produced enough food. Countries that had relied on food from other countries were now able to grow more than enough grain, and export the surplus. The development of these semi-dwarf grains began what was called the "Green Revolution." Borlaug was awarded the Nobel Peace Prize for his research on wheat, which is estimated to have saved a billion lives.

What changes in growth patterns made the new strains of wheat and rice successful?

See answer on p. 775.

37.1

How Does Plant Development Proceed?

As described in Chapter 34, plants are sessile organisms that must seek out resources above and below the ground. A number of unique features enable plants to obtain the resources they need to grow and reproduce:

- **Meristems.** Plants have permanent collections of stem cells (undifferentiated, constantly dividing cells) that allow them to continue growing throughout their lifetimes (see Section 34.3).
- **Post-embryonic organ formation.** Unlike animals, plants can initiate development of new organs such as leaves and flowers throughout their lifetimes.
- **Differential growth.** Plants can allocate their resources so that they grow more of the organs that will benefit them most—for example, more leaves to harvest more sunlight or more roots to obtain more water and nutrients.

Plants must continuously monitor their ever-changing environments and redirect their growth appropriately. For example, the amount of available light changes from day to night and from season to season. In addition, other plants are often vying for what light there is, and plants modulate their growth to compete with their neighbors for this precious resource. As you will see in this chapter, several mechanisms have evolved in plants that enable them to sense changes in their environments, and trigger appropriate growth responses.

The development of a plant—the series of progressive changes that take place throughout its life—is regulated in many ways. Key factors involved in regulating plant growth and development are:

- **Environmental cues**, such as day length, water availability, and various chemicals in the environment
- **Receptors** that allow a plant to sense environmental cues, such as photoreceptors that absorb light, and chemoreceptors that signal the presence of pathogens (see Chapter 39)
- **Hormones**—chemical signals that mediate the effects of the environmental cues, including those sensed by receptors
- **Regulatory proteins and enzymes** that catalyze the biochemical reactions of development

We will explore these regulatory mechanisms in more detail later in this chapter. But first let's look at the initial steps of plant development—from seed to seedling—and the types of internal and external cues that guide them.

In early development, the seed germinates and forms a growing seedling

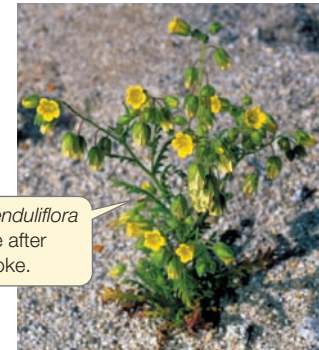

Chapter 38 will describe the events of plant reproduction and development that lead to the formation of seeds. Here we begin with the seed, the structure that contains the early embryo. Unlike most animal embryos, plant seeds may be held in “suspended animation,” with the development of the embryo halted, for long periods. If development stops even when

external conditions (such as water supply) are adequate for development, the seed is said to be **dormant**.

DORMANCY Seed dormancy may last for weeks, months, or years. Plants use several mechanisms to maintain dormancy:

- **Exclusion of water or oxygen** from the embryo by an impermeable seed coat
- **Mechanical restraint** of the embryo by a tough seed coat
- **Chemical inhibition** of germination by growth regulators
- **Photodormancy:** some seeds need a period of light or dark before they can germinate
- **Thermodormancy:** some seeds need high or low temperatures to germinate

Dormancy can be broken by factors that overcome these mechanisms. For example, the seed coat may be damaged by passage through an animal's digestive system, or heavy rains may wash away chemical inhibitors. There are many unusual methods to overcome dormancy. One interesting example is the breaking of dormancy by components of smoke. *Emmenanthe penduliflora* is a common plant in dry chaparral of the southwestern U.S., an area that is prone to wildfires.

Emmenanthe penduliflora seeds germinate after exposure to smoke.

These plants germinate rapidly after a fire. John Keeley of Occidental College in Los Angeles found that dormancy in seeds of this plant is broken not by heat but by smoke—in particular, by the nitrogen oxides found in smoke. Other molecules in smoke have been identified that regulate seed germination.

Plant biologists distinguish between seed *dormancy*, which prevents germination under conditions that are suitable for plant growth, and seed *quiescence*, which occurs when a seed fails to germinate because conditions are unfavorable for growth. Some seeds may remain quiescent, yet viable, for centuries: botanists have germinated a 1,300-year-old lotus seed recovered from a dry lake bed in China.

Seed dormancy and quiescence are common, so they must provide selective advantages for plants. Dormancy ensures that the seed will germinate at a time suitable for the plant to complete its life cycle. For example, some seeds require exposure to a long cold period (winter) before they germinate in the spring; this ensures that the plant has the entire growing season to mature and set new seeds. Dormancy and quiescence also help seeds survive droughts or long-distance dispersal, allowing plants to colonize new territory.

37.1 Patterns of Early Shoot Development

(A) In grasses and some other monocots, growing shoots are protected by a coleoptile until they reach the soil surface. (B) In most eudicots, the growing point of the shoot is protected within the cotyledons.

Life10e.com/ac37.2

GERMINATION Seeds begin to **germinate**, or sprout, when dormancy is broken and environmental conditions are satisfactory. The first step in germination is the uptake of water, called **imbibition** (from *imbibe*, “to drink in”). Before germination, a seed contains very little water: only 5 to 15 percent of its weight is water, compared with 80 to 95 percent for most other plant parts. Seeds also contain polar macromolecules, such as cellulose and starch, which attract and bind polar water molecules. Consequently a seed has a very negative water potential (see Chapter 35) and will take up water if the seed coat is permeable to water. The force exerted by imbibing seeds, which expand several-fold in volume, demonstrates the magnitude of their water potential; for example, imbibing cocklebur seeds can exert a pressure of up to 1,000 atmospheres.

As a seed takes up water, it undergoes metabolic changes: enzymes are activated upon hydration, RNA and then proteins are synthesized, the rate of cellular respiration increases, and other metabolic pathways are activated. In many seeds, cell division is not initiated during the early stages of germination. Instead, growth results solely from the expansion of small, preformed cells.

As germination proceeds, starch, proteins, and lipids that are stored in the seed are hydrolyzed to provide metabolic energy and chemical building blocks—carbohydrates, amino acids, and lipid monomers—for the growing embryo. These reserves are stored in the cotyledons (the first leaf or leaves of the embryo) or in the endosperm (the non-embryonic storage tissue of the seed). Germination is completed when the **radicle** (embryonic root) emerges from the seed coat. The plant is then called a **seedling**.

If the seed germinates underground, the new seedling must elongate rapidly (in the right direction!) and cope with a period of life in darkness or dim light. Photoreceptors that sense light and specialized cells that sense gravity direct this stage of development and prepare the seedling for growth in the light.

The pattern of early shoot development varies among the flowering plants. **Figure 37.1** shows the shoot development patterns of monocots and eudicots. In monocots, the growing

(A) Monocot (corn)

(B) Eudicot (bean)

shoot is protected by a sheath of cells called the **coleoptile** as it pushes its way through the soil. In dicots, the shoot is protected by the cotyledons.

Several hormones and photoreceptors help regulate plant growth

The above description of the early stages of plant development illustrates some of the environmental cues that influence plant growth. A plant's responses to these cues involve signal transduction pathways. Various mechanisms are used by the plant to sense changes in the environment, and these mechanisms activate signal transduction pathways that result in the synthesis and activation of specific plant hormones. In turn, these hormones act as signals that trigger pathways resulting in changes in plant growth. In some cases these changes involve alterations in the expression of specific genes.

Hormones are chemical signals that act at very low concentrations at sites often distant from where they are produced. Most plant hormones are very different from their counterparts in animals (**Table 37.1**). Each plant hormone plays multiple

TABLE 37.1
Comparison of Plant and Animal Hormones

Characteristic	Plant Hormones	Animal Hormones
Size, chemistry	Small organic molecules	Peptides, proteins, small molecules
Site of synthesis	Many locations in the plant	Specialized glands or cells
Site of action	Local or distant	Distant, transported
Effects	Often diverse	Often specific
Regulation	By biochemical feedback	By feedback and by central nervous system

TABLE 37.2
Plant Growth Hormones

Hormone	Structure	Typical Activities
Abscissic acid*		Maintains seed dormancy; closes stomata
Auxins (mainly indole-3-acetic acid)		Promote stem elongation, adventitious root initiation, and fruit growth; inhibit axillary bud outgrowth, leaf abscission, and root elongation
Brassinosteroids		Promote stem and pollen tube elongation; promote vascular tissue differentiation
Cytokinins		Inhibit leaf senescence; promote cell division and axillary bud outgrowth; affect root growth
Ethylene		Promotes fruit ripening and leaf abscission; inhibits stem elongation and gravitropism
Gibberellins (e.g., gibberellic acid)		Promote seed germination, stem growth, and ovule and fruit development; break winter dormancy; mobilize nutrient reserves in grass seeds

*See Chapter 38.

regulatory roles, and interactions among them can be complex. Several hormones regulate the growth and development of plants from seedling to adult (Table 37.2). Other hormones (for example, jasmonic acid and salicylic acid) are involved in the plant's defenses against herbivores and microorganisms, as we will discuss in Chapter 39.

Perhaps the most important environmental cue for a plant is light: the source of energy for photosynthesis. Plants have an abundance of **photoreceptors** that detect changes in the quality and direction of light as well as the timing of light availability (daylength). Photoreceptors are often proteins associated with pigments. Light acts directly on photoreceptors, which in turn regulate developmental processes that need to be responsive to light, such as the many changes that occur as a seedling emerges from the soil.

Genetic screens have increased our understanding of plant signal transduction

In Chapter 19 we described how genetic studies can be used to identify the steps along a developmental pathway. The reasoning behind these experiments is that if a mutation in a specific gene disrupts a developmental process, then the product of that gene must be involved in that process. Similarly, genetic studies can be used to analyze pathways of receptor activation and signal transduction in plants: if proper signaling does not occur in a mutant plant, then the mutant gene must be involved in the signal transduction process. Mapping the mutant gene and identifying its function is a starting point for understanding the signaling pathway. *Arabidopsis thaliana* has been a major model organism for plant biologists investigating signal transduction.

One technique for identifying the genes involved in a plant signal transduction pathway is illustrated in Figure 37.2. This technique, called a **genetic screen**, involves creating a large, random collection of mutant plants and identifying those individuals that are likely to have a defect in the pathway of interest. Plant genes can be randomly mutated in a variety of ways, including treatment with a chemical mutagen or the insertion of transposons (see Section 17.2) randomly in the genome. After treatment, the plants are grown and then examined for a specific phenotype, usually a characteristic that is influenced by the pathway of interest. Once mutant plants have been selected, their genotypes are compared with those of wild-type plants. *Arabidopsis* mutants with altered developmental patterns have provided a wealth of new information about the mechanisms of hormone and receptor (particularly photoreceptor) action.

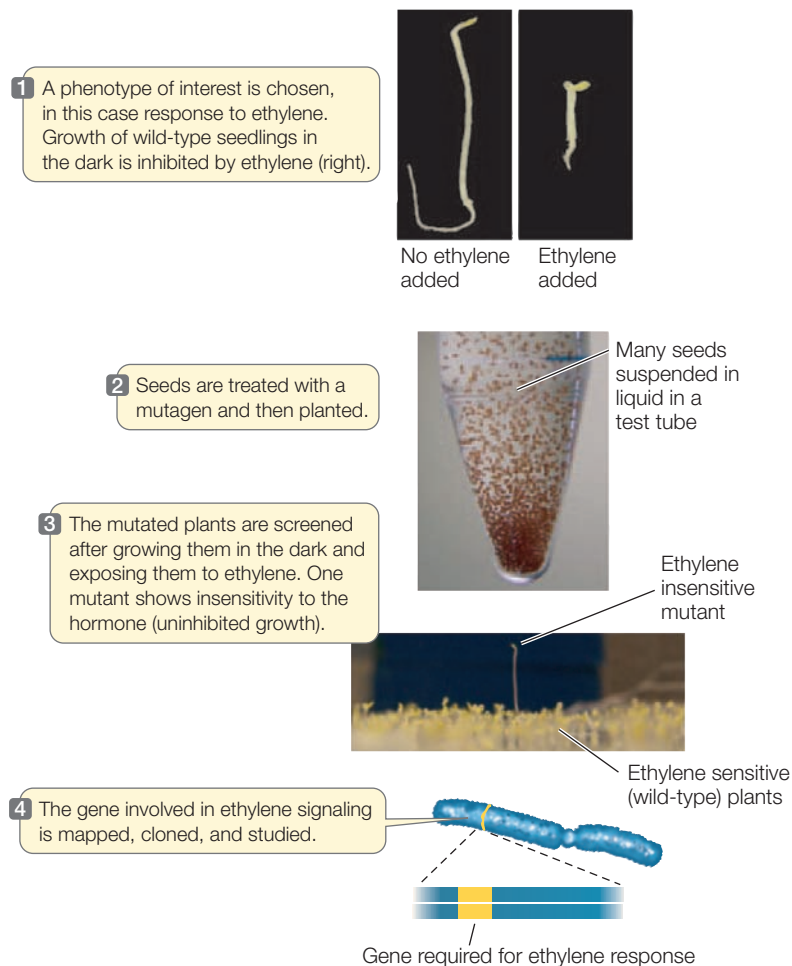

RECAP 37.1

Plant development is under the control of external cues in the environment and is mediated by hormones. These signals activate pathways that may result in changes in gene expression. Genetic screens have been useful in describing signal transduction pathways in the model plant *Arabidopsis thaliana*. Seed dormancy often precedes seed germination.

RESEARCHTOOLS

37.2 A Genetic Screen Genetics of the model plant *Arabidopsis thaliana* can be used to identify the steps of a signal transduction pathway. If a mutant strain does not respond to a hormone (in this case, ethylene), the corresponding wild-type gene must be essential for the pathway (in this case, ethylene response). This method has been instrumental to scientists in understanding plant growth regulation.

You have now seen the early stages of plant development and growth, and how the environment influences these processes. We will now turn to the subject of plant hormones, which are central to the internal regulation of development. We will describe how hormones were discovered and what physiological effects they have on plants. We will emphasize how genetic screens and other methods have led to a deeper molecular understanding of the action of plant hormones.

37.2 What Do Gibberellins and Auxin Do?

The discovery of two key plant hormones exemplifies the experimental approaches that plant biologists have used to

investigate the mechanisms of plant development. **Gibberellins** (there are several active forms) and **auxin** (there are several forms, but one predominates) were the first plant hormones to be discovered, early in the twentieth century. Initially, the discoveries came from observations of natural phenomena:

- **Gibberellins:** In rice plants, a disease caused by the fungus *Gibberella fujikori* resulted in plants that grew overly tall and spindly.
- **Auxin:** Biologists and indoor gardeners noted that seedlings would bend toward the light when placed near a light source.

A chemical substance was then isolated that could cause each phenomenon:

- Gibberellic acid (see Table 37.2) made by the *G. fujikori* fungus caused rice plants to overgrow. Later it was found that plants make gibberellic acid as well, and that applying it to plants caused growth.
- Indole-3-acetic acid (see Table 37.2) applied asymmetrically to the growing tips of seedlings caused cell elongation on the side away from the light, which resulted in the shoot bending toward the light.

Finally, mutant plants that do not make each hormone exhibit a phenotype expected in the absence of the hormone, and adding the hormone reverses that phenotype (**Figure 37.3**):

- Tomato plants that do not make gibberellic acid are very short; supplying them with the hormone results in normal growth.
- *Arabidopsis thaliana* individuals that do not make auxin are also short; supplying them with that hormone reverses that phenotype.

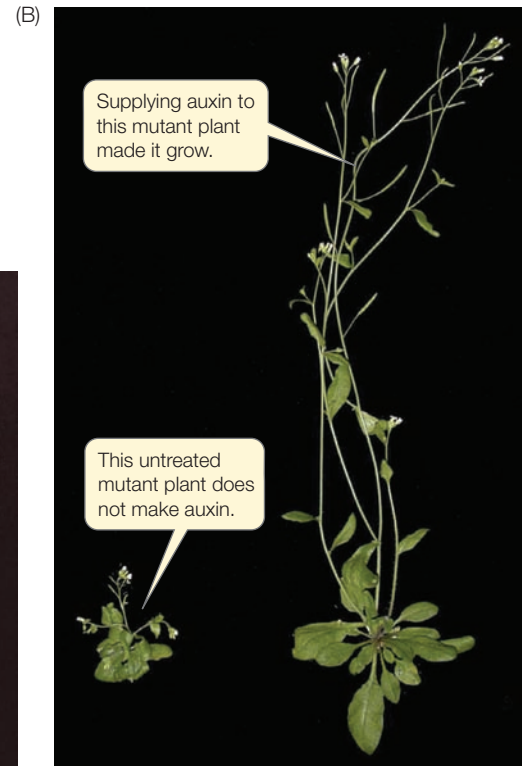

Note that the phenotype involved—short stature, or dwarfism—is similar in both mutant plants. This observation exemplifies a concept that is important to keep in mind when studying plant hormones: their actions are not unique and specific, as is the case with animal hormones (see Table 37.1).

The approaches outlined above—observation, hormone isolation, hormone treatment, and analysis of mutants—are just some of the methods used to identify plant hormones and understand their roles in plant development. Plant biologists have also studied hormones using chemical inhibitors and using plant transformation experiments that alter hormone levels or the plants' responses to hormones.

Gibberellins have many effects on plant growth and development

The functions of gibberellins can be inferred from the effects of experimentally decreasing gibberellins or blocking their action at various points in plant development. Such experiments reveal that gibberellins have multiple roles in regulating plant growth.

37.3 Hormones Reverse a Mutant Phenotype (A) The two mutant dwarf tomato plants in this photograph were the same size when the one on the right was treated with a gibberellin solution. (B) The short phenotype of this *Arabidopsis* mutant was reversed in the plant on the right by supplying auxin.

STEM ELONGATION The effects of gibberellins on wild-type plants are not as dramatic as those seen on dwarf plants. However, gibberellins are indeed active in wild-type plants, because inhibitors of gibberellin synthesis cause a reduction in stem elongation. Such inhibitors can be put to practical uses. For example, plants such as chrysanthemums that are grown in greenhouses tend to get tall, but leggy plants do not appeal to consumers. Flower growers spray such plants with gibberellin synthesis inhibitors to control their height. Some wheat crops are similarly sprayed to keep them short, so they do not fall over when they produce grain; the result is chemically produced semi-dwarfs similar to the genetically produced varieties described in the opening story of this chapter. In some plants, such as cabbage, the normal growth habit is to be a squat, leafy head near the ground. When environmental signals are right, however, the plant “bolts,” quickly producing a tall stem with flowers—a response that can be mediated by gibberellins.

FRUIT GROWTH Gibberellins and other hormones regulate the growth of fruits. Grapevines that produce seedless grapes develop smaller fruits than varieties that produce seed-bearing grapes. Biologists wanting to explain this phenomenon removed seeds from immature seeded grapes and found that this prevented normal fruit growth, suggesting that the seeds are sources of a growth regulator. Biochemical studies showed that developing seeds produce gibberellins, which diffuse into the immature fruit tissue. Spraying young seedless grapes with a gibberellin solution causes them to grow as large as seeded ones, and this is now a standard commercial practice (Figure 37.4).

MOBILIZATION OF SEED RESERVES Early in seed germination, hydrolytic enzymes are produced to break down stored reserves of

starch, proteins, and lipids. Just after imbibition in germinating seeds of barley and other cereals, the embryo secretes gibberellins. The hormones diffuse through the endosperm to a surrounding tissue called the **aleurone layer**, which lies underneath the seed coat. The gibberellins trigger a cascade of events in the aleurone layer, causing it to synthesize and secrete enzymes that hydrolyze proteins and starch stored in the endosperm (Figure 37.5). These observations have practical importance: in the beer brewing industry, gibberellins are used to enhance the “malting” (germination) of barley and the breakdown of its endosperm, producing sugar that is fermented to alcohol.

37.4 Gibberellins and Fruit Growth Spraying developing seedless grapes with gibberellins (right) increases their size compared with untreated fruit (left).

37.5 Embryos Mobilize Their Reserves During seed germination in cereal grasses, gibberellins trigger a cascade of events that result in the conversion of starch and protein reserves into monomers that can be used by the developing embryo.

Go to Activity 37.3 Events of Seed Germination
Life10e.com/ac37.3

Another hormone, abscisic acid (ABA) (see Table 37.2) plays an antagonistic role with gibberellins in seed dormancy and germination. As we will describe in Section 38.1, ABA levels are high in dormant seeds and fall off during germination. Thus ABA plays a role in maintaining seed dormancy, whereas gibberellins function to break dormancy and promote germination.

Auxin plays a role in differential plant growth

Auxin was first discovered for its role in the bending of plants toward light. Subsequent research has shown that auxin is involved in many other aspects of plant growth and development.

IDENTIFYING AUXIN AND ITS TRANSPORT Auxin (from the Latin “to increase”) was discovered in the context of **phototropism**: a response to light in which plant stems bend toward a light source. This was a familiar observation by biologists and home gardeners when the ever-curious Charles Darwin and his son Francis investigated this phenomenon and concluded that a signal was made in the shoot apex and diffused down the shoot in a polar (unidirectional) fashion, stimulating cell elongation.

 **Go to Animated Tutorial 37.1**
Tropisms
Life10e.com/at37.1

The Darwins worked with canarygrass (*Phalaris canariensis*) seedlings grown in the dark. While underground, a young grass seedling is protected by a coleoptile (see Figure 37.1). The coleoptiles of grasses are phototropic—they grow toward the light.

To find the light-receptive region of the coleoptile, the Darwins “blindfolded” the coleoptiles of dark-grown canarygrass seedlings in various places and then illuminated them from one side (Figure 37.6). The coleoptile grew toward the light whenever its tip was exposed. If the top millimeter or more of the coleoptile was covered, however, the coleoptile showed no phototropic response. The Darwins concluded that the tip contains the photoreceptor that responds to light. The actual bending toward the light, however, takes place in a growing region a few millimeters below the tip. Therefore, the Darwins reasoned, *some type of signal must travel from the tip of the coleoptile to the growing region*.

Others showed that placing the coleoptile tip (the source of the growth signal) on a decapitated coleoptile led to bending, even when a block of gelatin separated the tip and coleoptile.

In these experiments, the growth signal moved from the coleoptile tip into the gelatin and then down into the decapitated coleoptile; later the growth signal was isolated from such gelatin blocks and identified as indole-3-acetic acid (see Table 37.2), the major form of auxin.

INVESTIGATINGLIFE

37.6 The Darwins' Phototropism Experiment Charles Darwin and his son Francis wanted to know how plants bend toward the light. They grew canarygrass seedlings (coleoptiles) in the dark. To discover what part of the coleoptile responds to light, they covered up ("blindfolded") different regions of each coleoptile and then exposed the seedlings to light from one side. The Darwins discovered that the tip of the seedling senses the light and that growth occurs below the tip. Their observations led them to hypothesize the existence of a growth-promoting signal produced by the coleoptile tip.^a

HYPOTHESIS Only part of the coleoptile senses the light that triggers phototropism.

Method

Results

CONCLUSION The part of the coleoptile that senses light is in the tip, and it sends a signal from the tip to the growing region.

^aDarwin, C. R. 1880. *The Power of Movement in Plants*. London, John Murray.

MECHANISM OF AUXIN TRANSPORT The movement of auxin down a coleoptile is an example of polar (apical-to-basal) transport. Polar transport of auxin (**Figure 37.7**) depends on four biochemical processes that may be familiar from earlier chapters:

- *Diffusion across a plasma membrane.* Polar molecules (in the chemical sense) diffuse across plasma membranes less readily than nonpolar molecules (see Chapter 6).
- *Membrane protein asymmetry.* Active transport carriers (see Chapter 6) for auxin are located only in the portion of the plasma membrane at the basal (bottom) end of the cell.
- *Proton pumping/chemiosmosis.* A proton pump (see Chapter 36) moves H^+ from the cytoplasm to the cell wall, thereby increasing the intracellular pH and decreasing the pH in the cell wall. Proton pumping also sets up an electrochemical gradient, which provides potential energy to drive the transport of auxin by the carriers mentioned above (see Chapter 9).
- *Ionization of a weak acid.* The main form of auxin, indole-3-acetic acid, is a weak acid:

When the pH is low, this reaction is driven to the right, and HA (non-ionized auxin) is the predominant form. When the pH is higher, there is more A^- (ionized auxin).

While polar auxin transport distributes the hormone along the longitudinal axis of the plant, lateral (side-to-side) redistribution

37.7 Polar Transport of Auxin Proton pumps set up a chemiosmotic gradient directing ionized auxin (A^-) toward the basally placed active transport carriers for auxin, which leads to a net movement of auxin in a basal direction.

The Darwins' Phototropism Experiment

Original Paper

Darwin, C. R. 1880. *The Power of Movement in Plants*. Chapter IX: Sensitiveness of plants to light: Its transmitted effects. London, John Murray.

Analyze the Data

Fascinated by experiments showing that light induces plants to bend toward it and that this is due to increased growth on the "dark side" of the stem, Charles Darwin and his son Francis performed experiments to learn more about how plants respond to light. Their experiments were done on canarygrass (*Phalaris canariensis*) seedlings grown in the dark to simulate events that occur when the seed germinates in the soil. These seedlings have a sheath—the coleoptile—that covers the developing leaf. When placed in a box with an opening at a window (unidirectional light), the seedlings bent toward the light source. This bending seemed to be led by the very tip of the coleoptile, and the Darwins hypothesized that the light-sensing mechanism might reside in the coleoptile, while growth occurs in tissue below the tip. Their hypothesis was validated when they repeated their experiments with the coleoptile tip cut off: bending did not occur. Because it was possible that the cut plants did not bend because they had been irreversibly damaged in some way, the Darwins repeated their initial experiment with undamaged seedlings whose coleoptile tips had been covered with a thin glass tube cap that was blacked out with India ink. In this case the plants did not bend. The Darwins' conclusion that the tip of the coleoptile senses the light and transmits a message to tissue below the tip to grow was initially controversial but ultimately led to the identification of auxin, the first plant growth hormone.

QUESTION 1

The figure shows a drawing from the Darwins' book of the bending of coleoptiles after 8 hours of light exposure. From which direction was the light shone?

QUESTION 2

The Darwins reported:

"Seven cotyledons [Note: The Darwins used the term "cotyledon" for what is now called a coleoptile.] had their tips cut off for lengths varying between 0.1 and 0.16 of an inch, and these, when left exposed all day to a lateral light, remained upright. In another set of 7 cotyledons, the tips were cut off for a length of only about 0.05 of an inch (1.27 mm) and these became bowed towards a lateral light, but not nearly so much as the many other seedlings in the same pots."

What do these data indicate about the possible role of the tip and about the possibility that injury in cutting blocks the bending response?

QUESTION 3

The Darwins describe their further experiments:

"The summits of nine cotyledons, differing somewhat in height, were enclosed for rather less than half their lengths in uncoloured or transparent tubes; and these were then exposed before a south-west window on a bright day for 8 h. All of them became strongly curved towards the light, in the same degree as the many other free seedlings in the same pots; so that the glass-tubes certainly did not prevent the cotyledons from bending towards the light. Nineteen other cotyledons were, at the same time, similarly enclosed in tubes thickly painted with Indian ink. On five of them, the paint, to our surprise, contracted after exposure to the sunlight, and very narrow cracks were formed, through which a little light entered; and these five cases were rejected. Of the remaining 14 cotyledons, the lower halves of which had been fully exposed to the light for the whole time, 7 continued quite straight and upright; 1 was considerably bowed to the light, and 6 were slightly bowed, but with the exposed bases of most of them almost or quite straight."

What do these data indicate about the role of the tip? Can you explain why there was slight bending in the 6 coleoptiles that were covered with painted tubes?

QUESTION 4

The Darwins observed that the leaves of the insect-consuming Venus flytrap do not bend toward light. Why would this response not be important to an insectivorous plant?

Go to [BioPortal](#) for all WORKING WITH DATA exercises

of auxin is responsible for directional plant growth. This was shown in early experiments that followed the Darwins' when a coleoptile tip containing the growth hormone was placed asymmetrically on the decapitated coleoptile. The asymmetric distribution of growth hormone down the coleoptile resulted in excess growth on that side, and bending away from it, even in the absence of light:

The redistribution of auxin to one side is carried out by auxin carrier proteins that move from the base of the cell to one side; because of this, auxin exits the cell only on that side of the cell, rather than at the base, and moves sideways within the tissue.

This lateral movement of auxin explains the bending of canarygrass seedlings toward light that the Darwins observed. When light strikes a canarygrass coleoptile on one side, auxin at the tip moves laterally toward the shaded side. The asymmetry thus established is maintained as polar transport moves auxin down the coleoptile, so that in the growing region below, the auxin concentration is highest on the shaded side. Cell elongation is thus speeded up on that side, causing the coleoptile to bend toward the light (**Figure 37.8A**).

Light is not the only signal that can cause the redistribution of auxin. Auxin moves to the lower side of a shoot that has been

(A) Phototropism

(B) Negative gravitropism of shoot

37.8 Plants Respond to Light and Gravity Phototropism (A) and gravitropism (B) occur in shoot apices in response to a redistribution of auxin.

tipped sideways, causing more rapid growth in the lower side and hence an upward bending of the shoot. Such growth in a direction determined by gravity is called **gravitropism** (Figure 37.8B). The upward gravitropic response of shoots is defined as negative gravitropism; that of roots, which bend downward, is positive gravitropism. Gravitropism in roots also involves differential growth caused by lateral movement of auxin, but the details of the mechanism differ between the root and the shoot.

Auxin affects plant growth in several ways

Like the gibberellins, auxin has many roles in plant development. It affects the vegetative and reproductive growth of plants in several ways.

ROOT INITIATION Cuttings from the shoots of some plants can produce roots and develop into entire new plants. For this to occur, certain undifferentiated cells in the interior of the shoot, originally destined to function only in food storage, must set off on a new mission: they must change their cell fate and become organized into the apical meristem of a new root. These changes

37.9 Changes Occur When a Leaf Is about to Fall The breakdown of cells in the abscission zone of the petiole causes the leaf to fall.

are similar to those that take place in the pericycle of a root when a lateral root forms (see Figure 34.10). Shoot cuttings of many species can be made to develop roots by dipping the cut surfaces into an auxin solution. These observations suggest that in an intact plant, the plant's own auxin plays a role in the initiation of lateral roots. Commercial preparations that enhance the rooting of plant cuttings typically contain synthetic auxins.

LEAF ABSCISSION In contrast to its stimulatory effect on root initiation, auxin inhibits the detachment of old leaves from stems. This detachment process, called **abscission**, is the cause of autumn leaf fall. Many leaves consist of a blade and a petiole that attaches the blade to the stem. Abscission results from the breakdown of a specific part of the petiole, the abscission zone (Figure 37.9). If the blade of a leaf is cut off, the petiole falls from the plant more rapidly than if the leaf had remained intact. If the cut surface is treated with an auxin solution, however, the petiole remains attached to the plant, often longer than an intact leaf would have. The timing of leaf abscission in nature appears to be determined in part by a decrease in the movement through the petiole of auxin produced in the blade.

APICAL DOMINANCE Auxin helps maintain **apical dominance**, a phenomenon in which apical buds inhibit the growth of axillary buds (see Figure 34.1), resulting in the growth of a single main stem with minimal branching. Apical dominance can be demonstrated by an experiment with a young seedling. If the plant remains intact, the stem elongates and the axillary buds remain inactive. Removal of the apical bud—the major site of auxin production—results in growth of the axillary buds. If the cut surface of the stem is treated with auxin, however, the axillary buds do not grow. The apical buds of branches also exert apical dominance: the axillary buds on the branch are inactive unless the apex of the branch is removed. That is why gardeners prune shrubs to encourage branching.

37.10 How Auxin Affects the Cell Wall The plant cell wall is an extensive network of cross-linked polymers. Auxin induces wall loosening by activating a proton pump that reduces pH in the cell wall.

Go to Animated Tutorial 37.3
Auxin Affects Cell Walls
Life10e.com/at37.3

In the experiments on leaves and stems just discussed, removal of a particular part of the plant elicits a response—abscission or loss of apical dominance—and that response is prevented by treatment with auxin. These results are consistent with other data showing that the excised part of the leaf or stem is an auxin source and that auxin in the intact plant delays the abscission of leaves and helps maintain apical dominance.

FRUIT DEVELOPMENT Fruit development normally depends on prior fertilization of the ovule (egg), but in many species treatment of an unfertilized ovary with auxin or gibberellins causes **parthenocarpy**—fruit formation without fertilization. Parthenocarpic fruits form spontaneously in some cultivated varieties of plants, including seedless grapes, bananas, and some cucumbers.

CELL EXPANSION Cell division followed by cell expansion is what causes plant growth. Because the plant cell wall normally prevents expansion of the cell contents inside the plasma membrane (see Section 34.1), the cell wall plays a key role in controlling the rate and direction of plant cell growth. Auxin acts on cell walls to regulate this process.

The expansion of a plant cell is driven primarily by the uptake of water, which enters the cytoplasm of the cell and accumulates in its central vacuole (see Section 35.1). Growth of the vacuole accounts for most of the increase in volume of a growing cell, and the vacuole often makes up more than 90 percent of the volume of a mature cell. As the vacuole expands, it presses the cytoplasm against the cell wall, and the wall resists this force (the basis of turgor pressure). The cell wall is an extensively cross-linked network of polysaccharides and proteins, dominated by cellulose microfibrils. If the cell is to expand, some adjustments must be made in the wall structure to allow the wall to “give” under turgor pressure. Think of a balloon (the cell surrounded by a membrane) inside a box (the cell wall). How does the cell wall “box” loosen to allow expansion?

The **acid growth hypothesis** explains auxin-induced cell expansion (Figure 37.10). The hypothesis holds that protons (H^+) are pumped from the cytoplasm into the cell wall, lowering the pH of the wall and activating enzymes called expansins that catalyze changes in the cell wall structure such that the polysaccharides adhere to each other less strongly. This loosens the cell wall, making it easier to stretch as the cell expands. Auxin has two roles in this process: to increase the synthesis of the proton

37.11 Gibberellins and Auxin Have Similar Signal Transduction Pathways Although the specific proteins involved are different, both hormones act to stimulate gene transcription by inactivating a repressor protein.

Go to Media Clip 37.1
Gibberellin Binding to Its Receptor
[Life10e.com/mc37.1](https://www.life10e.com/mc37.1)

pumps, and to guide their insertion into the plasma membrane. Auxin may also increase the activity of proton pump proteins already in the plasma membrane. Several lines of evidence support the acid growth hypothesis. For example, adding acid to the cell wall to lower the pH stimulates cell expansion even in the absence of auxin. Conversely, when a buffer is used to prevent the wall from becoming more acidic, auxin-induced cell expansion is blocked. The acid growth hypothesis holds more or less well depending on species; in some plants, auxin stimulates secretion of new cell wall components quickly enough to account for even rapid changes in growth rate.

At the molecular level, auxin and gibberellins act similarly

The molecular mechanisms underlying both auxin and gibberellin action have been worked out with the help of genetic screens (see Figure 37.2). Biologists started by identifying mutant plants whose growth and development are insensitive to the hormones—that is, plants that are *not* affected by added hormone. Such mutants fall into two general categories:

- *Excessively tall plants.* These plants resemble wild-type plants given an excess of hormone and grow no taller when given extra hormone. They grow tall even when treated with inhibitors of hormone synthesis. Their hormone response is always “on,” even in the absence of the hormone. In such cases, it is presumed that the normal allele for the mutant gene codes for an inhibitor of the hormone signal transduction pathway. In wild-type plants, that pathway is “off,” but in the mutant plants, the pathway is “on” and the plant grows tall.
- *Dwarf plants.* These plants resemble dwarf plants that are deficient in hormone synthesis (see Figure 37.3), but they do not respond to added hormone. In these mutants the hormone response is always “off,” regardless of the presence of the hormone.

Remarkably, some mutations of both types turned out to affect the same protein, which turns out to be a repressor of a transcription factor that stimulates the expression of growth-promoting genes. The repressor protein has two important domains, which explains how mutations in the same protein can have seemingly opposite effects:

- *One region of the repressor protein binds to the transcription complex to inhibit transcription of growth-promoting genes.* This is the region mutated in the excessively tall plants: the growth-promoting genes are always “on” because the repressor does not bind to the transcription complex.
- *Another region of the repressor protein causes it to be removed from the transcription complex.* This is the region mutated in the dwarf plants: the growth-promoting genes are always “off” because the repressor is always bound to the complex.

These observations allowed biologists to figure out how auxin and gibberellins work in wild-type plants. Of course, the repressor proteins involved in responding to the two hormones are different, but the actions of both hormones are similar: they *act by removing the repressor from the transcription complex* (Figure 37.11). The hormones do this by binding to a receptor protein, which in turn binds to the repressor. Binding of the hormone–receptor complex stimulates polyubiquitination of the repressor, targeting it for breakdown in the proteasome (see Figure 16.25). The receptors contain or associate with a region called an F-box that facilitates protein–protein interactions necessary for causing polyubiquitination of a target protein. Whereas animal genomes have few F-box-containing proteins, plant genomes have hundreds, an indication that this type of gene regulation is common in plants.

RECAP 37.2

Gibberellins are plant hormones that affect stem growth, fruit size, seed germination, and many other aspects of plant development; the effects vary from species to species. Auxin regulates cell expansion and thus mediates phototropism and gravitropism; it also plays roles in apical dominance, leaf abscission, fruit development, and root initiation. The acid growth hypothesis explains auxin-induced cell wall loosening. Similar molecular mechanisms explain the effects of auxin and gibberellins on gene expression.

- How were gibberellins and auxin shown to be plant hormones? **See p. 760**
- How do gibberellins contribute to the germination of barley seeds? **See Figure 37.5**
- What is the evidence for polar transport of auxin, and how does it occur? **See pp. 762–763 and Figures 37.6 and 37.7**
- Explain why, even though auxin moves away from the lighted side of a coleoptile tip, the coleoptile bends *toward* the light. **See p. 764 and Figure 37.8**
- How does auxin cause cell wall loosening? **See p. 766 and Figure 37.10**
- What is the general signal transduction pathway for auxin and gibberellin? **See p. 767 and Figure 37.11**

How can a single hormone, such as auxin or a gibberellin, have so many effects? As we have seen, a single signal transduction pathway may affect more than one gene. We will learn about other important plant hormones in the next section, and they too have multiple effects.

37.3 What Are the Effects of Cytokinins, Ethylene, and Brassinosteroids?

Like animal cells, plant cells differentiate after they form from undifferentiated stem cells (called meristem cells in plants). But unlike animal cells, which generally do not divide after differentiation, plant cells retain the ability to divide. For example, in leaf abscission (see Figure 37.9) differentiated parenchyma cells in the petiole resume division, forming a specialized, weak layer of cells. Also, cells of the phloem and cortex can resume division and form secondary meristems. What stimulates these cells to divide? An answer came from studies of cells isolated from plants and cultured in the laboratory.

Cytokinins are active from seed to senescence

Like bacteria and yeasts, plant cells such as parenchyma cells can be grown in a liquid or solidified growth medium containing sugars and salts. The cells will divide continuously until they run out of nutrients. In the early days of plant cell culturing, scientists experimented with many supplements to determine the optimal chemical environment for growth. The best supplement was coconut milk, the fluid that surrounds the developing embryo in coconut fruit. Investigators suspected that a molecule in the fluid must stimulate plant cell division.

A clue to the identity of the molecule came when Folke Skoog at the University of Wisconsin tested various pure substances that might substitute for coconut milk. DNA was among the substances tested, and it did not work; however, heating DNA at high pressure in an autoclave produced a mixture that strongly promoted plant cell division. A derivative of adenine called kinetin was identified as the active ingredient. Because it stimulated cell division (cytokinesis), it was called a **cytokinin**.

Kinetin does not exist in cells, but it gave scientists a hint as to what type of molecule might be the active ingredient in coconut milk. In 1963 an adenine derivative called **zeatin** was extracted from corn endosperm. Since then, more than 150 different cytokinins have been isolated, and most are derivatives of adenine.

Cytokinins (see Table 37.2) have several different effects, in many cases interacting with auxin:

- Adding an appropriate combination of auxin and cytokinins to a growth medium induces rapid proliferation of cultured plant cells.
- Cytokinins can cause certain light-requiring seeds to germinate even when kept in constant darkness.
- In plant tissue cultures, a high cytokinin-to-auxin ratio promotes the formation of shoots; a low ratio promotes the formation of roots.
- Cytokinins usually inhibit the elongation of stems, but they cause lateral swelling of stems and roots (the fleshy roots of radishes are an extreme example).
- Cytokinins stimulate axillary buds to grow into branches; the auxin-to-cytokinin ratio controls the extent of branching (bushiness) of a plant.
- Cytokinins delay the senescence of leaves. If leaf blades are detached from a plant and placed in water or a nutrient solution, they quickly turn yellow and show other signs of senescence. If instead they are placed in a solution containing a cytokinin, they remain green and senesce much more slowly. Roots contain abundant cytokinins, and cytokinin transport to the leaves delays senescence.

Cytokinin signaling appears to act through a two-component pathway (a type of signal transduction pathway common in bacteria):

- A *receptor* that can act as a protein kinase, phosphorylating itself as well as a target protein

- A target protein, generally a transcription factor, that can act as an *effector*

Genetic screens in *Arabidopsis* for defects in the response to cytokinin have identified the receptor (AHK; *Arabidopsis* histidine kinase) and target effector (ARR; *Arabidopsis* response regulator), the latter acting as a transcription factor when phosphorylated. The signal transduction pathway also includes a third protein (AHP; *Arabidopsis* histidine phosphotransfer protein), which transfers phosphates from the receptor to the effector (Figure 37.12). The *Arabidopsis* genome has more than 20 genes that are expressed in response to this signaling pathway.

Ethylene is a gaseous hormone that hastens leaf senescence and fruit ripening

Whereas the cytokinins delay senescence, another plant hormone promotes it: the gas **ethylene** (see Table 37.2), which is sometimes called the senescence hormone. Ethylene can be produced by all parts of the plant, and like all plant hormones, it has several effects.

Back when streets were lit by gas rather than by electricity, leaves on trees near street lamps dropped earlier than those on trees farther from the lamps. We now know why: ethylene, a combustion product of the illuminating gas, caused the early abscission. Whereas auxin delays leaf abscission, ethylene strongly promotes it; thus the balance of auxin and ethylene controls abscission.

FRUIT RIPENING By promoting senescence, ethylene also speeds the ripening of fruit. As a fruit ripens, it loses chlorophyll and its cell walls break down; ethylene promotes both of these processes. Ethylene also causes an increase in its own production. Thus once ripening begins, more and more ethylene forms, and because it is a gas, it diffuses readily throughout the fruit and even to neighboring fruits on the same or other plants. The old saying “one rotten apple spoils the barrel” is true. That rotten apple is a rich source of ethylene, which speeds the ripening and subsequent rotting of the other fruit in a barrel or other confined space.

Farmers used to poke holes in developing figs to make them ripen faster. We now know that wounding causes an increase in ethylene production by the fruit, and that the raised ethylene level promotes ripening in many fruits, including apples, bananas, melons, apricots, and tomatoes. Today commercial shippers and storers of such fruit hasten ripening by adding ethylene to storage chambers. This use of ethylene is the single most important use of a natural plant hormone in agriculture and commerce.

37.12 The Cytokinin Response Pathway Plant cells respond to cytokinins using a signal transduction pathway involving a receptor and an effector protein.

37.13 The Apical Hook of a Eudicot Asymmetrical production of auxin, controlled by ethylene, is responsible for the apical hook of this bean seedling. The ethylene concentration was highest on the right side, so more rapid growth on the left caused and maintained the hook.

Ripening can also be delayed by the use of “scrubbers” and adsorbents that remove ethylene from the atmosphere in fruit storage chambers. This strategy can even be used in the home. Many supermarkets sell plastic bags designed to keep fruits fresh; the bags are impregnated with a substance that binds ethylene.

As flowers senesce, their petals may abscise, decreasing their value in the cut-flower industry. Growers and florists often immerse the cut stems of ethylene-sensitive flowers in dilute solutions of silver thiosulfate before sale. Silver salts inhibit ethylene action by interacting directly with the ethylene receptor—thus they delay senescence, keeping flowers “fresh” for longer. An alternative product, used to delay fruit ripening and preserve cut flowers, is 1-methylcyclopropene, a gas that also binds ethylene receptors and blocks their function.

STEM GROWTH Although it is associated primarily with senescence, ethylene is active at other stages of plant development as well. Its effects on seedling development illustrate the interactions that occur among plant hormones. The hypocotyl of many eudicot seedlings forms an **apical hook** that protects the delicate shoot apex while the stem grows through the soil (Figure 37.13). As in phototropic and gravitropic responses, the apical hook is maintained through an auxin gradient, which promotes the elongation of cells on the outer surface of the hook. Once the seedling breaks through the soil surface and is exposed to light, the auxin level on the inside of the hook increases and the hook unfolds, raising the shoot apex and the expanding leaves into the sun.

There is evidence that ethylene controls the formation of the auxin gradient during seedling development. Treatment of dark-grown seedlings of some species with ethylene results in what is called the “triple response”: an exaggeration of the apical hook and a thickening and shortening of the hypocotyl and root (this response was exploited in a genetic screen for

37.14 The Signal Transduction Pathway for Ethylene This diagram shows the roles of four proteins (A, B, C, and D) in the signal transduction pathway through which ethylene exerts its many effects.

ethylene response mutants; see Figure 37.2). It has been shown that ethylene affects both auxin synthesis and transport during apical hook development.

THE ETHYLENE SIGNAL TRANSDUCTION PATHWAY The mechanism of ethylene action has been worked out by analyzing *Arabidopsis* mutants that have ethylene-related defects. Some of these mutants do not respond to applied ethylene, and others act as if they have been exposed to ethylene even though they have not. Researchers studied the mutant genes and compared their protein products with other known proteins; thus they worked out some of the details of the signal transduction pathway through which ethylene acts (Figure 37.14).

The pathway includes two membrane proteins in the endoplasmic reticulum. The first is an ethylene receptor (labeled A in the figure), and the second is a channel-like protein (C). In the absence of ethylene, receptor A activates a protein kinase (B) that keeps C inactive by phosphorylation. When receptor A binds ethylene, it stops activating B. Without B to inactivate it, C activates

a transcription factor (D), which then moves into the nucleus, where it turns on the genes that produce ethylene's effects in the cell. In other words, ethylene turns off the "off" signal.

Brassinosteroids are plant steroid hormones

In animals, steroid hormones such as cortisol and estrogen are formed from cholesterol (see Figure 41.2). Initially, biologists isolated a plant steroid hormone from the pollen of rape, a member of the Brassicaceae (mustard family). When applied to various plant tissues, this **brassinosteroid** (see Table 37.2) stimulated cell elongation, pollen tube elongation, and vascular tissue differentiation, but it inhibited root elongation. Since then, dozens of chemically related, growth-affecting brassinosteroids have been found in most plants.

Mutant plants that either do not make brassinosteroids or have defects in brassinosteroid reception and signal transduction are usually dwarf, infertile, and slow to develop. These effects can be reversed by adding small amounts of brassinosteroids, indicating that brassinosteroids are true hormones. These hormones have diverse effects, which vary among plants. Brassinosteroids can:

- promote xylem differentiation
- promote growth of pollen tubes during reproduction
- promote seed germination
- promote apical dominance and leaf senescence
- enhance cell elongation and cell division in shoots

The signaling pathway for these plant steroids differs sharply from those for steroid hormones in animals. In animals, steroids diffuse through the plasma membrane and bind to receptors in the cytoplasm. In contrast, the receptor for brassinosteroids is an integral protein in the plasma membrane.

RECAP 37.3

Cytokinins, ethylene, and brassinosteroids work in concert with auxin and gibberellins to mediate plant development. Their signaling pathways vary from a simple two-component receptor–effector system (cytokinin) to inhibition of an inhibitor of an effector (ethylene).

- How do cytokinins interact with auxin to regulate a plant's development? [See p. 768](#)
- What is the role of ethylene in fruit ripening? How is this knowledge used commercially? [See p. 769](#)
- How do the signaling pathways for cytokinins and ethylene differ? [See pp. 769–770 and Figures 37.12 and 37.14](#)

A plant's response to light—the energy source for photosynthesis—is crucial to its survival. We saw how the Darwins' pioneering investigations of phototropism led to the discovery of auxin. Let's now look more closely at how plants sense and respond to light.

37.4 How Do Photoreceptors Participate in Plant Growth Regulation?

As we pointed out in Section 37.1, plants respond to many different environmental cues, and light is possibly the most important of these cues. Much has been learned about the receptors that plants use to sense light, and we will focus on those receptors here.

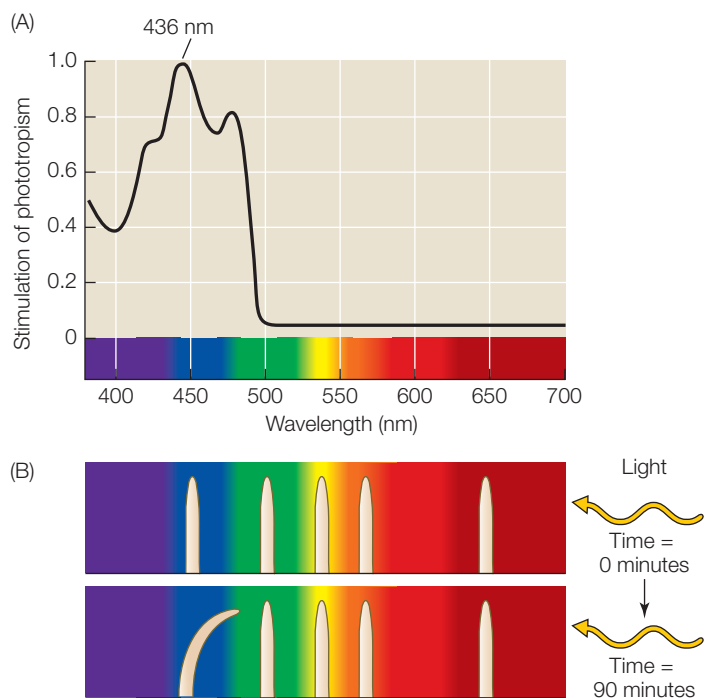

Plants respond to two aspects of light: (1) its *quality*—that is, the wavelengths of light that can be absorbed by molecules in the plant; and (2) its *quantity*—that is, the intensity and duration of light exposure.

Chapter 10 described photosynthesis: how chlorophyll and other pigments absorb light at certain wavelengths (quality), and how light intensity affects photosynthetic rate (quantity). Here we will consider how light affects plant development. Earlier in this chapter we described phototropism and how auxin mediates a plant stem's bending toward light. In addition to phototropism, light influences seed germination, shoot elongation, the initiation of flowering, and many other important aspects of plant development. Several photoreceptors take part in these processes. Three or more types of **blue-light receptors** mediate the effects of higher-intensity blue light, and phytochrome mediates the effects of red light.

Phototropins, cryptochromes, and zeaxanthin are blue-light receptors

Charles and Francis Darwin showed that the apical tip of a growing coleoptile receives light as a signal and then redistributes auxin to stimulate cell elongation below the tip on the shaded side. You may recall from Chapter 10 that an action spectrum involves exposing plants to different wavelengths of light to determine what wavelengths are most effective in driving a given process (e.g., photosynthesis). For photosynthesis, such studies showed that the most effective wavelengths are those absorbed by chlorophylls (see Figure 10.5). When an action spectrum was obtained for phototropism of coleoptiles, blue light (peak 436 nm) was found to be the most effective at inducing the coleoptile to curve (**Figure 37.15**). What is the blue-light-absorbing receptor/pigment? Biologists have used a genetic approach to answer this question, once again employing the model plant *Arabidopsis*.

Researchers recovered blue-light-insensitive *Arabidopsis* mutants from a genetic screen and identified the gene for a blue-light receptor protein located in the plasma membrane called **phototropin**. Phototropin protein has a flavin mononucleotide associated with it that absorbs blue light, leading to a change in the shape of the protein. This change exposes an active site for a protein kinase, which in turn initiates a signal transduction cascade that ultimately results in the stimulation of cell elongation by auxin.

37.15 Action Spectrum for Phototropism (A) The action spectrum for bending of a coleoptile toward light is similar to the absorption spectrum for the receptor, phototropin. (B) After 90 minutes, only the coleoptiles exposed to blue light bend.

Phototropin is also involved in chloroplast movements in relation to light, and participates with another type of blue-light receptor, the plastid pigment **zeaxanthin**, in the light-induced opening of stomata (see Figure 35.8).

Yet another class of blue-light receptors is the **cryptochromes**, which absorb blue and ultraviolet light. These yellow pigments are located primarily in the plant cell nucleus and affect seedling development and flowering. The exact mechanism of cryptochrome action is not yet known. Strong blue light inhibits cell elongation through the action of cryptochromes, although the most rapid responses are mediated by phototropins.

Phytochromes mediate the effects of red and far-red light

Photomorphogenesis refers to a number of physiological and developmental events in plants that are controlled by light. For example:

- A bean seedling germinating below ground has an elongated stem, a pale yellow, folded leaf, and a hook that protects the first leaves (see Figures 37.1 and 37.13)—it is **etiolated**. As the seedling reaches the surface of the soil, it undergoes several light-induced changes: the apical hook straightens, the rudimentary leaves unfold, and chlorophyll is made, so that photosynthesis can begin. Even very dim light will induce these changes.

- Lettuce seeds spread on the soil will germinate only in response to light. Even just a flash of dim light will suffice.
- Adult cocklebur plants flower when they are exposed to long nights. If there is a brief light flash in the middle of the night, they do not flower.

Action spectra of the above processes show that they are induced by red light (650–680 nm). This indicates that plants must have a photoreceptor pigment that absorbs red light and initiates photomorphogenesis.

What is especially remarkable about these red light responses is that *they are reversible by far-red light* (710–740 nm). For example, if lettuce seeds are exposed to brief, alternating periods of red and far-red light in close succession, they respond only to the final exposure. If it is red, they germinate; if it is far-red, they remain dormant (**Figure 37.16**). This reversibility of the effects of red and far-red light regulates many other aspects of plant development, including flowering and seedling growth.

The basis for the effects of red and far-red light resides in the bluish photoreceptor pigment protein in the cytosol of plants called **phytochrome**. Phytochrome exists in two

INVESTIGATINGLIFE

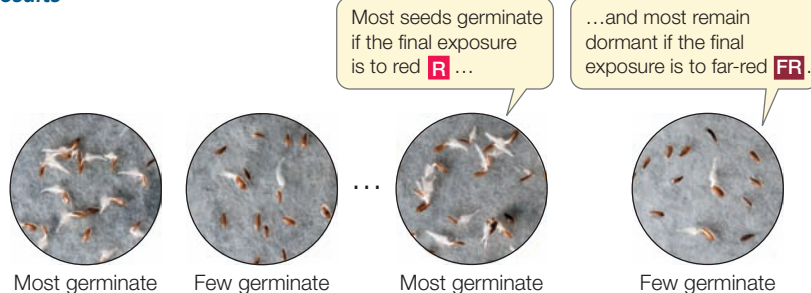

37.16 Sensitivity of Seeds to Red and Far-Red Light Lettuce seeds will germinate if exposed to a brief period of light. An action spectrum indicated that red light was most effective in promoting germination, but far-red light would reverse the stimulation if presented right after the red light flash. Harry Borthwick and his colleagues asked what would be the effect of repeated alternating flashes of red and far-red light. In each case, the final exposure determined the germination response.^a This observation led to the conclusion that a single, photoreversible molecule was involved. That molecule turned out to be phytochrome.

HYPOTHESIS The effects of red and far-red light on lettuce seed germination are mutually reversible.

Method Expose lettuce seeds to alternate periods of red light **R** for 1 minute and far-red light **FR** for 4 minutes.

R **R FR** ... **R FR R FR R FR R** **R FR R FR R FR R FR**

Results

CONCLUSION Red light and far-red light reverse each other's effects.

^aBorthwick, H. A. et al. 1952. *Proceedings of the National Academy of Sciences USA* 38: 662–666.

interconvertible “isoforms,” or states. The molecule undergoes a conformational change upon absorbing light at particular wavelengths. The default or “ground” state, which absorbs principally red light, is called P_r . When P_r absorbs a photon of red light it is converted into P_{fr} . P_{fr} is the active form of phytochrome—the form that triggers important biological processes in various plants.

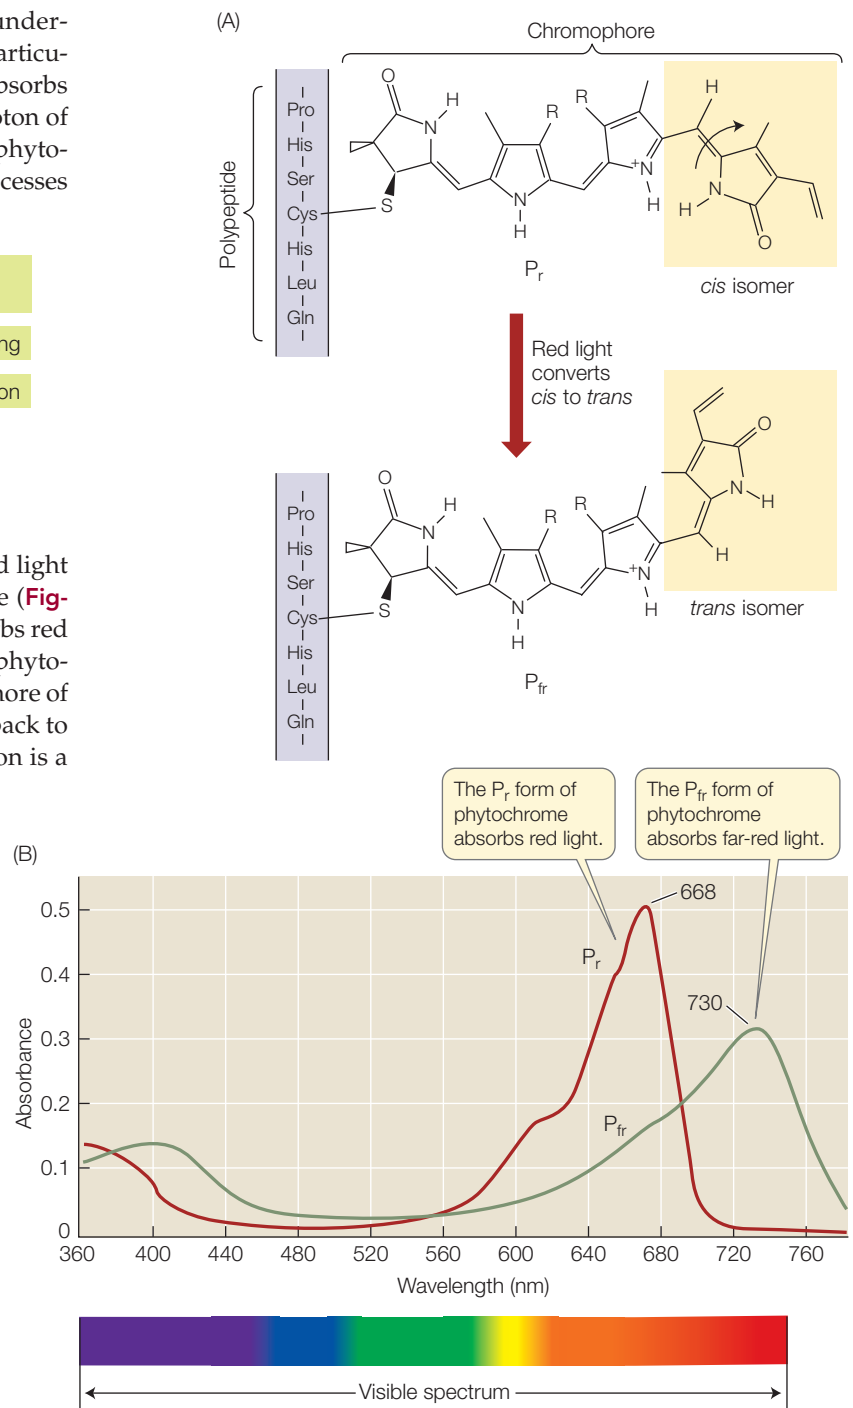

The part of phytochrome that absorbs red and far red light is a covalently attached pigment called a chromophore (Figure 37.17A). The chromophore of P_r preferentially absorbs red light; when it does so, it changes conformation and the phytochrome is converted to the P_{fr} form. When the chromophore of P_{fr} absorbs far red light, the phytochrome is converted back to the P_r form. If you know organic chemistry, this reaction is a familiar *cis-trans* isomerization.

The absorption spectra for P_r and P_{fr} correlate with their action spectra (Figure 37.17B). As we have seen, these processes include seed germination, shoot development after etiolation, and flowering. In *Arabidopsis* there is a gene family that encodes five slightly different phytochromes, each functioning in different photomorphogenic responses.

For a plant in nature, the ratio of red to far-red light determines whether a phytochrome-mediated response will occur. For example, during daylight the ratio is about 1.2:1; because there is more red than far-red light, the P_{fr} form predominates. But for a plant growing in the shade of other plants, the ratio is as low as 0.13:1, and phytochrome is mostly in the P_r form. The low ratio of red to far-red light in the shade results from absorption of red light by chlorophyll in the leaves overhead, so less of the red light gets through to the plants below. Shade-intolerant species respond by stimulating cell elongation in the stem and thus growing taller to escape the shade. Shade cast by other plants also prevents germination of seeds that require red light to germinate (see Figure 37.16). The reflective properties of the soil can also affect the red to far-red ratio—and thus plant behavior. For example, cotton seedlings grow more slowly on soils (such as clay) that reflect more red than far-red light.

Phytochrome stimulates gene transcription

How does phytochrome, or more specifically P_{fr} , work? Phytochrome has two subunits (Figure 37.18), each composed of a protein chain and a chromophore. Gene transcription is stimulated

37.17 Phytochrome Exists in Two Forms Absorption spectra of phytochrome reveal two interconvertible forms. (A) The *cis* and *trans* isomers of phytochrome’s chromophore. (B) The P_r form absorbs red light; the P_{fr} form absorbs far-red light.

when P_r is converted to the P_{fr} isoform. When P_r absorbs red light and the chromophore changes shape (see Figure 37.17A), this leads to a change in the conformation of the protein itself, from the P_r form to the P_{fr} form. Conversion to the P_{fr} form exposes two important regions of the phytochrome protein (see Figure 37.18), both of which affect transcriptional activity:

37.18 Phytochrome Stimulates Gene

Transcription Phytochrome is composed of two polypeptide chains, each with a chromophore. This pair of polypeptides undergoes a conformational change upon absorbing light. When phytochrome absorbs red light, it converts to the P_{fr} form, which activates transcription of phytochrome-responsive genes.

- Exposure of a *nuclear localization sequence* (see Figure 14.19) results in movement of P_{fr} from the cytosol to the nucleus. Once in the nucleus, P_{fr} binds to transcription factors and thereby stimulates expression of genes involved in photomorphogenesis.
- Exposure of a *protein kinase* domain causes P_{fr} protein to phosphorylate itself and other proteins involved in red-light signal transduction, resulting in changes in the activity of transcription factors.

The effect of activating these transcription factors is quite large: in *Arabidopsis*, phytochrome affects an amazing 2,500 genes (10 percent of the entire genome!) by either increasing or decreasing their expression. Some of these genes are related to hormones. For example, when P_{fr} is formed in seed germination, genes for gibberellin synthesis are activated and genes for gibberellin breakdown are repressed. As a result, gibberellins accumulate and seed reserves are mobilized.

Circadian rhythms are entrained by light reception

The timing and duration of biological activities in living organisms are governed in all eukaryotes and some prokaryotes by what is commonly called a “biological clock”—an oscillator within cells that alternates back and forth between two states at roughly 12-hour intervals. The major outward manifestations of this clock are known as **circadian rhythms** (Latin *circa*, “about”; *dies*, “day”). Think of your own life: in all probability you sleep at night and are awake during the day. The circadian rhythms of animals are discussed in Section 53.3. In plants, circadian rhythms influence, for example, the opening (during the day) and closing (at night) of stomata in *Arabidopsis*, and the raising toward the sun

(during the day) and lowering (at night) of leaves in bean plants. From these two examples, it is obvious that circadian rhythms are ecologically useful adaptations, in that they relate the plant’s physiology to its environment.

Two qualities characterize circadian rhythms, as well as other regular biological cycles: the **period** is the length of one cycle, and the **amplitude** is the magnitude of the change over the course of a cycle. The circadian rhythms of plants have several noteworthy characteristics:

- The period of a circadian rhythm is remarkably insensitive to temperature, although lowering the temperature may drastically reduce the amplitude.
- Circadian rhythms are highly persistent; they may continue for days, even in the absence of environmental cues, such as light–dark periods.
- Circadian rhythms can be entrained, within limits, by light–dark cycles that do not exactly correspond to 24 hours. That is, the period of a rhythm can be made to coincide (within limits) with that of the light–dark cycle to which the organism is exposed.

Consider what happens when a person abruptly moves across many time zones: what was the night becomes the day, and gradually the person’s sleep–wakefulness circadian rhythm entrains to the new environmental cues. Similar entrainment occurs in plants adapting to day length as the seasons progress during the year. The action spectrum for plant entrainment indicates that phytochrome (and to a lesser extent, blue-light receptors) is very likely involved. At sundown phytochrome is mostly in the active P_{fr} form. But as the night progresses, P_{fr} gradually gets converted back to the inactive P_r form. By dawn phytochrome is mostly in the P_r state, but as daylight begins,

it rapidly converts to P_{fr} . The switch to the P_{fr} state resets the plant's biological clock. However long the night, the clock is still reset at dawn every day. Thus while the total period measured by the clock is consistent, the clock adjusts to changes in day length over the course of the year.

RECAP 37.4

Light controls several physiological and developmental events in plants, a process called photomorphogenesis. Pigment photoreceptors such as phototropin, cryptochromes, and phytochrome mediate the effects of light on plant growth and development. Phytochrome exists in two interconvertible states; conversion from one state to the other is controlled by the ratio of red to far-red light. Circadian rhythms are influenced by light reception.

- Give the evidence for blue-light receptors in plants. **See pp. 771–772 and Figure 37.15**
- Why does red light affect seed germination differently than far-red light does? **See pp. 772–773 and Figure 37.16**
- What are circadian rhythms, and how are they related to photoreception? **See p. 774**

Photoreceptors also play a regulatory role in flowering. In addition to light, another environmental cue—temperature—regulates flowering. We will examine these topics and others in the next chapter, which focuses on reproduction in flowering plants.

What changes in growth patterns made the new strains of wheat and rice successful?

ANSWER

In normal wheat plants, gibberellins stimulate stem elongation. But in the semi-dwarf plants, a mutation affects the signal transduction mechanism for gibberellins so that the stem cells do not respond to it and growth is reduced. In rice, the mutation is in the gene for an enzyme in the biochemical pathway for the synthesis of gibberellins. Without the hormone, the stem does not elongate. The lives of countless people have been saved by intentional disruptions of hormone signaling.

37.1 How Does Plant Development Proceed?

- As sessile organisms, plants maximize their ability to grow by using meristems, forming new organs, and growing throughout life.
- The environment, photoreceptors, hormones, and the plant's genome all regulate plant development.
- Seed **dormancy**, which has adaptive advantages, is maintained by a variety of mechanisms. In nature, dormancy is broken by, for example, abrasion, fire, leaching, and low temperatures. When dormancy ends and the seed **imbibes** water, it **germinates** and develops into a **seedling**. **Review Figure 37.1, ACTIVITIES 37.1, 37.2**
- Plant hormones differ in structure and physiology from animal hormones. **Review Table 37.1**
- Plants have several hormones, each of which regulates multiple aspects of development. Interactions among these hormones are often complex. **Review Table 37.2**
- **Genetic screens** using the model organism *Arabidopsis thaliana* have contributed greatly to our understanding of signaling in plants. **Review Figure 37.2**

37.2 What Do Gibberellins and Auxin Do?

- Both **gibberellins** and **auxin** can induce growth in plants otherwise genetically destined to be dwarfs. **Review Figure 37.3**
- Gibberellins have many effects that vary among different plants, including cell elongation, fruit ripening, and mobilization of seed storage polymers. **Review Figures 37.3–37.5, ACTIVITY 37.3**

CHAPTER SUMMARY 37

- Auxin was discovered in the context of stem and coleoptile growth, in particular **phototropism**. In the shoot, it is made in the growing tip and transported down to stimulate cell elongation. **Review Figures 37.6, 37.7, ANIMATED TUTORIALS 37.1, 37.2**
- According to the **acid growth hypothesis**, auxin stimulates cell elongation through the release of protons into the cell wall (acidification of the cell wall). **Review Figure 37.10, ANIMATED TUTORIAL 37.3**
- Both auxin and gibberellins act through the breakdown of transcriptional repressors.

37.3 What Are the Effects of Cytokinins, Ethylene, and Brassinosteroids?

- **Cytokinins** are adenine derivatives that promote plant cell division, promote seed germination in some species, inhibit stem elongation, promote lateral swelling of stems and roots, stimulate the growth of axillary buds, promote the expansion of leaf tissue, and delay leaf senescence.
- A balance between auxin and **ethylene** controls leaf abscission. Ethylene promotes senescence and fruit ripening. It indirectly causes the formation of a protective **apical hook** in eudicot seedlings. In stems, it inhibits elongation, promotes lateral swelling, and causes a loss of gravitropic sensitivity.
- Ethylene acts on cells by a protein kinase pathway located in the endoplasmic reticulum. **Review Figure 37.14**
- Dozens of different **brassinosteroids** affect cell elongation, pollen tube elongation, vascular tissue differentiation, and root elongation. These steroids act at a plasma membrane receptor.

continued

37.4

How Do Photoreceptors Participate in Plant Growth Regulation?

- **Phototropins** are blue-light photoreceptors for phototropism and chloroplast movements. **Zeaxanthin** acts in conjunction with the phototropins to mediate the light-induced opening of stomata. **Cryptochromes** are blue-light photoreceptors that control seedling development, stem elongation, and floral initiation.
- **Phytochrome** exists in the cytosol in two interconvertible forms, P_r and P_{fr} . The relative amounts of these two forms are a function of the ratio of red to far-red light. Phytochrome affects seedling growth, flowering, and etiolation. **Review Figure 37.16**

- The phytochrome signal transduction pathway affects transcription in two different ways; the P_{fr} form interacts directly with some transcription factors, and influences transcription indirectly through interactions with protein kinases. **Review Figure 37.18**
- **Circadian rhythms** are activities that occur on a near-24-hour cycle. Light can entrain these activities through photoreceptors such as phytochrome.

CHAPTERREVIEW

REMEMBERING

- Which of the following is *not* an advantage of seed dormancy?
 - It makes the seed more likely to be digested by birds that disperse it.
 - It counters the effects of year-to-year variations in the environment.
 - It increases the likelihood that a seed will germinate in the right place.
 - It favors dispersal of the seed.
 - It may result in germination at a favorable time of year.
- The gibberellins
 - are responsible for phototropism and gravitropism.
 - are gases at room temperature.
 - are produced only by fungi.
 - cause flowering in plants.
 - inhibit the synthesis of digestive enzymes by barley seeds.
- In coleoptile tissue, auxin
 - is transported from base to tip.
 - is transported from tip to base.
 - can be transported toward either the tip or the base, depending on the orientation of the coleoptile with respect to gravity.
 - is transported by simple diffusion, with no preferred direction.
 - is not transported, because auxin is used where it is made.
- Signal transduction for both auxin and gibberellins involves
 - binding of the hormone to a nuclear receptor.
 - degradation of a repressor of gene transcription.
 - production of a small molecule second messenger.
 - light absorption followed by chemical changes.
 - breakdown of the hormone.
- Ethylene
 - causes the triple response in seedlings growing underground.
 - is liquid at room temperature.
 - delays the ripening of fruits.
 - generally promotes stem elongation.
 - inhibits the swelling of stems, in opposition to cytokinin's effects.
- Phytochrome
 - is the only photoreceptor pigment in plants.
 - exists in two forms that are interconvertible by light.
 - is a pigment that is colored red or far-red.
 - is a green-light receptor.
 - is the photoreceptor for phototropism in coleoptiles.

UNDERSTANDING & APPLYING

- Describe the circumstances under which it would be advantageous for a species to have the dormancy of its seeds broken by fire.
- Cocklebur fruits contain two seeds each that are kept dormant by two different mechanisms. Why might having two mechanisms of dormancy be advantageous to cockleburs?
- Supermarkets sell plastic bags that are impregnated with activated charcoal, which binds gases. The bags are designed to keep fruit fresh. How do they work?

ANALYZING & EVALUATING

10. Corn stunt spiroplasma (a bacterium) causes a great reduction in the growth rate of infected corn plants. Diseased plants take on a dwarfed form. Since their appearance is reminiscent of genetically dwarfed corn, you suspect that the bacterium may inhibit the synthesis of gibberellins by corn plants. Describe two experiments you might conduct to test this hypothesis, only one of which should require chemical measurement.

A corn plant infected with corn stunt spiroplasma

11. The semi-dwarf wheat and rice plants that led to the Green Revolution described in the chapter opening have mutations in the signal transduction pathway for gibberellins. You wish to use genetic engineering to make corn plants that are semi-dwarf.
- How would you do a genetic screen to identify the genes in corn involved in gibberellin signaling?
 - Assuming that the signal transduction pathway is similar to that in *Arabidopsis*, what gene would you select for inactivation?
 - Besides short stature, what other effects would you expect for the signal transduction mutant strain? How would you use other hormones to overcome them?

Reproduction in Flowering Plants

CHAPTER OUTLINE

- 38.1** How Do Angiosperms Reproduce Sexually?
- 38.2** What Determines the Transition from the Vegetative to the Flowering State?
- 38.3** How Do Angiosperms Reproduce Asexually?

YOU MAY NOT CONSIDER A BOTANIST specializing in plant reproduction to be “cool,” but Arthur Hemmings, a fictional plant biologist at the famous Kew Botanical Gardens in London, might change your mind. In addition to being a plant biologist, Hemmings is an undercover agent for Britain’s Office of Food Security. Hemmings is the protagonist in the recent novel *Day of the Dandelion* by Paul Pringle. The theft of a packet of seeds from the lab of an Oxford University geneticist, coupled with the disappearance of the scientist and his lab assistant, prompts the government to assign Hemmings to the case. The stolen seeds are unusual and highly valued. The seeds will be a hybrid between corn (*Zea mays*) and its close relative gamagrass (*Tripsacum dactyloides*), having the high grain production and disease-resistance characteristics of modern corn and an ability to reproduce asexually in a method called apomixis (thanks to a gene from gamagrass). The race to find the country (China? Russia?) or company (a multinational corporation that wants to dominate the food supply?) that has stolen the seeds takes the fictional scientist-spy around the world. It is an exciting tale, with a basis in reality because scientists at the U.S. Department of Agriculture have indeed bred a corn-*Tripsacum* hybrid that shows apomixis, although its productivity is low.

As we described in Chapter 12, modern farmers typically plant hybrid corn, created by seed companies from crosses between homozygous inbred strains. The heterozygous offspring of these crosses show hybrid vigor, with valuable characteristics such as high grain production. If a farmer allows these plants to reproduce among themselves, however, the result will be a collection of plants with some homozygosity and some heterozygosity (think of the results from this cross: $AaBbCc \times AaBbCc$), and hybrid vigor will be lost. So crosses

Dandelion This plant can reproduce by forming seeds without sex.

between inbred lines must be done every time hybrid seeds are needed.

Some species of plants, such as dandelions, blackberries, and gamagrass, have genes for apomixis, which prevents meiosis in the cells that form the female gametes during sexual reproduction. Instead of forming haploid egg cells, these plants can form diploid egg cells that don’t need to be fertilized by male gametes. The egg cells go on to form clone diploid offspring: plants that are genetically identical to the mother plant. For these plant species, apomixis provides an evolutionary advantage in that it allows for reproduction without pollination, and for the propagation of well-adapted genotypes. However, a disadvantage is that the genetic variation that results from sexual reproduction is lost.

For the plant breeder, apomixis could be a boon. Apomixis would allow for the rapid propagation of hybrid plants without the need to make crosses and recreate the hybrids every time they are grown. The potential profits are staggering—thus the excitement of *Day of the Dandelion*.

By what genetic mechanism is apomixis brought about?

See answer on p. 794.

38.1

How Do Angiosperms Reproduce Sexually?

Most angiosperms (flowering plants) have evolved to reproduce sexually because this strategy has the selective advantage of producing the genetic diversity that is the raw material for evolution. Sexual reproduction in angiosperms involves mitosis, meiosis, and the alternation of haploid and diploid generations (see Figure 11.15). There are several important differences between sexual reproduction in angiosperms and in vertebrate animals (the latter also discussed in Chapter 43):

- Meiosis in plants produces spores, after which mitosis produces gametes; in animals, meiosis usually produces gametes directly.
- In most plants, there are multicellular diploid (sporophyte) and haploid (gametophyte) life stages (alternation of generations); in animals, there is no multicellular haploid stage.
- In plants, the cells that will form gametes are determined in the adult organism, usually in response to environmental conditions; in animals, the germline cells are determined before birth.

The flower is an angiosperm's structure for sexual reproduction

The plant life cycle typically involves the alternation of haploid and diploid generations (see Chapter 11):

In angiosperms, the plant that we see in nature is a sporophyte, and the male and/or female gametophytes are contained in the flowers (see Section 29.3 for a description of flower parts and floral evolution). A complete flower consists of four concentric groups of organs arising from modified leaves: the carpels, stamens, petals, and sepals.

The parts of the flower are usually borne on a stem tip, and derive from a meristem.

- The carpels are the female sex organs that contain the developing female gametophytes.
- The stamens are the male sex organs that contain the developing male gametophytes.

The differentiation of the meristem into the various organs of the flower is controlled by specific transcription factors (see Figure 19.9).

Most angiosperm species are **hermaphroditic**, and have flowers with both stamens and carpels; such flowers are termed *perfect* (Figure 38.1A). *Imperfect* flowers, by contrast, are those with only male or only female sex organs. Male flowers have stamens but not carpels, and female flowers have carpels but not stamens. Some plants, such as corn, bear both male and female flowers on an individual plant; such species are called **monoecious** (“one house”) (Figure 38.1B). In **dioecious** species, individual plants bear either male-only or female-only flowers; an example is American holly (Figure 38.1C).

Flowering plants have microscopic gametophytes

Figure 38.2 offers a detailed look at the gametophytes central to angiosperm reproduction. The haploid gametophytes—the gamete-producing structures—develop from haploid spores in the flower:

- Each female gametophyte (megagametophyte) is called an **embryo sac**, and it develops inside an ovule. One or more ovules are contained within the ovary, which is the lower part of the carpel.
- Male gametophytes (microgametophytes), which are called **pollen grains**, develop inside the anther, which is part of the stamen.

FEMALE GAMETOPHYTE Of the four haploid megaspores resulting from meiosis, three undergo apoptosis (programmed cell death). The remaining megaspore undergoes three mitotic divisions without cytokinesis, producing eight haploid nuclei, all initially contained within a single cell—three nuclei at one end, three at the other, and two in the middle. Subsequent cell wall formation leads to an elliptical, seven-celled megagametophyte with a total of eight nuclei:

- At one end of the megagametophyte are three small cells: the *egg cell* and two cells called *synergids*. The egg cell is the female gamete, and the synergids participate in fertilization by attracting the pollen tube. The pollen tube enters one of the synergids before the sperm cells are released for fertilization.
- At the opposite end of the megagametophyte are three antipodal cells, which eventually degenerate.
- In the large central cell are two **polar nuclei**.

The megagametophyte, or embryo sac, is the entire seven-cell, eight-nucleus structure.

(A) Perfect: lily (*Lilium* sp.)(C) Imperfect dioecious: American holly (*Ilex opaca*)

Male flower with stamens

Female flower with carpels

(B) Imperfect monoecious: corn

38.1 Perfect and Imperfect Flowers (A) A lily is an example of a perfect flower, meaning one that has both male and female sex organs. (B) Imperfect flowers are either male or female. Corn is a monoecious species: both types of imperfect flowers are borne on the same plant. (C) American holly is a dioecious species; some American holly plants bear male imperfect flowers whereas others bear female imperfect flowers.

MALE GAMETOPHYTE The four haploid products of meiosis (the microspores) each develop a cell wall and undergo a single mitotic division, producing four two-celled pollen grains that are released into the environment. The two cells in a pollen grain have different roles:

- After pollination (see below) the generative cell divides by mitosis to form two sperm cells that participate in fertilization.
- The tube cell forms the elongating pollen tube that delivers the sperm to the embryo sac.

These events occur after the pollen grain is transferred to a stigma (part of the female reproductive organ)—a process called **pollination**.

Pollination in the absence of water is an evolutionary adaptation

As Chapter 28 described, the union of gametes in aquatic plants is accomplished in the water. Fertilization of mosses and ferns also requires at least a film of water for the movement of gametes. While there are mechanisms to ensure that fertilization occurs if and when the two gametes meet, fertilization is clearly a low-probability event. The evolution of pollen made it possible

for male gametes to reach the female gametophyte without an aqueous conduit.

In the first seed plants, wind was the primary vehicle by which pollen reached its destination, and the majority of gymnosperms are wind-pollinated today. Wind-pollinated flowers have sticky or featherlike stigmas, and they produce pollen grains in great numbers.

Pollen transport by wind is, however, a relatively chancy means of achieving pollination, explaining why about 90 percent of all angiosperms still rely on animals—including insects, birds, and bats—for pollen transport. Pollen transport by animals greatly increases the probability that pollen will get to the female gametophyte. As described in Sections 29.3 and 56.3, the structures of flowers have coevolved with their animal pollinators to enhance the plants' chances of successful pollination. Suitably pigmented, shaped, and scented flowers attract the pollinating animal, resulting in a pollen transfer from flower to flower within the same plant species (**Figure 38.3**).

A pollen tube delivers sperm cells to the embryo sac

When a functional pollen grain lands on the stigma of a compatible stigma, it germinates. A key event is water uptake

38.2 Sexual Reproduction in Angiosperms The embryo sac is the female gametophyte; the pollen grain is the male gametophyte. The male and female cells meet and fuse within the embryo sac. Angiosperms have double fertilization, in which a zygote and an endosperm form from separate fusion events. The zygote forms by the fusion of one sperm cell with the egg cell. The endosperm forms

after the other sperm cell fuses with the central cell, which contains two nuclei. The three nuclei fuse, forming a triploid cell.

Sexual Reproduction in Angiosperms
Life10e.com/ac38.1

38.3 Flower and Pollinator

Some flowers, such as these *Cavendishia* sp. flowers, have red pigments and a shape that attracts certain birds.

by pollen from the stigma: pollen loses most of its water as it matures. Germination involves the development of a **pollen tube** (Figure 38.4). The pollen tube either traverses the spongy tissue of the style (part of the carpel; see Figure 38.2) or, if the style is hollow, grows on the inner surface of the style until it reaches an ovule. The growth rate of the pollen tube varies greatly among species, but it can be as fast as 3 millimeters an hour.

The growth of the pollen tube is guided in part by a chemical signal in the form of a small protein produced by the synergids within the ovule. If one synergid is destroyed, the ovule still attracts pollen tubes, but destruction of both synergids renders the ovule unable to attract pollen tubes, and fertilization does not occur. The attractant appears to be species-specific: in some cases, isolated female gametophytes attract only pollen tubes of the same species.

Many flowering plants control pollination or pollen tube growth to prevent inbreeding

You may recall from discussions of Mendel's work (see Section 12.1) that some plants can reproduce sexually by both cross-pollination and self-pollination. Self-pollination increases the chances of successful pollination but leads to homozygosity, which reduces genetic diversity. Because diversity is the raw material of evolution by natural selection, homozygosity can be selectively disadvantageous. Most plants have evolved mechanisms that prevent self-fertilization. A multitude of strategies exist (for example, see Figure 29.13). Two primary means to prevent self-fertilization are (1) physical separation of male and female gametophytes and (2) genetic self-incompatibility.

SEPARATION OF MALE AND FEMALE GAMETOPHYTES Self-fertilization is prevented in dioecious species, which bear only male or female flowers on a particular plant. Pollination in

38.4 Pollen Tubes Begin to Grow Staining pollen with a fluorescent dye allows it to be seen through a fluorescence microscope. These pollen grains have landed on the stigmas of a crocus.

Go to Media Clip 38.1

Pollen Germination in Real Time

Life10e.com/mc38.1

dioecious species is accomplished only when one plant pollinates another. In monoecious plants, which bear both male and female flowers on the same plant, the physical separation of the male and female flowers is often sufficient to prevent self-fertilization. Some monoecious species prevent self-fertilization by staggering the development of male and female flowers so they do not bloom at the same time, making these species functionally dioecious.

GENETIC SELF-INCOMPATIBILITY A pollen grain that lands on the stigma of the same plant will fertilize the female gamete *only if the plant is self-compatible*, meaning capable of self-pollination. To prevent self-fertilization, many plants are genetically self-incompatible. **Self-incompatibility** depends on the ability of a plant to determine whether pollen is genetically similar or genetically different from itself. Rejection of “same-as-self” pollen prevents self-fertilization. How does it occur?

Self-incompatibility in plants is controlled by a cluster of tightly linked genes called the *S* locus (for self-incompatibility). The *S* locus encodes proteins in the pollen and style that interact during the recognition process. A self-incompatible species typically has many alleles of the *S* locus. The pollen phenotype may be determined by its own haploid genotype or by the diploid genotype of its parent plant. In either case, if the pollen expresses an allele that matches either of the alleles expressed in the recipient pistil, the pollen is rejected. Depending on the type of self-incompatibility system, the rejected pollen either fails to germinate or is prevented from growing through the style (Figure 38.5); either way, self-fertilization is prevented.

38.5 Self-Incompatibility In a self-incompatible plant, pollen is rejected if it expresses an *S* allele that matches one of the *S* alleles of the stigma and style. Self pollen may (A) fail to germinate or (B) its pollen tube may die before reaching an ovule. In either case, the egg cannot be fertilized by a sperm from the same plant.

Angiosperms perform double fertilization

In most angiosperm species, the mature pollen grain consists of two cells: a large tube cell enclosing a much smaller generative cell. When a compatible pollen grain lands on the stigma of a plant of the same species, it germinates, and the pollen tube grows through the style tissue to the embryo sac. During this process, the generative cell undergoes one mitotic division and cytokinesis to produce two haploid **sperm cells** (Figure 38.6, steps 1 and 2).

Two fertilization events now occur. One of the two synergids degenerates when the pollen tube arrives and the two sperm cells are released into its remains. (Figure 38.6, step 3). Each sperm cell then fuses with a different cell of the embryo sac (Figure 38.6, steps 4 and 5). One sperm cell fuses with the egg cell, and the two nuclei fuse, producing the diploid zygote. The other sperm cell fuses with the central cell, and its nucleus fuses with the two polar nuclei, forming a **triploid ($3n$) cell**. Immediately after fertilization the triploid nucleus undergoes rapid mitotic divisions to form a specialized nutritive tissue, the **endosperm**. In most species the endosperm nucleus initially divides without cytokinesis, forming a large, multinucleate cell, and cell walls form later between the nuclei. After the endosperm begins developing, the zygote undergoes mitotic division to form the new sporophyte embryo. The developing embryo uses the endosperm tissue as a source of nutrients, energy, and carbon-based anabolic building blocks. In some cases the endosperm persists until germination and is used as a source of nutrients by the developing seedling. This source of nutrients is important because the seedling often begins its development underground and cannot perform photosynthesis right away.

The remaining cells of the male and female gametophytes—the antipodal cells, the remaining synergid, and the pollen tube nucleus—degenerate as the embryo begins to develop.

Double fertilization is so named because it involves two cell fusion events:

- One sperm cell fuses with the egg cell.
- The other sperm cell fuses with the central cell.

The fusion of a sperm cell with the central cell to form the triploid endosperm nucleus is one of the defining characteristics of angiosperms.

Go to Animated Tutorial 38.1
Double Fertilization
Life10e.com/at38.1

38.6 Double Fertilization Two sperm are involved in two cell fusion events, hence the term “double fertilization.” One sperm is involved in the formation of the diploid zygote, and the other results in the formation of the triploid endosperm cell that divides to form endosperm. Double fertilization is a characteristic feature of angiosperm reproduction.

5 The other sperm cell fuses with the central cell, then the three nuclei combine, forming a triploid ($3n$) nucleus.

1 Initially the pollen tube consists of two haploid cells, the generative cell and the tube cell.

2 The generative cell divides mitotically, producing two haploid sperm cells. One synergid cell degenerates when the pollen tube arrives.

3 The sperm cells are released from the pollen tube.

4 One sperm cell fertilizes the egg cell, forming the zygote, the first cell of the $2n$ sporophyte generation.

Embryos develop within seeds contained in fruits

Fertilization initiates the highly coordinated growth and development of the embryo, endosperm, integuments, and carpel. The integuments—protective tissue layers surrounding the ovule—develop into the seed coat, and the ovary wall becomes the outer layers of the fruit that encloses the seed (see Figure 38.2).

In Chapter 37 we described the events in plant embryonic development and its hormonal control. As seeds develop, they prepare for dispersal and dormancy by losing up to 95 percent of their water content. You can see this desiccation by comparing corn grains (e.g., popcorn) with ripe corn from the cob or a can. A dry seed is still alive; it has protective proteins that keep its cells in a viscous state.

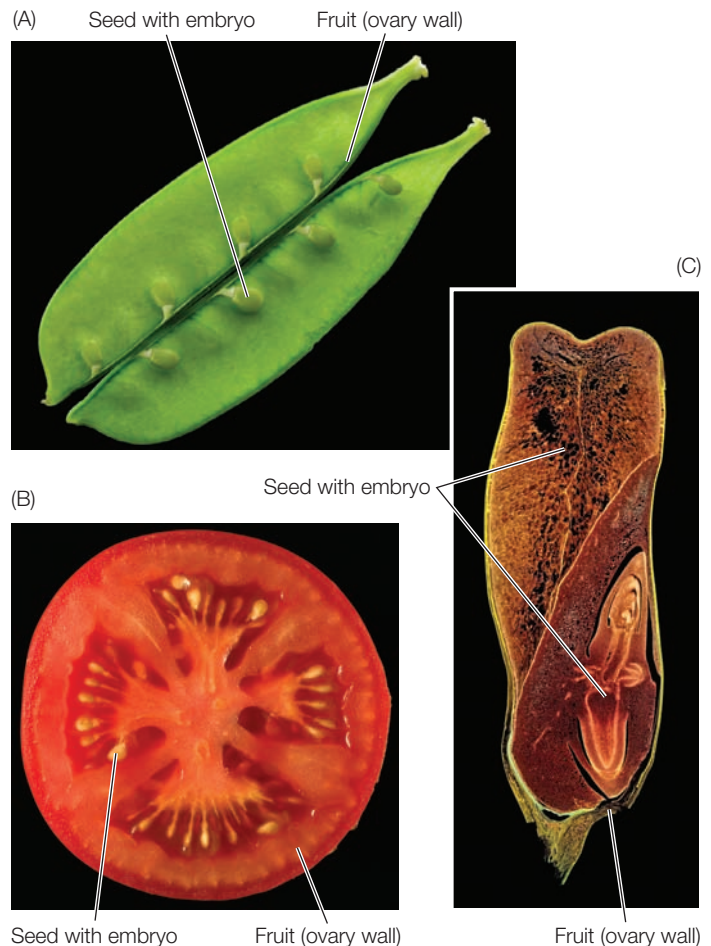

In angiosperms, the ovary—together with the seeds it contains—develops into a fruit after fertilization has occurred. Fruits have two main functions:

- They protect the seed from damage by animals and infection by microbial pathogens.
- They aid in seed dispersal.

A **fruit** may consist of only the mature ovary and seeds, or it may include other parts of the flower. Some species produce fleshy, edible fruits, such as peaches and tomatoes, whereas the fruits of other species are dry or inedible (Figure 38.7).

The diverse forms of fruits reflect the varied strategies plants use to disperse their progeny. Because plants cannot move, their progeny need some mechanism for separating themselves from their parents. Wide dispersal of progeny may not always be advantageous, however. If a plant has successfully grown and reproduced, its location is likely to be favorable for the next generation too. Some offspring do indeed stay near their parents. This is the case in many tree species, whose seeds simply fall to the ground. However, this strategy has several potential disadvantages. If the species is a perennial, the offspring that germinate near their parents will be competing with their parents for resources, which may be too limited to support a dense population. Furthermore, even though local conditions were good enough for the parent to produce at least some seeds, there is no guarantee that conditions will still be good the next year, or that they won't be better elsewhere. Thus in many cases seed dispersal is vital to a species' survival.

Many fruits help disperse seeds over substantial distances, increasing the probability that at least a few of the seeds will find suitable conditions for germination and growth to sexual maturity. Some wind-dispersed seeds have fruits with "wings," like those of the familiar maple. In other cases, the fruits and seeds are tiny, and they include feathery structures, such as this thistle:

38.7 Angiosperm Fruits There are a variety of fruits, but all have seed containing the embryo, surrounded by a fruit that comes from the wall of the ovary. (A) Garden pea. (B) Tomato. (C) Corn.

Other fruits, such as these burs, attach themselves to animals (or to your clothes and shoes):

Water disperses some fruits; coconuts have been known to float thousands of miles between islands. Seeds swallowed whole by an animal along with fruits such as berries travel through the animal's digestive tract and are deposited some distance from the parent plant.

Biologists are beginning to understand the relationships between seed development (from ovules) and fruit development (from carpels). Some seedless fruits, such as varieties of

watermelons and grapes, develop when fertilization occurs but the embryo then aborts. In other cases, such as bananas and pineapples, the fruit develops without fertilization. In most cases, however, fruit development does not occur in the absence of fertilization. Several years ago a farmer in Spain who grows sugar apples (*Annona squamosa*) noticed a seedless fruit and brought it to the attention of scientists. A single gene was subsequently identified whose mutated form results in this seedless phenotype. The wild-type version of this gene encodes a transcription factor important to the development of the outer tissues of the ovule. The gene is present in the genomes of all angiosperms examined. In the future, therefore, it may be possible to produce other seedless fruits by engineering mutations in this gene.

Seed development is under hormonal control

Chapter 37 described the role of the gibberellin hormones in the mobilization of stored macromolecules in the seed endosperm during germination. The development of seeds is under the control of a different hormone, **abscisic acid (ABA)**. (Unfortunately, its name is misleading, because it does not directly control leaf abscission.) Most plant tissues make ABA, and like other plant hormones, it has multiple effects (see Table 37.2). For example, ABA plays a role in stomatal closing under water stress conditions (see Section 35.3). During early seed development the ABA level is low, and it rises as the seed matures. This increase stimulates the endosperm to synthesize seed storage proteins. It also stimulates the synthesis of proteins that prevent cell death as the seeds dry.

ABA also keeps the developing seed from germinating on the plant before it dries. Premature germination, termed **vivipary**, is undesirable in seed crops (such as wheat) because the grain is damaged if it starts to sprout. Viviparous seedlings are also unlikely to survive if they remain attached to the parent plant and are unable to establish themselves in the soil. Mutants of corn that are insensitive to ABA have viviparous seeds, indicating the importance of ABA in preventing precocious germination.

The general effect of ABA in preventing germination extends to seed dormancy. Seeds stay dormant if their ABA levels are high and germinate when the levels go down. This usually occurs as dormancy is broken.

RECAP 38.1

Flowers contain the organs for sexual reproduction in angiosperms. Plants that use pollen for reproduction have several selective advantages, among them the ability to accomplish fertilization without water. After fertilization, the flower develops into seed(s) and fruit. The selective advantages of seeds and fruits include long-term viability and multiple modes of dispersal.

- What are the relationships between an ovule and an ovary, and between a fruit and a seed? [See p. 779 and Figure 38.2](#)
- How do plants prevent self-pollination? [See p. 782 and Figure 38.5](#)
- Describe the roles of the two sperm cells in double fertilization. [See p. 783 and Figure 38.6](#)
- How is plant development controlled by the hormone abscisic acid? [See p. 785](#)

We have now traced the sexual life cycle of angiosperms from the flower to the gametophytes, pollination, fertilization, and the dispersal of seeds. We discussed seed germination and seedling development in Chapter 37, and indeterminate, vegetative plant growth in Chapter 34. The next section will cover the rest of the angiosperm life cycle—the transition from the vegetative to the flowering state—and how this transition is regulated.

38.2 What Determines the Transition from the Vegetative to the Flowering State?

Flowering is one of the major events in a plant's life. Flowering requires a reallocation of energy and materials away from making more plant parts (vegetative growth) to making flowers and gametes (reproductive growth). Once a plant is old enough, it can respond to internal or external signals to initiate reproduction. Flowering can happen right at maturity as part of a predetermined developmental program (as in a dandelion plant in the summer) or in response to environmental cues such as light or temperature (as with most ornamental flowers).

Plants fall into three categories depending on when they mature and initiate flowering, and what happens after they flower:

- **Annuals** complete their lives in one year. This class includes many crops important to the human diet, such as corn, wheat, rice, and soybean. When the environment is suitable, these plants grow rapidly, with little or no secondary growth. After flowering, they use most of their materials and energy to develop seeds and fruits, and the rest of the plant withers away.
- **Biennials** take 2 years to complete their lives. They are much less common than annuals and include carrots, cabbage, and onions. Typically, biennials produce only vegetative growth during the first year and store carbohydrates in underground roots (carrot) and stems (onion). In the second year they use most of the stored carbohydrates to produce flowers and seeds rather than vegetative growth, and the plant dies after seeds form.
- **Perennials** live 3 or more—sometimes many more—years. Maple trees can live up to 400 years. Perennials include many trees and shrubs, as well as wildflowers. Typically these plants flower every year but stay alive and keep growing for another season; the reproductive cycle repeats each year. However, some perennials (e.g., century plant) grow vegetatively for many years, flower once, and die.

No matter what type of life cycle they have, angiosperms all make the transition to flowering. This transition entails significant developmental changes, to which we now turn.

Shoot apical meristems can become inflorescence meristems

The first visible sign of a transition to the flowering state may be a change in one or more apical meristems in the shoot

38.8 Flowering and the Apical Meristem A vegetative apical meristem (A) grows without producing flowers. Once the transition to the flowering state is made (B), inflorescence meristems give rise to bracts and to floral meristems (C), which become the flowers.

system. As described in Chapter 34, meristems have a pool of undetermined cells. During vegetative growth, a shoot apical meristem continually produces leaves, axillary buds, and stem tissues (**Figure 38.8A**) in a kind of unrestricted growth called *indeterminate growth* (see Section 34.3).

Flowers may appear singly or in an orderly cluster that constitutes an **inflorescence**. If a vegetative apical meristem becomes an **inflorescence meristem**, it ceases production of leaves and axillary buds and produces other structures: smaller leafy structures called bracts, as well as new meristems in the angles between the bracts and the stem (**Figure 38.8B**). These new meristems may also be inflorescence meristems, or they

may be **floral meristems**, each of which gives rise to a flower.

Each floral meristem typically produces four consecutive whorls or spirals of organs—the sepals, petals, stamens, and carpels discussed earlier in the chapter—separated by very short internodes, keeping the flower compact (**Figure 38.8C**). In contrast to vegetative apical meristems and some inflorescence meristems, floral meristems are responsible for *determinate growth*—growth of limited duration.

A cascade of gene expression leads to flowering

The genes that determine the transition from shoot apical meristems to inflorescence meristems and from inflorescence meristems to floral meristems have been studied in model organisms such as *Arabidopsis*.

MERISTEM IDENTITY GENES Expression of two **meristem identity genes** initiates a cascade of further gene expression that leads to flower formation. These genes encode the transcription factors *LEAFY* and *APETALA1*, which together are necessary and sufficient for determining the transition to flowering. Evidence for the roles of these factors comes from both genetic and plant transformation experiments. For example, a mutant allele of the *APETALA1* gene leads to continued vegetative growth, even if conditions are suitable for flowering. However, if the wild-type *APETALA1* gene is coupled with a constitutive (always on) promoter and used to transform *Arabidopsis* plants, the plants will flower prematurely, regardless of environmental conditions. This is powerful evidence that *APETALA1* plays a role in switching meristem cells from a vegetative to a reproductive fate (see **Figure 38.8B**).

FLORAL ORGAN IDENTITY GENES The products of the meristem identity genes trigger the expression of **floral organ identity genes**. As described in Section 19.4, these genes work in concert to specify the successive whorls of the flower (see **Figure 19.9**). The floral organ identity genes encode transcription factors that determine whether cells in the floral meristem will be sepals, petals, stamens, or carpels. For example, *AGAMOUS* is a class C gene that causes florally determined cells to form stamens and carpels.

Depending on the species, plants initiate these gene expression changes, and the events that follow, in response to either internal or external cues. The most well studied external cues are photoperiod (day length) and temperature. We will begin with photoperiod.

38.9 Mammoth Plant Wild-type tobacco (left) is much smaller than the Maryland Mammoth mutant of the same age (right), which does not respond to an environmental cue to stop growing and flower.

Photoperiodic cues can initiate flowering

The study of how light affects the transition to flowering began with two observations in the early twentieth century:

- Normally, tobacco grows to about 1.5 meters tall before flowering in the summer, but a variety called Maryland Mammoth grows to 5 meters (Figure 38.9). Farmers in Virginia were frustrated because they could not easily get seeds from this luxuriant plant for successive crops. Instead of flowering, it continued to grow until the late fall frost killed it.
- Because of improvements in agricultural techniques, soybean yields became so great that it was hard for farmers to harvest all the plants at once. Hoping to stagger the harvests, farmers tried planting the seeds in groups several weeks apart, but all resulting plants nevertheless formed flowers and seeds at the same time.

The explanation for both of these observations was the same: the signal that set the plants' shoot apical meristems on the path to flowering was the length of daylight, or **photoperiod**. When soybeans experience days of a certain length, they flower, regardless of how "old" they are. Maryland Mammoth tobacco *can* flower, but it doesn't do so in Virginia because it dies when the weather there gets cold. When the plant is grown in a greenhouse to prevent freezing, however, it flowers in December, when the days are short. Maryland Mammoth is now grown commercially in Florida.

Scientists used greenhouse experiments to measure the day length required for different plant species to flower. Maryland Mammoth tobacco did not flower if exposed to more than 14

hours of light per day; flowering was only initiated once day length became shorter than 14 hours, as it does in December. Other plants (such as soybeans and henbane) flowered only when the days were long (Figure 38.10). Control of an organism's responses by the length of day or night is called **photoperiodism**.

Plants vary in their responses to photoperiodic cues

Plants that flower in response to photoperiodic stimuli fall into two main classes:

- **Short-day plants (SDPs)** flower only when the day is shorter than a critical maximum. They include poinsettias and chrysanthemums, as well as Maryland Mammoth tobacco. Thus, for example, we see chrysanthemums in nurseries in the fall and poinsettias in winter.
- **Long-day plants (LDPs)** flower only when the day is longer than a critical minimum. Spinach and clover are examples of LDPs. For example, spinach tends to flower in the summer, so it is normally planted in early spring.

While there are variations on these two patterns, photoperiodic control of flowering serves an important role: it synchronizes the flowering of plants of the same species in a local population, and this promotes cross-pollination and successful reproduction.

38.10 Day Length and Flowering Flowering of Maryland Mammoth tobacco is initiated when the days become shorter than a critical length. Maryland Mammoth tobacco is thus called a short-day plant. Henbane, a long-day plant, shows an inverse pattern of flowering.

38.11 Night Length and Flowering Greenhouse experiments using cocklebur, a short-day plant, showed that night length, not day length, is the environmental cue that initiates flowering.

Night length is a key photoperiodic cue that determines flowering

The terms “short-day plant” and “long-day plant” imply that *day length* is the environmental cue that triggers flowering. Actually, the important cue is *night length*, as a series of greenhouse experiments confirmed (**Figure 38.11**). In a greenhouse, the overall length of a day or night can be varied, irrespective of the 24-hour natural cycle. For example, if cocklebur, an SDP, is exposed to several long periods of light (16 hours each), it will still flower as long as the dark period between them is 9 hours or longer. This 9-hour inductive dark period also induces flowering even if the light period varies from 8 hours to 12 hours.

Biologists noticed that when the inductive dark period was interrupted by a brief period of light, the flowering signal generated by the long night disappeared. It took several days of long nights for the plant to recover and initiate flowering. Interrupting the day with a dark period had no effect on flowering. A clue as to what occurred in the plant when the flash of light was given came when biologists determined the action spectrum for the wavelengths of light that were effective. As with lettuce seed germination (see Figure 37.16), red light was most effective at breaking the “night” stimulus, and its effect was reversible by far-red light (**Figure 38.12**). Later, the photoreceptor involved was identified as a phytochrome.

One way that plants sense night length is through phytochrome activity. As explained in Section 37.4, during the day there is more light in the red than in the far-red range, and the inactive P_r isoform of phytochrome is converted to the active P_{fr} isoform. At night there is a gradual, spontaneous conversion of this P_{fr} back to P_r , so at the end of the night the phytochrome is predominantly in its inactive form. But a short burst of red light in the middle of the night will disrupt this rhythm by converting the P_r to P_{fr} again.

INVESTIGATINGLIFE

38.12 Interrupting the Night Knowing that plants measure night duration, the question became whether the dark hours to which a plant is exposed must be continuous. Using SDPs and LDPs as test subjects, Karl Hamner and James Bonner demonstrated that this was the case by interrupting the night with short bursts of light. Sterling Hendricks and William Siegelman repeated the experiments using light of different wavelengths to gain information about the photoreceptor involved.^a

HYPOTHESIS Red light participates in the photoperiodic timing mechanism.

Method Grow plants under short-day conditions, but interrupt the night with light of different wavelengths.

Short-day plants	Light/dark combinations	Long-day plants
Flowering		No flowering

Results

No flowering		Flowering
Flowering		No flowering
Flowering		No flowering
No flowering		Flowering
Flowering		No flowering

CONCLUSION When plants are exposed to red (R) and far-red (FR) light in alternation, the final treatment determines the effect. Phytochrome is the photoreceptor.

The Effect of Interrupted Days and Nights
Life10e.com/at38.2

As described in Section 37.4, phytochromes and a blue-light receptor function together to “entrain” a circadian rhythm in plants. These photoreceptors cycle through active and inactive phases over repeated 24-hour periods, and in doing so they activate signaling pathways that result in regular cycles in the expression of specific genes. One gene whose expression follows a circadian rhythm is *CONSTANS* (*CO*), which encodes a transcriptional regulator that controls the expression of flowering genes.

Experiments with *Arabidopsis*, an LDP, have shown that photoperiodic flowering times are determined by interactions between photoreceptors and the *CO* protein. *CO* gene expression goes through regular 24-hour cycles with peak expression late in the day. On long days, this occurs in daylight, late in the afternoon, but on short days the peak expression occurs after dark. On long days, the active forms of phytochrome and a blue-light receptor activate pathways that stabilize the *CO* protein, which promotes flowering. This process does not occur on short days.

The flowering stimulus originates in a leaf

Early experiments indicated that reception of the photoperiodic stimulus occurs within the leaf. For example, in the LDP spinach, flowering occurred if the leaves were exposed to long-day periods of light, while the shoot apical meristem was masked to simulate short days. Flowering could *not* occur when the

INVESTIGATING LIFE

38.13 The Flowering Signal Moves from Leaf to Bud The receptors for photoperiod are in the leaf, but the transition to flowering occurs in the shoot apical meristem. To investigate whether there is a diffusible substance that travels from leaf to bud, Hamner and Bonner exposed only the leaf to the photoperiodic stimulus^a

HYPOTHESIS The leaves measure the photoperiod.

Method Grow cocklebur plants (short-day) under long days and short nights. Mask a leaf on some plants and see if flowering occurs.

Results If even one leaf is masked for part of the day—thus shifting that leaf to short days and long nights—the plant will flower.

CONCLUSION The leaves measure the photoperiod. Therefore some signal must move from the induced leaf to the flowering parts of the plant.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATING LIFE** figures.

^aHamner, K. C. and J. Bonner. 1938. *Botanical Gazette* 100: 388–431.

leaves were masked to simulate short days, while the bud was exposed to long-day periods of light.

These “masking” experiments were extended to SDP plants as well (Figure 38.13). Because the receptor of the stimulus (in the leaf) is physically separated from the tissue on which the stimulus acts (the bud meristem), the inference can be drawn that a systemic signal travels from the leaf through the plant’s tissues to the bud meristem. Other evidence that a diffusible chemical travels from the leaf to the bud meristem signal includes the following:

- If a photoperiodically induced leaf is immediately removed from a plant after the inductive dark period, the plant does not flower. If, however, the induced leaf remains attached to the plant for several hours, the plant will flower. This

WORKING WITH DATA:

The Flowering Signal Moves from Leaf to Bud

Original Paper

Hamner, K. C. and J. Bonner. 1938. Photoperiodism in relation to hormones as factors in floral initiation and development. *Botanical Gazette* 100: 388–431.

Analyze the Data

In 1938 Karl Hamner at the University of Chicago was working on the role of plant nutrition in flowering. The plant he studied, cocklebur, is a short-day plant that requires 16 hours of darkness to flower. When the plants were kept in 6 hours darkness (16 hours light) in a greenhouse, they did not flower. One day Hamner came to the lab to find all the plants flowering. It turned out that there had been a power outage, and the plants had received a single inductive short day (long night). Realizing that this provided a simple system to study flowering, Hamner invited a major scientist in the field, James Bonner from Caltech, to join him for the summer. The two biologists carried out a series of experiments using the single inductive period that showed that flowering is induced by night length as opposed to day length (see Figure 38.12) and that the flowering signal is received by the leaf from which it travels to a bud, inducing flowering. A Russian plant physiologist, Mikhail Chailakhyan, named this signal florigen. More recently, the molecular nature of this signal was described.

QUESTION 1

Intact cocklebur plants (6) or plants with their leaves removed (6) were placed in the inductive (short day) photoperiod. After 14 days, the researchers obtained the results in **TABLE A**. Based on these data, which part of the plant senses the photoperiod?

QUESTION 2

Cocklebur plants were treated so that a single leaf was exposed to the inductive (short) photoperiod while the rest of the plant received the long photoperiod. After 18 days, the results were as shown in **TABLE B**. What do these results indicate about the location of the receptor for flowering?

QUESTION 3

What do the data tell you about the signal generated by the plant in response to photoperiod and that induces flowering in the apical meristem?

TABLE A

Treatment	Number of plants that flowered
No inductive period, intact plant	0
Inductive period, intact plant	6
Inductive period, leaves removed	0

TABLE B

Treatment	Number of plants	Result
Untreated	6	Vegetative
Treated, one leaf	32	Flower

38.14 Florigen and Its Molecular Biology

Florigen is a protein (FT) made in the phloem companion cells. It travels in the sieve elements from the leaf to the bud meristem. There, florigen combines with another protein to stimulate transcription of genes that initiate flower formation.

result suggests that something is synthesized in the leaf in response to the inductive dark period, and then moves out of the leaf to induce flowering.

- If two cocklebur plants are grafted together, and if only one of the plants is exposed to inductive long nights, both plants flower.
- In several species, if an induced leaf from one species is grafted onto another, noninduced plant of a different species, the recipient plant flowers.

The transmissible signal was given a name, **florigen** ("flower inducing"), in 1937, but its chemical nature has been described only in the past decade.

Florigen is a small protein

The characterization of florigen was made possible by genetic and molecular studies of the model plant *Arabidopsis*. Three genes are involved in the signaling response for flowering (**Figure 38.14**).

- **FT (FLOWERING LOCUS T)** codes for florigen. FT is a small (20 kDa) protein that can travel through plasmodesmata. FT is synthesized in the phloem companion cells of the leaf and then diffuses into the adjacent sieve elements. It then is carried through the phloem to the apical meristem. If the FT gene is coupled to an active promoter and expressed at high levels in the shoot meristem, flowering is induced even in the absence of an appropriate photoperiodic stimulus.
- **CO (CONSTANS)** codes for the transcription factor that activates the synthesis of FT. As described above, CO expression follows a circadian rhythm, and stabilization of the CO protein by photoreceptors allows it to function. Like FT, CO is expressed in leaf companion cells. If CO is experimentally overexpressed in the leaf, flowering is induced. However, if CO is overexpressed in the apical meristem, flowering is not induced, indicating that CO functions in the leaf.
- **FD (FLOWERING LOCUS D)** encodes a protein that binds to FT protein when it arrives in the apical meristem. The FD

protein is a transcription factor that, when bound to FT, activates promoters for meristem identity genes, such as *APETALA1* (see **Figure 38.8**). The expression of FD primes meristem cells to change from a vegetative fate to a reproductive fate once FT arrives.

Before FT was isolated, grafting experiments indicated that many different plant species could be induced to flower by the same chemical signal. Results of molecular experiments confirmed that the FT gene is involved in photoperiod signaling in many species:

- Transgenic plants (e.g., tobacco and tomato) that express the *Arabidopsis* FT gene at high levels flower regardless of day length.
- Transgenic *Arabidopsis* plants that express FT homologs from other plants (e.g., rice and tomato) flower regardless of day length.

While the molecular basis of the action of florigen has been elucidated, commercial applications of this knowledge have been harder to realize. It was hoped that florigen might be a very small molecule, like an auxin or gibberellin, that could be sprayed on economically important plants to induce flowering at will. The fact that florigen is a protein that cannot readily enter cells from the outside environment makes the development of commercial florigen treatments unlikely.

We have considered the photoperiodic regulation of flowering, from photoreceptors in the leaf to florigen that travels from the induced leaf to the sites of flower formation. In some plants, however, flowering is induced by other stimuli. These additional stimuli can function with photoperiodism or independently of it.

Flowering can be induced by temperature or gibberellin

Whereas some plants use the environmental cue of day length to induce flowering, other plants use different mechanisms. These include temperature (another environmental cue) and gibberellin (an internal, hormonal cue).

38.15 Vernalization A genetic strain of *Arabidopsis* (winter-annual *Arabidopsis*) requires vernalization for flowering. Without it, the plant is large and vegetative (left), but with the cold period it is smaller and flowers (right).

TEMPERATURE In some plant species, notably certain cereal grains, the environmental signal for flowering is cold temperature, a phenomenon called **vernalization** (Latin *vernus*, “spring”). In both wheat and rye, we distinguish two categories of flowering behavior. Spring wheat, for example, is a typical annual plant: it is sown in the spring and flowers in the same year. Winter wheat is sown in the fall, grows to a seedling, overwinters (often covered by snow), and flowers the following summer. If winter wheat is not exposed to cold in its first year, it will not flower normally the next year.

How vernalization leads to flowering has been elucidated using model organisms such as *Arabidopsis*. In strains of *Arabidopsis* that require vernalization to flower (Figure 38.15), a gene called *FLC* (*FLOWERING LOCUS C*) encodes a transcription factor that blocks the FT–FD florigen pathway (see Figure 38.14) by inhibiting expression of FT and FD. Cold temperature inhibits the synthesis of FLC protein, allowing the FT and FD proteins to be expressed, and flowering to

proceed. Similar proteins control some steps in vernalization in cereals.

Epigenetics (see Section 16.4) plays an important role in the inhibition of *FLC* gene expression by cold temperature. Before vernalization, the chromatin at the promoter of the *FLC* gene is in a relaxed configuration, with histone protein acetylation lowering the ionic attraction of these proteins for DNA, which allows transcription (Figure 38.16A). During vernalization, a gene is expressed whose protein product is involved in the deacetylation of histones on the *FLC* gene. Deacetylation causes the chromatin to be more compact, which blocks *FLC* gene expression (Figure 38.16B).

GIBBERELLIN *Arabidopsis* plants do not flower if they are genetically deficient in the hormone gibberellin, or if they are treated with an inhibitor of gibberellin synthesis. These observations implicate gibberellins in flowering. Direct application of gibberellins to *Arabidopsis* buds results in activation of the

38.16 Chromatin Remodeling during Vernalization (A) In the absence of vernalization, *Flowering Locus C* (*FLC*) is expressed and flowering is repressed. (B) Prolonged cold weather leads to chromatin remodeling that represses expression of *FLC*. The absence of *FLC* protein allows flowering genes to be expressed.

meristem identity gene *LEAFY*, which in turn promotes the transition to flowering.

Some plants do not require an environmental cue to flower

Several plant species and strains do not require a photoperiod or vernalization to flower, but instead flower on cue from an “internal clock.” For example, flowering in some strains of tobacco will be initiated in the terminal bud when the stem has grown four phytomers in length (recall that stems are composed of repeating units called phytomers; see Figure 34.1). If such a bud with a single adjacent phytomer is removed and planted, the cutting will flower because the bud has already received the cue for flowering. But the rest of the shoot below the bud that has been removed will not flower because it is only three phytomers long. After it grows an additional phytomer, it will flower. These results suggest that there is something about the *position* of the bud (atop four phytomers of stem) that determines its transition to flowering.

The bud might “know” its position by the concentration of some substance that forms a positional gradient along the length of the plant. Such a gradient could be formed if the root makes a diffusible inhibitor of flowering whose concentration diminishes with plant height. When the plant reaches a certain height, the concentration of the inhibitor would become sufficiently low at the tip of the shoot to allow flowering. What this inhibitor might be is unclear, but there is evidence that it acts by decreasing the amount of FLC, allowing the FT–FD pathway to proceed (just as cold acts on FLC in vernalization). A positional gradient that acts on FLC would be consistent with other mechanisms affecting flowering, which all converge on *LEAFY* and *APETALA1*:

RECAP 38.2

Flowering of some angiosperms is controlled by night length, a phenomenon called photoperiodism. Low temperatures can induce flowering in some species (vernalization). Some species flower when their stems have grown by a certain amount, independent of environmental cues. All pathways to flowering converge on the meristem identity genes.

- What are the differences between apical meristems, inflorescence meristems, and floral meristems? What genes control the transitions between them? **See p. 786 and Figure 38.8**
- Explain why “short-day plant” is a misleading term. **See p. 788 and Figure 38.11**
- What is the evidence for florigen? What is its molecular mechanism of action? **See pp. 788–790 and Figures 38.13 and 38.14**

We have seen how environmental factors interact with genes to control flowering in angiosperms. The function of flowers is sexual reproduction, which maintains beneficial genetic variation in a population. Many angiosperms, however, also benefit from being able to reproduce asexually.

38.3 How Do Angiosperms Reproduce Asexually?

Although sexual reproduction takes up most of the space in this chapter, asexual reproduction accounts for many of the individual plants present on Earth. This fact suggests that in some circumstances asexual reproduction must be advantageous.

We have noted that genetic recombination is one of the advantages of sexual reproduction. Self-fertilization is a form of sexual reproduction, but offers fewer opportunities for genetic recombination than does cross-fertilization. A diploid, self-fertilizing plant that is heterozygous for a certain locus can produce both kinds of homozygotes for that locus plus the heterozygote among its progeny, but it cannot produce any progeny carrying alleles that it does not itself possess. Nevertheless many self-fertilizing plant species produce viable and vigorous offspring.

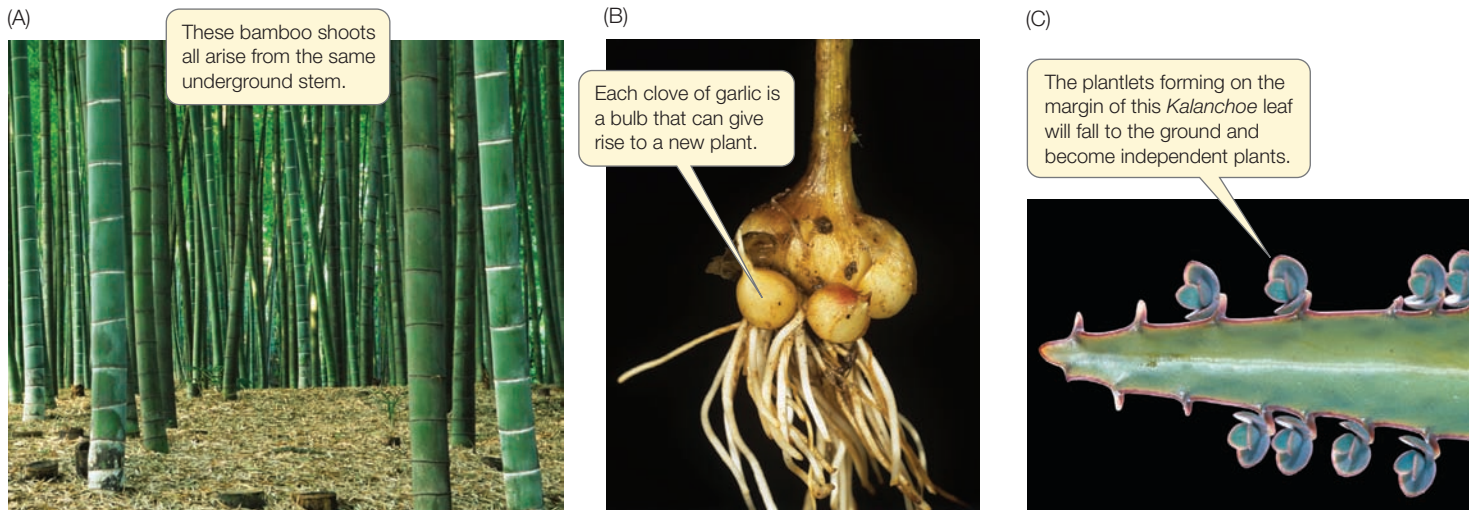

Asexual reproduction eliminates genetic recombination altogether. A plant that reproduces asexually produces progeny genetically identical to the parent (clones). What, then, is the advantage of asexual reproduction? If a plant is well adapted to its environment, asexual reproduction allows it to pass on to all its progeny a superior combination of alleles, which might otherwise be separated by sexual recombination.

Many forms of asexual reproduction exist

Stems, leaves, and roots are considered vegetative organs and are distinguished from flowers, the reproductive parts of the plant. Asexual reproduction is often accomplished through the modification of a vegetative organ, which is why the term **vegetative reproduction** is sometimes used to describe asexual reproduction in plants. Another type of asexual reproduction, apomixis (see the opening story), involves flowers but no fertilization.

Often the stem is the organ that is modified for vegetative reproduction. Strawberries, for example, produce horizontal stems, called stolons or runners, which grow along the soil surface, form roots at intervals, and establish potentially independent plants. Asexual reproduction by shoot tips is accomplished when the tips of upright branches sag to the ground and develop roots, as in blackberry and forsythia.

Some plants, such as potatoes, form enlarged fleshy tips of underground stems, called tubers, that can produce new plants (from the “eyes”). Rhizomes are horizontal underground stems that can give rise to new shoots. Bamboo is a striking example of a plant that reproduces vegetatively by means of rhizomes. A single bamboo plant can give rise to a stand—even a forest—of plants constituting a single, physically connected entity (**Figure 38.17A**).

Whereas stolons and rhizomes are horizontal stems, bulbs and corms are short, vertical, underground stems. Lilies and garlic form bulbs (**Figure 38.17B**), short stems with many fleshy, highly modified leaves that store nutrients. These storage leaves make up most of the bulb. They can give rise to new plants by dividing or by producing new bulbs from axillary buds. Crocuses, gladioli, and many other plants produce corms, underground stems that function very much as bulbs do. Corms are disclike and consist primarily of stem tissue; they lack the fleshy modified leaves that are characteristic of bulbs.

Stems are not the only vegetative organs modified for asexual reproduction. Leaves may also be the source of new plantlets, as in some succulent plants of the genus *Kalanchoe* (**Figure 38.17C**). Many kinds of angiosperms, ranging from grasses to trees such as aspens and poplars, form interconnected, genetically homogeneous populations by means of suckers—shoots produced by roots. What appears to be a whole stand of aspen trees, for example, may be a clone derived from a single tree by suckers. This is why the leaves of a whole stand of aspens typically turn yellow at the same time.

Plants that reproduce vegetatively often grow in physically unstable environments such as eroding hillsides. Plants with stolons or rhizomes, such as beach grasses, rushes, and sand verbena, are common pioneers on coastal sand dunes. Rapid vegetative reproduction enables these plants, once introduced, not only to multiply but also to survive burial by the shifting sand; in addition, the dunes are stabilized by the extensive network of rhizomes or stolons that develops. Vegetative reproduction is also common in some deserts, where the environment is often not suitable for seed germination and the establishment of seedlings.

Vegetative reproduction has a disadvantage

Vegetative reproduction is highly efficient in an environment that is stable over the long term. A change in the environment, however, can leave an asexually reproducing species at a disadvantage.

38.17 Vegetative Organs Modified for Reproduction (A) The rhizomes of bamboo are underground stems that produce plants at intervals. (B) Bulbs are short stems with large leaves that store nutrients and can give rise to new plants. (C) In *Kalanchoe*, new plantlets can form on leaves.

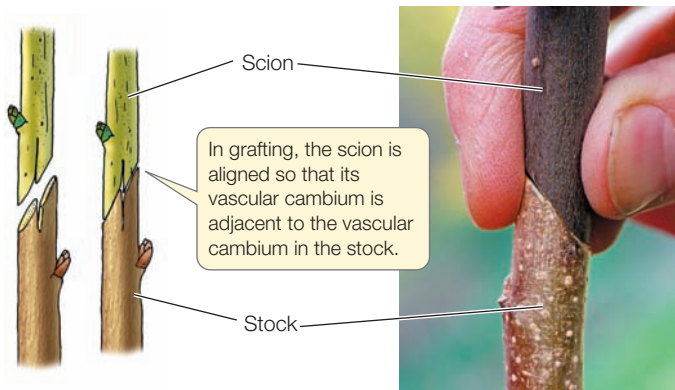

A striking example is provided by the demise of the English elm, *Ulmus procera*, which was apparently introduced into England as a clone by the ancient Romans. This tree reproduces asexually by suckers and is incapable of sexual reproduction. In 1967 Dutch elm disease first struck the English elms. After two millennia of clonal growth, the population lacked genetic diversity, and no individuals carried genes that would protect them against the disease. Today the English elm is all but gone from England.

Vegetative reproduction is important in agriculture

One of the oldest methods of vegetative reproduction used in agriculture consists of simply making cuttings of stems, inserting them in soil, and waiting for them to form roots and become autonomous plants. The cuttings are usually encouraged to root by treatment with auxin, a plant hormone.

Woody plants can be propagated asexually by **grafting**: attaching a bud or a piece of stem from one plant to a root or root-bearing stem of another plant. The part of the resulting plant that comes from the root-bearing “host” is called the **stock**; the part grafted on is the **scion** (**Figure 38.18**). The vascular cambium of the scion associates with that of the stock, forming a continuous cambium that produces xylem and phloem. The cambium allows the transport of water and minerals to the scion and of photosynthate to the stock. Much of the fruit grown for market in the United States is produced on grafted trees, as are wine grapes.

Another method widely used for asexual plant propagation is **meristem culture**, in which pieces of shoot apical meristem are cultured on growth media to generate plantlets, which can then be planted in the field. This strategy is vital when uniformity is desired, as in forestry, or when virus-free plants are the goal, as with strawberries and potatoes.

38.18 Grafting Grafting—attaching a piece of a plant to the root or root-bearing stem of another plant—is a common horticultural technique. The “host” root or stem is the stock; the upper grafted piece is the scion. In the photo, a scion of one apple variety is being grafted onto a stock of another variety.

RECAP 38.3

Angiosperms may reproduce asexually by means of modified stems, roots, or leaves. Asexual reproduction is advantageous when a plant has a superior genotype well adapted to its environment, but it decreases the genetic diversity of plant populations.

- What are the advantages and disadvantages of asexual reproduction for a plant? **See pp. 792–793**
- Explain how vegetative reproduction of plants is advantageous to humans. **See pp. 793–794**

We have seen how angiosperms reproduce sexually and asexually. A disadvantage of asexual reproduction is that its genetic inflexibility may leave a population unable to cope with new challenges. In the next chapter we will focus on the mechanisms that have evolved in plants to cope with biological and physical challenges in their environment.

By what genetic mechanism is apomixis brought about?

ANSWER

Apomixis involves several processes, including abnormal meiosis, followed by the development of an embryo within a seed. *Arabidopsis* plants with a mutation in the *SWII* gene show apomixis but no viable seeds. In normal plants, the expression of *SWII* is essential for chromosome pairing during meiosis I (see Figure 11.16). But in the mutant strain, meiosis I resembles mitosis, and the chromosomes replicate again before what would

be meiosis II. The search is now on for genes that promote embryo and seed development in plants that exhibit apomixis. Scientists are trying to isolate and transfer such genes into corn and other cereal crops with the hope that plant breeders can use apomixis to propagate plants with desirable traits (such as high yields and disease- and insect-resistance) without compromising their hybrid vigor.

38.1

How Do Angiosperms Reproduce Sexually?

- Sexual reproduction promotes genetic diversity in a population. The flower is an angiosperm’s structure for sexual reproduction.
- Flowering plants have microscopic gametophytes. The megagametophyte is the **embryo sac**, which typically contains eight nuclei in a total of seven cells. The microgametophyte is the **pollen grain**, which usually contains two cells. **Review Figure 38.2, ACTIVITY 38.1**
- Following **pollination**, the pollen grain delivers **sperm cells** to the embryo sac by means of a **pollen tube**. **Review ANIMATED TUTORIAL 38.1**
- Plants have both physical and genetic methods of preventing inbreeding. Physical separation of the gametophytes and genetic **self-incompatibility** prevent self-pollination. **Review Figure 38.5**
- Most angiosperms exhibit **double fertilization**: one sperm cell fertilizes the egg cell, forming a zygote, and the other sperm cell

fertilizes the central cell, where its nucleus unites with the two **polar nuclei** to form a triploid **endosperm**. **Review Figure 38.6**

- Ovules develop into seeds, and the ovary wall and the enclosed seeds develop into a **fruit**.
- The hormone **abscisic acid** promotes seed development and dormancy.

38.2

What Determines the Transition from the Vegetative to the Flowering State?

- In **annuals** and **biennials**, flowering and seed formation usually leads to death of the rest of the plant. **Perennials** live a long time and typically reproduce repeatedly.
- For a vegetatively growing plant to flower, an apical meristem in the shoot system must become an **inflorescence meristem**, which in turn must give rise to one or more **floral meristems**. These events are under the influence of **meristem identity genes** and **floral organ identity genes**. **Review Figure 38.8**

continued

CHAPTERSUMMARY 38

- Some plants flower in response to **photoperiod**. **Short-day plants** flower when the nights are longer than a critical night length specific to each species; **long-day plants** flower when the nights are shorter than a critical night length. **Review Figure 38.11**
- The mechanism of photoperiodic control involves phytochromes and a biological clock. **Review Figure 38.12, ANIMATED TUTORIAL 38.2**
- A flowering signal, called **florigen**, is formed in a photoperiodically induced leaf and is translocated to the sites where flowers will form. **Review Figures 38.13, 38.14**
- In some angiosperm species, exposure to low temperatures—**vernalization**—is required for flowering; in others, internal signals (one of which is gibberellin in some plants) induce flowering. **Review Figures 38.15, 38.16**

38.3 How Do Angiosperms Reproduce Asexually?

- Asexual reproduction allows rapid multiplication of organisms that are well suited to their environment.
- **Vegetative reproduction** involves the modification of a vegetative organ—usually the stem—for reproduction. **Review Figure 38.17**
- Horticulturists often **graft** different plants together to take advantage of favorable properties of both **stock** and **scion**. **Review Figure 38.18**

CHAPTERREVIEW

REMEMBERING

1. The typical angiosperm female gametophyte
 - a. is called a microspore.
 - b. has eight nuclei.
 - c. has eight cells.
 - d. is called a pollen grain.
 - e. is carried to the male gametophyte by wind or animals.
2. Pollination in angiosperms
 - a. always requires wind.
 - b. never occurs within a single flower.
 - c. always requires help by animal pollinators.
 - d. is also called fertilization.
 - e. makes most angiosperms independent of external water for reproduction.
3. Which statement about double fertilization is *not* true?
 - a. It is found in most angiosperms.
 - b. It includes fusion between the microsporocyte and the megasporocyte.
 - c. One of its products is a triploid nucleus.
 - d. One sperm cell fuses with the egg cell.
 - e. One sperm cell fuses with the central cell.
4. Which statement about photoperiodism is *not* true?
 - a. It is related to the biological clock.
 - b. Phytochrome plays a role in the timing process.
 - c. It is based on measurement of the length of the night.
 - d. Some plants do not flower in response to photoperiod.
 - e. It is limited to plants.
5. Florigen is
 - a. produced in the leaves and transported to the apical bud.
 - b. produced in the roots and transported to the shoots.
 - c. produced in the apical meristem of the stem and transported to the base.
 - d. the same as gibberellin.
 - e. activated by prolonged (more than a month) high temperature.

6. Which statement about vernalization is *not* true?
 - a. It decreases the abundance of an inhibitor of flowering.
 - b. It involves exposure to cold temperatures.
 - c. It only occurs in crop plants such as cereals.
 - d. It inhibits synthesis of the FLC protein.
 - e. If winter wheat is not exposed to cold, it will not flower.

UNDERSTANDING & APPLYING

7. Thompson Seedless grapes are produced by vines that are triploid. Think about the consequences of this chromosomal condition for meiosis in the flowers. Why are these grapes seedless? Describe the role played by the flower in fruit formation when no seeds are being formed. How do you suppose Thompson Seedless grapes are propagated?
8. Poinsettias are popular ornamental plants that typically bloom just before Christmas. Their flowering is photoperiodically controlled. Are they long-day or short-day plants? Explain.

9. You plan to induce the flowering of a crop of long-day plants in the field by using artificial light. Is it necessary to keep the lights on continuously from sundown until the point at which the critical day length is reached? Why or why not?

ANALYZING & EVALUATING

10. Describe the proteins and mutations that could be involved in the following observations:
 - a. A mutant plant flowers without its normal inductive dark period. When a leaf from the mutant plant is grafted onto an unexposed wild-type plant, the recipient plant flowers.
 - b. A mutant plant does not flower when exposed to the normal inductive dark period. When a leaf from a mutant plant that has been exposed to the inductive dark period is grafted onto an unexposed wild-type plant, the recipient plant flowers.
 - c. A plant flowers only after exposure to cold.
 - d. If a gene is experimentally overexpressed in the leaf, flowering is induced. Overexpression of the gene in the shoot apical meristem does not, however, induce flowering.
11. The isolation of a mutation in the *Arabidopsis SWI* gene that results in abnormal meiosis has offered insights into apomixis. How would you try to identify other genes or mutations that function along with the gene product of *SWI*, with the goal of producing fully fertile apomictic plants?

Plant Responses to Environmental Challenges

CHAPTER OUTLINE

- 39.1** How Do Plants Deal with Pathogens?
- 39.2** How Do Plants Deal with Herbivores?
- 39.3** How Do Plants Deal with Environmental Stresses?
- 39.4** How Do Plants Deal with Salt and Heavy Metals?

A *ARTEMISIA ANNUA*, or sweet wormwood, is a fernlike shrub about 2 meters tall that is native to Asia but grows all over the world. Unlike animals, which can sometimes escape their enemies, plants must confront their enemies in place. Over time, plants have evolved elaborate mechanisms to fight off attackers. One such mechanism is the production of defensive chemicals. *Artemisia* produces a chemical called artemisinin that is toxic to certain cells, including those of the parasite that causes malaria.

Malaria has infected humans for more than 50,000 years. Today about 400 million cases arise worldwide and close to 1 million people die from malaria each year. The disease is caused by a mosquito-borne parasite that infects liver and blood cells in the human body.

Many cultures have long histories of extracting medicines from plants growing in their environments. About 1,700 years ago the Chinese herbalist Ge Hong noted that drinking a tea made from *Artemisia* was useful in treating malaria. Meanwhile, the indigenous people of Peru were using tinctures from the bark of a different plant—cinchona—to treat malaria. In the 1600s Jesuit priests noted how effective the cinchona treatment was, and brought it back to Europe. During the nineteenth century the active ingredient of cinchona was identified as quinine, and quinine became the most widely used medicine for both the prevention and treatment of malaria. But during the twentieth century, the supply of quinine could not keep up with demand, especially for soldiers fighting in the world wars. This led to the development of various synthetic antimalarial drugs.

A New Way to Fight Malaria Sweet wormwood (*Artemisia annua*) grows in forests throughout the world. It synthesizes a defensive chemical, called artemisinin, that is now being used to treat people with malaria.

As more modern drugs were developed to treat malaria, traditional herbs such as *Artemisia* fell into disuse. But gradually the parasite developed resistance to the drugs, and doctors turned back to *Artemisia*. Indeed, during the Vietnam War, drinking *Artemisia* tea helped Vietnamese soldiers cope with the quinine-resistant malaria that struck American soldiers. Chinese scientists isolated the active ingredient of the anti-malarial tea and called it artemisinin.

The exact mechanism of action of artemisinin is still unclear. It appears that the drug reacts with iron in red blood cells, forming free radicals that damage lipids and DNA in the infecting parasite. Because of political differences between China and the rest of the world, news of the discovery of artemisinin, and access to the drug, were restricted until the early 1980s. Now it is widely available.

Until recently, hundreds of such plant chemicals were contemplated only in the context of plant biochemistry (how plants make them). Today we view them as adaptations arising from a plant's interactions with its environment.

What is the current status of artemisinin therapy for malaria?

See answer on p. 812.

39.1 How Do Plants Deal with Pathogens?

Botanists know of thousands of diseases that can affect plants. Each is caused by a different strain of pathogen. Plant pathogens—which include bacteria, fungi, protists, nematodes, and viruses—are part of nature, and for that reason alone they merit our study in biology. For example, many diseases affect tomato plants, some of which may be familiar to you from growing tomatoes in your backyard or shopping for them (**Figure 39.1**). Like some human infectious diseases such as pneumonia, which may be bacterial or viral, plant diseases are named for the symptoms rather than the agent that causes them. For example, the term “blight,” characterized by browning and death of plant tissues, can be caused by bacteria, fungi, or oomycetes. Just as medical schools have departments of pathology, many universities in agricultural regions have departments of plant pathology.

Successful infection by a pathogen can have significant effects on a plant, reducing photosynthesis and causing massive cell and tissue death. Like the responses of the human immune system (see Chapter 42), the responses by which plants fight off disease are varied and fascinating. Plants and pathogens have evolved together in a continuing “arms race”: pathogens have evolved ways to attack plants, and plants have evolved ways to defend themselves against those attacks.

What determines the outcome of a battle between a plant and a pathogen? The key to success for the plant is to respond to information from the pathogen quickly and massively. Plants use both mechanical and chemical defenses in this effort. These defenses can either be:

- **Constitutive**, always present in the plant, or
- **Induced**, produced in reaction to damage or stress.

Physical barriers form constitutive defenses

A plant’s first line of defense is its outer surfaces, which can prevent the entry of pathogens. As Chapter 34 described, the organs of a growing plant that are exposed to the outside environment are largely covered with cutin, suberin, and waxes. These substances not only prevent water loss by evaporation but can also prevent fungal spores and bacteria from entering the underlying tissues. Some fungi get around this defense by secreting enzymes that hydrolyze these substances, breaking them down to gain entry.

Much more important to the plant are the induced resistance mechanisms, summarized in **Figure 39.2**, that are initiated when a pathogen lands on a plant.

Plants can seal off infected parts to limit damage

Whereas animals generally repair tissues that have been damaged by pathogens, plants do not. Instead, plants seal off and sacrifice damaged tissues so that the rest of the plant does not

39.1 Diseases of Tomato Plants A wide variety of disease agents cause a variety of symptoms.

become infected. Plants have the option of discarding damaged tissues because most plants, unlike most animals, can replace damaged parts by growing new ones.

Before we look at the details of the defensive process, note that a key response by plant cells to invasion by pathogens is the rapid deposition of additional polymers on the inside of the cell wall. These macromolecules not only reinforce the mechanical barrier formed by the cell wall, but also block the plasmodesmata, limiting the ability of viral pathogens to move from cell to cell. The polysaccharides also serve as a base on which lignin may be laid down. Lignin enhances the mechanical barrier, and the toxicity of lignin precursor chemicals makes the cell inhospitable to some pathogens. These lignin building blocks are only one example of the toxic substances that plants use as chemical defenses.

Induced responses to pathogens are controlled by receptors. Plant pathogens cause the host plant to activate various chemical defense responses. A wide range of molecules called **elicitors** have been identified that trigger these defenses. These molecules vary in character, from peptides made by bacteria to cell wall fragments from fungi. Elicitors can also be derived from fragments of plant cell wall components broken down by pathogens.

39.2 Signaling between Plants and Pathogens

Molecular interactions between plants and pathogens are highly coevolved. The presence of a pathogen stimulates the plant to produce defensive molecules that work in many different ways.

Go to Animated Tutorial 39.1
Signaling between Plants and
Pathogens Life10e.com/at39.1

The responses of plants to elicitors can be described in terms of the "plant immune system." Two forms of immunity are recognized (see Figure 39.2):

- **General immunity** is triggered by general elicitors called pathogen associated molecular patterns (PAMPs). PAMPs are usually molecules that are produced by entire classes of pathogens, such as flagellin (found in bacterial flagella) or chitin (found in fungal cell walls). Thus general immunity is an overall response rather than a response that is triggered by a specific pathogen in a particular plant. PAMPs are recognized by transmembrane receptors called pattern recognition receptors, which activate signaling pathways that lead to general immunity (also called PAMP-triggered immunity, or PTI).
- **Specific immunity** is triggered by specific elicitors called effectors. Effectors include a wide variety of specific pathogen-produced molecules that enter the plant cell. Once inside the cell, effectors bind to cytoplasmic receptors called R proteins that trigger the specific immunity response (also called effector-triggered immunity, or ETI).

General and specific immunity both involve multiple responses

Many of the signaling pathways associated with general and specific immunity are the same, although the latter is specific for particular pathogens in particular plants, and is much stronger than general immunity. Both forms of immunity involve signaling pathways that are triggered by binding between the elicitors (PAMPs or effectors) with their receptors. These pathways lead to various responses:

- **Formation of reactive oxygen and NO:** Receptor binding triggers the rapid production of nitric oxide (NO) and reactive

oxygen species such as superoxide and hydrogen peroxide. These reactive molecules are toxic to some pathogens, and they are components of signal transduction pathways leading to local and systemic (plantwide) defenses.

- **Callose deposition:** The β -1,3-glucan polymer callose is deposited on the inside of the cell wall to strengthen the wall and seal off the cell.
- **Hormone signaling:** Some pathways result in the production of plant hormones, including salicylic acid and jasmonic acid. We will describe the roles of these hormones in immunity later in the chapter.
- **Changes in gene expression:** Signal transduction cascades lead to changes in gene expression. The upregulated genes include pathogenesis-related (PR) genes and genes encoding the production of antimicrobial substances called phytoalexins.

PHYTOALEXINS **Phytoalexins** are antibiotics that are produced by infected plants and are toxic to many fungi and bacteria. Most are small molecules, and each is made by only a few plant species. They are produced by infected cells and their immediate neighbors within hours of the onset of infection. Because their antimicrobial activity is nonspecific, phytoalexins can destroy many species of fungi and bacteria in addition to the one that originally triggered their production. Some phytoalexins can also kill the plant cells that produced them, thus sealing off the infection site (the hypersensitive response; see below).

Phytoalexins are an example of an induced plant defense: they are not normally present in plants but are synthesized rapidly when a bacterial or fungal infection occurs. Physical injuries and viral infections can also induce the production of phytoalexins.

Camalexin, a phytoalexin made by the model organism *Arabidopsis thaliana*, appears to function by disrupting the cell membranes of invading fungal or bacterial pathogens. Its production is induced by a conserved protein kinase cascade (see Section 7.3) that is triggered by receptor binding in either general or specific immunity. This protein kinase cascade results in the upregulation of genes encoding enzymes that convert the amino acid tryptophan to camalexin:

PATHOGENESIS-RELATED PROTEINS Plants produce several types of **pathogenesis-related (PR) proteins**. Some are enzymes that break down the cell walls of pathogens. Chitinase, for example, is a PR protein that breaks down chitin, which is found in many fungal cell walls. In some cases the breakdown products of the pathogen cell walls serve as elicitors that trigger further defensive responses.

Another class of PR proteins are the plant defensins, which are similar to defensins produced by animals (see Section 42.2). These small peptides bind to fungal membranes and are toxic to a wide range of fungal targets, but they are not toxic to plant or animal cells.

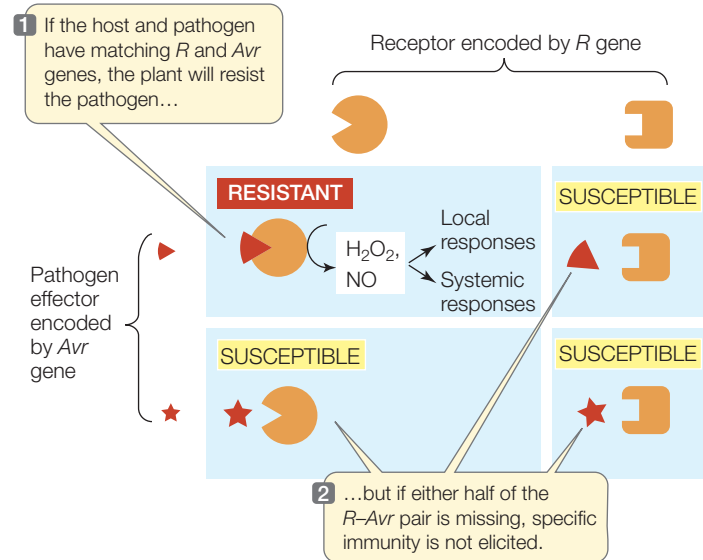

Other PR proteins may serve as alarm signals to plant cells that have not yet been attacked. In general, PR proteins appear not to be rapid-response weapons; rather, they act more slowly, perhaps after other, faster responses have blunted the pathogen's attack.

Specific immunity involves gene-for-gene resistance

As mentioned above, pathogen effectors are molecules that are secreted inside plant cells by fungal and bacterial pathogens. These molecules are often proteins whose function is to inhibit some aspect of plant immunity. For example, many effectors are proteases that break down specific plant proteins involved in immune responses. Thus effectors enable pathogens to overcome general immunity and invade the plant, causing disease. The genes that encode effectors have evolved as part of the “arms race” between plants and their pathogens.

In response to the evolution of effectors, plants have evolved intracellular receptors that recognize specific effectors. These receptors are called **R** (for resistance) proteins. When an R protein binds its ligand (a specific effector), it activates the signal transduction pathways of the specific immunity response. As we mentioned above, specific immunity is stronger than general immunity, and it enables the plant to prevent growth of the pathogen and remain healthy.

R proteins are encoded by **resistance (R) genes**. During the middle of the twentieth century, the plant pathologist Harold

39.3 Gene-for-Gene Resistance If a gene in a pathogen that codes for an elicitor “matches” a gene in a plant that codes for a receptor, the receptor binds the elicitor, and a defensive response results.

Henry Flor, at North Dakota State University, realized that there is a special relationship between *R* genes and certain pathogen genes named **Avirulence (Avr) genes**. Flor studied strains of the rust fungus *Melampsora lini* and the flax plant (*Linum usitatissimum*). He found that specific strains of rust fungus (with particular *Avr* genes) were able to cause disease only on some varieties of flax—those that *didn't* carry specific *R* genes. If a flax variety carried the right *R* gene, it was resistant to those strains of rust fungus. Thus a particular *Avr* gene rendered the fungus *avirulent* on flax plants with the corresponding *R* gene. Flor named this the **gene-for-gene concept**. We now know that *Avr* genes encode effector molecules that bind to receptors encoded by the *R* genes, resulting in the specific immunity response (Figure 39.3). Hundreds of *R* genes and their corresponding *Avr* genes have been identified. A major goal of plant breeders for the past 50 years has been to breed new *R* genes into crops to make them more resistant to pathogens.

Specific immunity usually leads to the hypersensitive response

Many signaling pathways and plant responses are shared between general and specific immunity, although in the latter these responses are accelerated and amplified. Furthermore, specific immunity usually leads to a form of programmed cell death called the **hypersensitive response**. When this occurs, plant cells at and near the site of pathogen infection die, forming a necrotic lesion (Figure 39.4). This cell death deprives the pathogen of nutrients and prevents the spread of the infection.

As described above, specific immunity is triggered by binding between specific pathogen effectors (*Avr* gene products) and *R* receptor proteins. The pathways that lead to cell death have not been worked out in detail, but the generation of nitric oxide and reactive oxygen species is an important component.

39.4 Sealing Off the Pathogen and the Damage These necrotic lesions on the leaves of a broad bean plant are a response to “chocolate spot” fungus, *Botrytis fabae*.

These reactive molecules may contribute to cell death directly—for example, by disrupting cellular membranes. They also function as signaling molecules that activate pathways leading to cell death.

Systemic acquired resistance is a form of long-term immunity

Thus far we have described the events that occur in plant cells at or near the site of invasion by a pathogen. In both general and specific immunity, the infected cells also send hormonal signals to the rest of the plant, stimulating a systemic response.

Systemic acquired resistance is a general increase in the resistance of the entire plant to a wide range of pathogens. It is not limited to the pathogen that originally triggered it, or to the site of the original infection, and its effect may last as long as an entire growing season.

This defensive response is initiated by the plant hormone salicylic acid.

Salicylic acid production is triggered by receptor binding in both general and specific immunity; salicylic acid then functions as a signal that mediates various defense responses. For example, salicylic acid triggers the production of reactive oxygen species and the induction of genes that encode PR proteins. There are many classes of PR proteins, which function in various ways to protect plants against insect attack and against invasion by fungi, bacteria, viruses, and nematodes.

These responses occur at the site of infection and, to a lesser extent, throughout the plant. A derivative of salicylic acid can form a gas that can travel through the air, carrying the defense

signal not only to other parts of the same plant but to other nearby plants.

Another type of systemic acquired resistance is a more specific defense against viruses with RNA genomes. The plant uses its own enzymes to convert some of the single-stranded RNA of the invading virus into double-stranded RNA (dsRNA) and to chop that dsRNA into small interfering RNAs (siRNAs) (see Section 16.5). Simultaneously, some of the viral RNA is transcribed, forming mRNAs that advance the infection. However, the siRNAs interact with another cellular component to degrade those mRNAs, blocking viral replication. The siRNAs spread quickly throughout the entire plant through plasmodesmata, providing systemic resistance.

RECAP 39.1

Plants protect themselves against pathogens with constitutive and induced defenses. General and specific immunity involve several common signaling pathways, but specific immunity is a stronger response that usually leads to hypersensitive cell death. Systemic acquired resistance provides a longer-lasting, more general immunity throughout the plant.

- Name two types of defensive compounds that plant cells produce when they are infected by bacteria or fungi. **See pp. 799–800 and Figure 39.2**
- How do *R* and *Avr* genes determine which pathogens a plant can resist? **See p. 800 and Figure 39.3**
- How do infected plant cells signal infection to other parts of the plant, or to other plants? **See p. 801**

Not all biological threats to plants come from pathogens. Another threat comes from the many animals that eat plants.

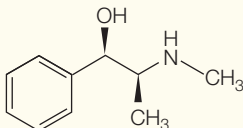

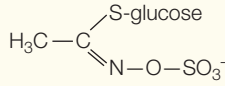

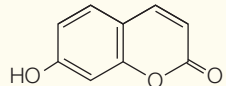

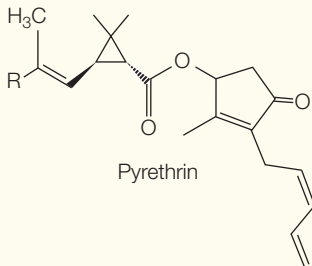

39.2 How Do Plants Deal with Herbivores?

Herbivores—animals that eat plants—depend on plants for energy and nutrients. Their foraging activities cause physical damage to plants, and they often spread disease among plants as well. While the majority of herbivores are insects (**Figure 39.5**), every major class of vertebrates includes at least a few herbivores (see also Section 56.2, which discusses herbivory in the ecological context of species interactions). Plants cannot evade their consumers by running away, but they have many other ways of protecting themselves against herbivory.

Mechanical defenses against herbivores are widespread

Plants have both constitutive and induced mechanical defenses against herbivores. Constitutive anatomical barriers include trichomes (specialized hairs; see p. 807) and thorns, spines that are specialized for defense. An example of an induced mechanical defense is the production of latex. Some plants, such as *Euphorbia* species, produce a thick, white aqueous suspension of cellular debris, oils, and resins called latex when they are injured by an herbivore. Insects trapped by this sticky substance starve to death.

TABLE 39.1
Secondary Metabolites Used in Defense

Class	Type	Role	Example
Nitrogen-containing	Alkaloids	Neurotoxin	Nicotine in tobacco
	Glycosides	Inhibit electron transport	Dhurrin in sorghum
	Nonprotein amino acids	Disrupt protein structure	Canavanine in jack bean
 Ephedrine (an alkaloid)			
Nitrogen–sulfur-containing	Glucosinolates	Inhibit respiration	Methylglucosinolate in cabbage
 Methylglucosinolate			
Phenolics	Coumarins	Block cell division	Umbelliferone in carrots
	Flavonoids	Phytoalexins	Capsidol in peppers
	Tannins	Inhibit enzymes	Gallotannin in oak trees
 Umbelliferone			
Terpenes	Monoterpenes	Neurotoxins	Pyrethrin in chrysanthemums
	Diterpenes	Disrupt reproduction and muscle function	Gossypol in cotton
	Triterpenes	Inhibit ion transport	Digitalis in foxglove
	Sterols	Block animal hormones	Spinasterol in spinach
	Polyterpenes	Deter feeding	Latex in <i>Euphorbia</i>
 Pyrethrin			

Plants produce constitutive chemical defenses against herbivores

Plants attract, resist, and inhibit other organisms with a wide range of chemicals known as secondary metabolites. You learned about one of these chemicals, artemisinin, in the opening of this chapter.

Primary metabolites are substances such as proteins, nucleic acids, carbohydrates, lipids, and their building blocks, which are produced and used by all living organisms, including plants. Primary metabolites are used in basic cellular processes such as photosynthesis, respiration, and nutrient uptake. **Secondary metabolites** are substances that are not used for basic cellular processes. Each is found in only certain organisms or groups of organisms.

The more than 10,000 known plant secondary metabolites range in molecular mass from about 70 to more than 390,000 daltons, but most have a low molecular mass (Table 39.1). Some are produced by only a single plant species, whereas

39.5 Insect Herbivores The great majority of herbivores are insects. (A) Some herbivores, such as this locust, are generalists that will attack nearly any plant. (B) Others are specialists, like this tobacco hornworm, which feeds only on tobacco and related plants.

39.6 Nicotine Is a Defense against Herbivores The secondary metabolite nicotine, made by tobacco plants, is an insecticide, yet most commercial varieties of tobacco are susceptible to insect attack. Ian Baldwin demonstrated that a tobacco strain with a reduced nicotine concentration was more susceptible to insect damage.^a

HYPOTHESIS Nicotine helps protect tobacco plants against insects.

Method

Create a strain of low-nicotine tobacco plants.

Plant wild-type (control) and low-nicotine plants together in a field where they are accessible to insects.

Assess the extent of leaf damage at 2-day intervals.

Results

The low-nicotine plants suffered more than twice as much leaf damage as did the wild-type controls.

CONCLUSION Nicotine provides tobacco plants with at least some protection against insects.

Go to **BioPortal** for discussion and relevant links for all INVESTIGATINGLIFE figures.

^aSteppuhn, A. et al. 2004. *PLoS Biology* 2(8): e217.

others are characteristic of entire genera or even families. The effects of defensive secondary metabolites on animals are diverse. Some act on the nervous systems of herbivorous insects, mollusks, or mammals. Others mimic the natural hormones of insects, causing some larvae to fail to develop into adults. Still others damage the digestive tracts of herbivores. Some secondary metabolites are toxic to fungal pathogens. For example, as we saw at the opening of this chapter, humans make use of secondary metabolites as medicines.

The secondary metabolite nicotine was one of the first insecticides to be used by farmers and gardeners. This molecule kills insects by inhibiting the functioning of the nervous system. Yet commercial varieties of tobacco and related plants that produce

nicotine are still attacked, with moderate damage, by pests such as the tobacco hornworm (see Figure 39.5B). Given that observation, does nicotine really deter herbivores? Biologists answered this question conclusively with a study that used tobacco plants in which an enzyme involved in nicotine biosynthesis had been silenced, lowering the nicotine concentration in the plants by more than 95 percent. These low-nicotine plants suffered much more damage from insect herbivory than did normal plants (Figure 39.6).

Some secondary metabolites play multiple roles

Canavanine is a secondary metabolite whose role is defensive and is based on its chemical structure. Canavanine is an amino acid that is not found in proteins, but is very similar to the amino acid arginine, which is found in almost all proteins:

When an insect larva consumes canavanine-containing plant tissue, the canavanine is incorporated into the insect's proteins in some of the places where the mRNA codes for arginine, because the enzyme that charges the tRNA specific for arginine fails to discriminate accurately between the two amino acids (see Section 14.5). The structure of canavanine, however, is different enough from that of arginine that some of the resulting proteins end up with a modified tertiary structure, and hence reduced biological activity. These defects in protein structure and function lead to developmental abnormalities that kill the insect.

In plants that produce them, canavanine and other secondary metabolites are constitutive defenses—that is, they are present regardless of whether the plant is under attack. Other chemical defenses come into play only when an herbivore strikes.

Plants respond to herbivory with induced defenses

In Section 39.1 we described the defenses that are induced in plants in response to pathogen attack. Plants also respond to wounding and herbivory with induced defenses involving signal transduction pathways. Less is known about the elicitors and receptors involved in these responses, but several classes of chemical elicitors have been identified. These elicitors are either derived from the herbivores themselves or are products of the digestion of plant tissues. For example, the enzymes

WORKING WITH DATA:

Nicotine Is a Defense against Herbivores

Original Paper

Steppuhn, A., K. Gase, B. Krock, R. Halitschke, and I. T. Baldwin. 2004. Nicotine's defensive function in nature. *PLoS Biology* 2(8): e217.

Analyze the Data

In 2004 Anke Steppuhn, Ian Baldwin, and colleagues at the Max Planck Institute for Chemical Ecology in Germany tested the hypothesis that nicotine helps protect tobacco plants against insects. They generated a line of low-nicotine transgenic plants by modifying the gene for putrescine *N*-methyl transferase, a key regulatory enzyme in the nicotine biosynthesis pathway. Both the low-nicotine and wild-type tobacco plants were transplanted into a field plantation where they were accessible to naturally occurring herbivores. The extent of leaf damage by insects was then measured at 2-day intervals for a period of 16 days. Results showed that the low-nicotine plants lost more than twice as much of their total leaf area as did the wild-type controls, indicating that nicotine provides tobacco plants with protection against insects (see Figure 39.6).

In a separate experiment, Baldwin and his colleagues showed that treatment with jasmonic acid (jasmonate) increased the concentration of nicotine in wild-type tobacco plants but not in the low-nicotine transgenic plants. The researchers then planted a group of wild-type and low-nicotine tobacco plants and treated them with jasmonate, a plant hormone, 7 days after planting. The plants were assessed for herbivore damage every 2 days after being planted. The results are shown in the figure.

QUESTION 1

Compare these data to those in Figure 39.6 for the untreated plants. What was the effect of jasmonate treatment on the resistance of wild-type plants to herbivore damage? What was the effect on low-nicotine plants?

QUESTION 2

What do these data reveal about the role of nicotine in preventing herbivore damage?

QUESTION 3

Explain how jasmonate could have had the effect it did on the transgenic low-nicotine plants, even though their nicotine levels were still low after jasmonate treatment.

QUESTION 4

What statistical test would you use to determine the possible significance of differences between the jasmonate-treated and untreated plants? At 10 days, the mean damage \pm standard deviation for untreated low-nicotine plants was 6.0 ± 1.5 percent ($n = 36$); for treated low-nicotine plants it was 2.2 ± 0.6 percent ($n = 28$). Run a statistical test comparing the two results, calculate the *P* value, and comment on significance (see Appendix B).

Go to **BioPortal** for all **WORKING WITH DATA** exercises

that insects use to digest plant carbohydrates and lipids can elicit defensive responses. Some elicitors are produced when plant material passes through an herbivore's digestive tract; these elicitors are composed of a fatty acid derived from the plant and an amino acid derived from the insect gut. One such elicitor, produced by insects feeding on corn plants, has been named volicitin for its ability to induce production of volatile signals that can travel to other plant parts—and to neighboring corn plants—and stimulate their defense responses. In addition, many herbivorous insects lay their eggs on plants, and some components of the fluids secreted during egg laying have been identified as elicitors.

The signal transduction pathways that are activated by herbivory or wounding involve several key components, some of which are shared by the pathways that are induced by pathogens:

- **Membrane signaling:** The plasma membrane is the part of the plant cell that is in contact with the environment. Within the first minute after an herbivore strikes, changes in the electric potential of the plasma membrane occur in the damaged area. As we will describe in our chapter

on the animal nervous system (see Section 45.2), such changes can be rapidly transmitted as a signal along the plasma membrane. In the case of plants responding to herbivory, the continuity of the symplast (see Figure 35.5) ensures that the signal travels over much of the plant within 10 minutes.

- **Reactive oxygen species:** Both wounding and herbivory trigger the production of reactive oxygen species (such as superoxide and hydrogen peroxide), which act as signaling molecules in pathways that lead to changes in gene expression.

Hormone signaling: Herbivory induces the production of several hormones that stimulate various plant responses. The most important of these is **jasmonic acid (jasmonate)**, which triggers systemic defenses against herbivores (**Figure 39.7**).

39.7 A Signal Transduction Pathway for Induced Defenses

The chain of events initiated by herbivory that leads to the production of a defensive chemical can consist of many steps. These steps may include the synthesis of one or two hormones, binding of receptors, gene activation, and finally, synthesis of defensive compounds.

Jasmonates trigger a range of responses to wounding and herbivory

When the plant senses an herbivore-produced elicitor, it makes jasmonate and a variety of jasmonate derivatives. These molecules trigger many plant defenses both at the site of herbivore attack and throughout the plant (see Figure 39.7). These defenses include the production of specific secondary metabolites and defensive proteins. Jasmonates induce changes in gene expression by binding a transcriptional inhibitor called a JAZ protein. After binding by jasmonate, the JAZ protein is targeted for degradation, and the previously inhibited genes can be expressed.

Protease inhibitors are an important group of defensive proteins that are synthesized in response to insect attack. Once inside an insect's gut, these inhibitors interfere with the digestion of proteins and thus stunt the insect's growth.

Jasmonates can also "call for help" by triggering the formation of volatile compounds that attract insects that prey on the herbivores attacking the plant.

Why don't plants poison themselves?

Why don't the defensive chemicals that are so toxic to herbivores and pathogens kill the plants that produce them? In some cases the defensive chemicals are directed at organs or systems that are not found in plants, such as the nervous, digestive, or endocrine systems of animals. In addition, plants that produce

toxic defensive chemicals use one or more other measures to protect themselves.

COMPARTMENTALIZATION Isolation of the toxic substance is a common means of avoiding exposure. Plants store their toxins in vacuoles if the toxins are water-soluble. If they are hydrophobic, the toxins may be dissolved in latex (see p. 806) and stored in a specialized compartment, or they may be dissolved in waxes on the epidermal surface. Such compartmentalized storage keeps the toxins away from the mitochondria, chloroplasts, and other parts of the plant's metabolic machinery.

STORAGE OF PRECURSORS Some plants store the precursors of toxic substances in one type of tissue, such as the epidermis, and store the enzymes that convert those precursors into the active toxin in another type, such as the mesophyll. When an herbivore chews part of the plant, cells are ruptured, the enzymes come into contact with the precursors, and the toxin is produced. The only part of the plant that is damaged by the toxin is that which was already damaged by the herbivore. Plants such as sorghum and some legumes, which respond to herbivory by producing cyanide (a potent inhibitor of cellular respiration), are among those that use this type of protective measure.

MODIFIED PROTEINS The plant has modified proteins that do not react with the toxin. As noted above, canavanine resembles arginine and therefore plays havoc with protein synthesis in insect larvae. In plants that make canavanine, the plant enzyme that charges the arginine tRNA discriminates correctly between arginine and canavanine, so canavanine is not incorporated into the plant's proteins.

39.8 Disarming a Plant's Defenses This beetle is inactivating a milkweed's defense system by cutting its laticifer supply lines.

Plants don't always win the arms race

Milkweeds such as *Asclepias syriaca* store their defensive chemicals in latex in specialized tubes called **laticifers**, which run alongside the veins in the leaves. When damaged, a milkweed releases copious amounts of toxic latex from its laticifers. Field studies have shown that most insects that feed on neighboring plants of other species do not attack laticiferous plants, but there are exceptions. One population of beetles that feeds on *A. syriaca* exhibits a remarkable prefeeding behavior: these beetles cut a few veins in the leaves before settling down to dine. Cutting the veins causes massive latex leakage from the adjacent laticifers and interrupts the latex supply to a downstream portion of the leaf. The beetles then move to the relatively latex-free portion and eat their fill (**Figure 39.8**).

We have described just one of many ways that herbivores circumvent plant defenses. A successful plant defense exerts strong selection pressure on herbivores to get around it somehow; a successful herbivore, in turn, exerts strong selection pressure on plants to develop new defensive strategies. One can imagine, for example, that over time *A. syriaca* might evolve to have thicker walls around the base of its laticifers, such that the beetles can no longer cut them, or to produce a different toxin that does not depend on laticifers.

RECAP 39.2

Many plants use secondary metabolites as constitutive defenses against herbivory. Other defenses are induced by herbivory through signal transduction pathways. The plant hormone jasmonate and its derivatives stimulate local and systemic responses to herbivores.

- Describe one example of a secondary metabolite and how it affects herbivores. **See pp. 802–803**
- What role do jasmonates play in plant defense? **See p. 805 and Figure 39.7**
- What are three ways in which a plant avoids being poisoned by its own defensive chemicals? **See p. 805**

A plant's survival depends not only on successful defenses against pathogens and herbivores but also on coping with a sometimes hostile physical environment. In the next section we will consider how plants deal with environmental stresses.

39.3

How Do Plants Deal with Environmental Stresses?

Plants are threatened by many aspects of the physical environment, such as drought, waterlogged soils, and extreme temperatures. These conditions are biologically harmful (**Table 39.2**). Plants cope with environmental stresses through adaptation or acclimation.

- **Adaptation** is genetically encoded resistance to stress. A plant may have structures or biochemical properties that aid in its survival in the face of environmental challenges.
- **Acclimation** is increased tolerance for environmental extremes because of prior exposure to them. An individual plant previously exposed to extreme cold, for example, may be more likely to survive the subsequent winter.

Leaves for Every Environment
Life10e.com/mc39.1

Some plants have special adaptations to live in very dry conditions

Many plants, especially those living in deserts, must cope with extremely limited water supplies. A variety of anatomical and life-cycle adaptations allow plants to survive under these conditions. Many of these adaptations are ways to avoid, reduce, or cope with the inevitable water loss through transpiration that occurs during active photosynthesis. Other adaptations help plants tolerate the excessive light and heat that are often found in deserts.

DROUGHT AVOIDERS Some desert plants have no special structural adaptations for water conservation. Instead, these desert annuals, called drought avoiders, simply evade periods of drought. Drought avoiders carry out their entire life cycle—from seed to seed—during a brief period in which rainfall has

TABLE 39.2 Environmental Stresses on Plants

Condition	Effect on Plants
Drought	Reduced water potential, dehydration
Flooding	Reduced O ₂ and respiration
High temperature	Changes in membrane fluidity and in proteins
Low temperature	Changes in membrane fluidity, damage by ice crystals
Salinity	Reduced water potential, dehydration
Metal element toxicity	Disruption of metabolism

39.9 Desert Annuals Avoid Drought The seeds of many desert annuals lie dormant for long periods, awaiting conditions appropriate for germination. When they do receive enough moisture to germinate, they grow and reproduce rapidly before the short wet season ends. During the long dry spells, only dormant seeds remain alive.

made the surrounding desert soil sufficiently moist for growth and reproduction (**Figure 39.9**). A different drought avoidance strategy is seen in some African and South American deciduous perennial plants, which shed their leaves in response to drought as a way to conserve water. These plants remain dormant until conditions are again favorable for growth, much as deciduous trees in temperate climates shed their leaves in fall and are dormant until the following spring.

LEAF STRUCTURES Most desert plants are not drought avoiders, but rather grow in their dry environment year-round. Plants adapted to dry environments are called **xerophytes** (Greek *xeros*, “dry”). Three structural adaptations are found in the leaves of many xerophytes:

- Specialized leaf anatomy that reduces water loss
- A thick cuticle and a profusion of hairs over the leaf epidermis, which retard water loss
- Trichomes that diffract and diffuse sunlight, thereby decreasing the intensity of light impinging on the leaves and the risk of damage to the photosynthetic apparatus by excess light

In some xerophytes the stomata are strategically located in sunken cavities below the leaf surface (known as **stomatal crypts**), where they are sheltered from the drying effects of air

39.10 Stomatal Crypts Stomata in the leaves of some xerophytes are located in sunken cavities called stomatal crypts. The trichomes (hairs) covering these crypts trap moist air.

currents (**Figure 39.10**). Trichomes surrounding the stomata slow air currents further. Cacti and similar plants have spines rather than typical leaves, and photosynthesis is confined to the fleshy stems. The spines may help the plants cope with desert conditions by reflecting solar radiation or by dissipating heat. The spines may also deter herbivores.

WATER-STORING STRUCTURES Succulence—the possession of fleshy, water-storing leaves or stems—is another adaptation to dry environments (**Figure 39.11**). This adaptation allows plants to take up large amounts of water when it is available (such as after a brief thunderstorm) and then draw on the stored water during subsequent dry periods. Other adaptations of succulents include a reduced number of stomata and a variant form of photosynthesis (the CAM pathway; see Section 10.4), both of which reduce water loss.

39.11 Succulence The Aloe plant stores water in its fleshy leaves.

39.12 Mining Water with Deep Taproots

In Death Valley, California, the root of this mesquite tree must reach far beneath the dunes for its water supply.

**ROOT SYSTEMS THAT MAXIMIZE WATER UPTAKE**

Roots may also be adapted to dry environments. Cacti have shallow but extensive fibrous root systems that effectively intercept water at the soil surface following even light rains. Mesquite (*Prosopis*) (Figure 39.12) obtains water through taproots that grow to great depths, reaching water supplies far underground, as well as from condensation on its leaves. The Atacama Desert in northern Chile often goes for several years without measurable rainfall, but the landscape there has many surprisingly large mesquite shrubs.

SOLUTE ACCUMULATION Xerophytes and other plants that must cope with inadequate water supplies may accumulate high concentrations of the amino acid proline or of secondary metabolites in their vacuoles. This solute accumulation lowers the water potential in the plant's cells below that of the soil, which allows the plant to take up water via osmosis. Plants living in saline environments share this and several other adaptations with xerophytes, as we will see shortly.

Some plants grow in saturated soils

For some plants, the environmental challenge is too much water, the opposite of that faced by xerophytes. They live in environments so wet that the diffusion of oxygen to their roots is severely limited. These plants have shallow root systems that grow slowly; oxygen levels are likely to be highest near the

surface of the soil, and slow growth decreases the roots' need for oxygen.

The root systems of some plants adapted to swampy environments, such as cypresses and some plants that grow in coastal mangrove habitats, have **pneumatophores**, which are extensions that grow out of the water and up into the air (Figure 39.13A). Pneumatophores contain lenticels (openings; see Figure 34.17) that allow oxygen to diffuse through them, aerating the submerged parts of the root system.

Many submerged or partly submerged aquatic plants have large air spaces in the leaf and stem parenchyma and in the petioles. Tissue containing such air spaces is called **aerenchyma** (Figure 39.13B). Aerenchyma stores oxygen produced by photosynthesis and permits its ready diffusion to parts of the plant where it is needed for cellular respiration. Aerenchyma also imparts buoyancy. Furthermore, because aerenchyma contains far fewer cells than most other plant tissues, metabolism in aerenchyma proceeds at a lower rate, so the need for oxygen is much reduced.

39.13 Coming Up for Air (A) The roots of these mangroves obtain oxygen through pneumatophores. (B) This scanning electron micrograph of a cross section of a petiole of the yellow water lily shows the structure of the air-filled channels that make up aerenchyma tissue.

Plants can respond to drought stress

The adaptations of xerophytes for coping with dry environments are generally constitutive—they are always present—and under normal conditions they prevent the plants from experiencing drought stress. When conditions become so dry that even xerophytes are stressed, however, the plants turn to inducible responses. The same responses are found in many other plants, including those that are not adapted to grow in dry climates.

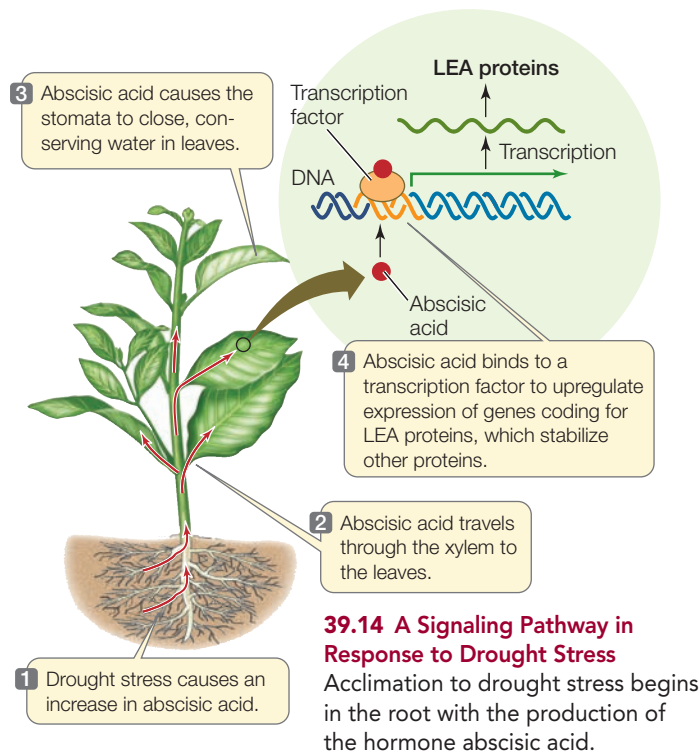

When the weather is abnormally dry, the water content of the soil is reduced and less water is available to plants. Water deficits in plant cells have two major biochemical effects:

- A reduction in membrane integrity as the polar–nonpolar forces that orient the lipid bilayer are reduced
- Changes in the three-dimensional structures of proteins

Plant growth is reduced when the structure of plant cells is compromised in these ways. Indeed, inadequate water supply is the single most important factor that limits production of our most important food crops.

When plants sense a water deficit in their roots, a signaling pathway is set in motion that initiates several measures to conserve water and maintain cellular integrity. This pathway begins with the production of the hormone abscisic acid in the roots. This hormone travels from the roots to the shoot, where it results in stomatal closure and initiates gene transcription that leads to other physiological events that conserve water and cellular integrity (Figure 39.14).

Many plant genes whose expression is altered by drought stress have been identified, largely through research using DNA microarrays, proteomics, and other molecular approaches (see Chapters 17 and 18). One group of proteins whose production is upregulated during drought stress is the *late embryogenesis*

abundant (LEA; pronounced “lee-yuh”) group of proteins. These hydrophobic proteins also accumulate in maturing seeds as they dry out (hence their name). LEA proteins bind to membrane proteins and other cellular proteins to stabilize them, preventing their aggregation during desiccation. The importance of LEA proteins in coping with drought stress was shown by Ray Wu and colleagues at Cornell University, who found that transgenic rice plants expressing a high level of LEA protein in leaves and roots grew better than normal plants under drought conditions (Figure 39.15). Genes that encode LEA proteins occur in many plants and confer drought tolerance.

INVESTIGATINGLIFE

39.15 A Molecular Response to Drought Stress Understanding the responses of plants to drought conditions is vital for agriculture. Ray Wu and colleagues transformed rice cells with a gene that codes for a LEA protein that is expressed in seeds as they mature and dry out. The investigators then measured the response of the transgenic rice plants to 28 days of drought.^a

HYPOTHESIS LEA proteins protect plants from the effects of drought stress.

Method

Results

CONCLUSION Plants with higher *LEA* gene expression grow better under drought conditions.

Plants can cope with temperature extremes

Temperatures that are too high or too low can stress plants and even kill them. Plant species differ in their sensitivity to heat and cold, but all plants have their limits. Any temperature extreme can damage cellular membranes.

- High temperatures destabilize membranes and denature many proteins, especially some of the enzymes of photosynthesis.
- Low temperatures cause membranes to lose their fluidity and alter their permeabilities to solutes.
- Freezing temperatures may cause ice crystals to form, damaging membranes.

Plants have both constitutive adaptations and inducible responses for coping with temperature extremes.

ANATOMICAL ADAPTATIONS Many plants living in hot environments have constitutive adaptations similar to those of xerophytes. These adaptations include hairs and spines that dissipate heat and leaf forms that intercept less direct sunlight.

HEAT SHOCK RESPONSE The plant inducible response to heat stress is similar to the response to drought stress in that new proteins are made, often under the direction of an abscisic acid-mediated signaling pathway. Within minutes of experimental exposure to raised temperatures (typically a 5°C–10°C increase), plants synthesize several kinds of **heat shock proteins**. Among these proteins are chaperonins, which help other proteins maintain their structures and avoid denaturation. Threshold temperatures for the production of heat shock proteins vary, but 39°C is sufficient to induce them in most plants.

COLD-HARDENING Low temperatures above the freezing point can cause chilling injury in many plants, including crops such as rice, corn, and cotton as well as tropical plants such as bananas. Many plant species can acclimate to cooler temperatures through a process called **cold-hardening**, which requires repeated exposure to cool temperatures over many days. A key change during hardening is an increase in the proportion of unsaturated fatty acids in cell membranes, which allows them to retain their fluidity and function normally at cooler temperatures (see Figure 3.21). Plants have a greater ability to modify the degree of saturation of their membrane lipids than animals do. In addition, low temperatures induce the formation of proteins similar to heat shock proteins, which protect against chilling injury.

If ice crystals form within plant cells, they can kill the cells by puncturing organelles and plasma membranes. Furthermore, the growth of ice crystals outside the cells can draw water from the cells and dehydrate them. Freeze-tolerant plants have a variety of adaptations to cope with these problems, including the production of antifreeze proteins that slow the growth of ice crystals.

RECAP 39.3

Plants that live in continually dry or water-saturated environments have structural adaptations to cope with those conditions. Mechanisms that protect plants from drought stress are initiated by a signaling pathway involving abscisic acid. Heat shock proteins help plants acclimate to high and low temperatures.

- Describe two structural adaptations for growth in water-saturated soils. [See p. 808](#)
- What is the role of abscisic acid in acclimation to drought stress? [See p. 809 and Figure 39.14](#)
- What environmental conditions induce the formation of heat shock proteins, and what functions do those proteins serve? [See p. 810](#)

Just as climatic extremes can limit plant growth, the presence of certain substances, such as salt and heavy metals, can make an environment inhospitable to plant growth.

39.4

How Do Plants Deal with Salt and Heavy Metals?

A number of toxic solutes are found in soils, but worldwide, no toxic substance restricts angiosperm growth more than ordinary salt (sodium chloride). Saline—salty—habitats support, at best, limited types of vegetation. Saline habitats are found in diverse locales, from hot, dry deserts to moist, cool coastal marshes. Along the seashore, saline environments are created by ocean spray. The ocean itself is a saline environment, as are estuaries, where fresh and salt water meet and mingle. Salinization of agricultural land is an increasing global problem ([Figure 39.16](#)). Even where crops are irrigated with fresh water, sodium ions from the water accumulate in the soil to ever greater concentrations as the water evaporates.

Saline environments pose an osmotic challenge for plants. Because of its high salt concentration, a saline environment

39.16 Salty Soil Accumulation of salt from irrigation water with inadequate drainage has caused this soil in central California to become unsuitable for most plant growth.

has an unusually negative water potential (see Figure 35.2). To obtain water from such an environment, a plant must have an even more negative water potential; otherwise water will diffuse out of its cells, and the plant will wilt and die. Plants in saline environments are also challenged by the potential toxicity of sodium, which inhibits enzymes and protein synthesis.

Most halophytes accumulate salt

Halophytes—plants adapted to saline habitats—are found in a wide variety of flowering plant groups. Most halophytes share one adaptation: they take up sodium and, usually, chloride ions and transport those ions to their leaves. The accumulated ions are stored in the central vacuoles of leaf cells, away from more sensitive parts of the cells. Nonhalophytes accumulate relatively little sodium, even when placed in a saline environment; of the sodium that is absorbed by their roots, very little is transported to the shoot. The increased salt concentration in the tissues of halophytes lowers their water potential and allows them to take up water from their saline environment.

Some halophytes have other adaptations to life in saline environments. Some, for example, have **salt glands** in their leaves. These glands excrete salt, which collects on the leaf surface until it is removed by rain or wind (Figure 39.17). This adaptation, which reduces the danger of poisoning by accumulated salt, is found in some desert plants, such as *Frankenia palmeri*, and in some mangroves growing in seawater.

Salt glands can play multiple roles, as in the desert shrub *Atriplex halimus*. This shrub has glands that secrete salt into small bladders on the leaves. By lowering the water potential of the leaves, this salt not only helps them obtain water from the roots but also reduces their transpirational loss of water to the atmosphere.

The adaptations we have just discussed are specific to halophytes. Several other adaptations are shared by halophytes and xerophytes, including thick cuticles, succulence, and CAM photosynthesis.

39.17 Excreting Salt This saltwater mangrove plant has special salt glands that excrete salt, which appears here as crystals on the leaves.

Some plants can tolerate heavy metals

Salt is not the only toxic solute found in soils. High concentrations of some heavy metal ions, such as chromium, mercury, lead, and cadmium, are toxic to most plants; many of these ions are more toxic than sodium at equivalent concentrations.

Some geographic sites are naturally rich in heavy metals as a result of normal geological processes. In other places, acid rain leads to the release of toxic aluminum ions in the soil. Human activities, notably the mining of metallic ores, leave localized areas—known as tailings—with high concentrations of heavy metals and low concentrations of nutrients. Such sites are hostile to most plants, and seeds falling on them generally do not produce adult plants.

Most mine tailings rich in heavy metals, however, are not completely barren. They may support healthy plant populations that differ genetically from populations of the same species on the surrounding normal soils. How do these plants survive?

Initially, botanists believed that some plants were able to tolerate heavy metals by excluding them: that by not taking up the metal ions, the plants avoided being poisoned. Further investigations have shown, however, that tolerant plants growing on mine tailings do take up heavy metals, accumulating concentrations that would kill most plants. More than 200 plant species have been identified as **hyperaccumulators** that store large quantities of metals such as arsenic (As), cadmium (Cd), nickel (Ni), aluminum (Al), and zinc (Zn).

Perhaps the best-studied hyperaccumulator is alpine pennycress (*Thlaspi caerulescens*). Before the advent of chemical analysis, miners used to use the presence of this plant as an indicator of mineral-rich deposits. A *Thlaspi* plant may accumulate as much as 30,000 ppm Zn (most plants contain 100 ppm) and 1,500 ppm Cd (most plants contain 1 ppm). Studies of *Thlaspi* and other hyperaccumulators have revealed the presence of several common mechanisms:

- Increased ion transport into the roots
- Increased rates of translocation of ions to the leaves
- Accumulation of ions in vacuoles in the shoot
- Resistance to the ions' toxicity

Knowledge of these hyperaccumulation mechanisms and the genes underlying them has led to the emergence of **phytoremediation**, a form of bioremediation (see Section 18.6) that uses plants to clean up environmental pollution. Some phytoremediation projects use natural hyperaccumulators, whereas others use genes from hyperaccumulators to create transgenic plants that grow more rapidly and are better adapted to a particular polluted environment. In either case, the plants are grown in the contaminated soil, where they act as natural “vacuum cleaners” by taking up the contaminants (Figure 39.18). The plants are then harvested and disposed of to remove the contaminants. Perhaps the most dramatic use of phytoremediation occurred after an accident at the nuclear power plant at Chernobyl, Ukraine (then part of the Soviet Union), in 1986, when sunflower plants were used to remove uranium from the nearby soil. Phytoremediation is now widely used in cleaning up land after strip mining.

39.18 Phytoremediation Plants that accumulate heavy metals can be used to clean up contaminated soils. Here, poplars are being used to remove contaminants from an air force base.

After finding plants that accumulate valuable metals such as Ni, cobalt (Co), and silver (Ag), some scientists have proposed using those plants for *phytomining*. As in phytoremediation, the plants would be used to take up metals from the soil, but the metals would be extracted from the plants after they are harvested.

RECAP 39.4

Halophytes have several adaptations to saline habitats, most of which involve mechanisms that lower their water potential. Some plants can tolerate heavy-metal-rich soils that are toxic to most other plants.

- What are some of the roles of salt glands in halophyte leaves? **See p. 811**
- How are plants used for phytoremediation? **See p. 811**

What is the current status of artemisinin therapy for malaria?

ANSWER

Since 2000, artemisinin has become a mainstay of malaria treatment worldwide. Millions of people take it every day. Because the solubility of the natural molecule is quite limited, chemists have synthesized derivatives of it that are more soluble and easier to take. There is, however, a serious danger that the malaria parasite will develop resistance to artemisinin and its derivatives, so these drugs are used in combination with other synthetic drugs.

CHAPTER SUMMARY 39

39.1 How Do Plants Deal with Pathogens?

- Plants and pathogens have evolved together in a continuing “arms race”: pathogens have evolved mechanisms for attacking plants, and plants have evolved mechanisms for defending themselves against those attacks.
- **Constitutive** defenses include plants’ ability to strengthen their cell walls and block plasmodesmata when attacked, limiting the ability of viral pathogens to move from cell to cell.
- **Induced** defenses are triggered by a wide range of molecular **elicitors** and fall into two main categories: general immunity and specific immunity. **Review Figure 39.2, ANIMATED TUTORIAL 39.1**
- The **gene-for-gene concept** depends on a match between a plant’s **resistance (R) genes** and a pathogen’s **Avirulence (Avr) genes**. **Review Figure 39.3**
- In the **hypersensitive response** to infection by bacteria or fungi, cells produce two kinds of defensive molecules: **phytoalexins** and **pathogenesis-related (PR) proteins**. Some cells around the infected area die, sealing off the pathogens and the damage they have caused.
- The hypersensitive response is often followed by **systemic acquired resistance**, in which salicylic acid activates further synthesis of defensive compounds.

- Plants use RNA interference to develop specific immunity to invading RNA viruses.

39.2 How Do Plants Deal with Herbivores?

- Some plants produce **secondary metabolites** as defenses against herbivores. **Review Table 39.1, Figure 39.6**
- Hormones, including **jasmonates**, participate in signal transduction pathways leading to the production of defensive compounds. **Review Figure 39.7**
- Plants protect themselves against their own toxic defensive chemicals by isolating them in specialized compartments, by producing them only after the plant has already been damaged, or by having modified enzymes or receptors that are not affected by the toxic substance.

39.3 How Do Plants Deal with Environmental Stresses?

- Plants cope with environmental stresses by **adaptation** (genetically encoded resistance) or **acclimation** (increased tolerance) **Review Table 39.2**
- **Xerophytes** are plants that are adapted to dry environments.

continued

- Some xerophytic adaptations are structural, including thickened cuticles, specialized trichomes, **stomatal crypts**, **succulence**, and long taproots.
- Some plants accumulate solutes, making their water potential lower so they can tolerate drought.
- Adaptations to water-saturated habitats include **pneumatophores**, extensions of roots that allow oxygen uptake from the air, and **aerenchyma**, tissue in which oxygen can be stored and ready for diffusion throughout the plant.
- A signaling pathway involving abscisic acid initiates a plant's response to drought stress. **Review Figures 39.14, 39.15**
- Membranes and proteins can be damaged by extremely high or low temperatures. Plants respond to extreme temperatures by producing **heat shock proteins**.
- Some plants undergo **cold-hardening**, an acclimation process that includes changes in membrane lipids and production of heat shock proteins.
- Some plants resist freezing by producing antifreeze proteins.

39.4 How Do Plants Deal with Salt and Heavy Metals?

- Most **halophytes** accumulate salt. Some have **salt glands** that excrete salt to the leaf surface.
- Some plants living in soils that are rich in heavy metals are **hyper-accumulators** that take up large amounts of those metals into their tissues.
- **Phytoremediation** is the use of hyperaccumulating plants or their genes to clean up environmental pollution.

See **ACTIVITY 39.1** for a concept review of this chapter.

CHAPTERREVIEW

REMEMBERING

- Plants sometimes protect themselves from their own toxic secondary metabolites by
 - producing special enzymes that destroy the toxin.
 - storing precursors of the toxic substances in one compartment and the enzymes that convert those precursors to toxic products in another compartment.
 - storing the toxic substances in mitochondria or chloroplasts.
 - distributing the toxic substances to all cells of the plant.
 - performing crassulacean acid metabolism.
- Which statement about secondary metabolites is *not* true?
 - They may be used in defense against fungi.
 - Some are poisonous to herbivores.
 - Some are amino acids that are normally part of proteins.
 - Water-soluble molecules are stored in vacuoles.
 - Some mimic the hormones of animals.
- Which of the following is *not* an adaptation to dry environments?
 - Increased solute concentration in the vacuoles
 - Hairy leaves
 - A heavier cuticle over the leaf epidermis
 - Sunken stomata
 - A root system that grows each rainy season and dies back when it is dry
- Some plants adapted to swampy environments meet the oxygen needs of their roots by means of a specialized tissue called
 - parenchyma.
 - aerenchyma.
 - collenchyma.
 - sclerenchyma.
 - chlorenchyma.
- Halophytes
 - may accumulate abscisic acid in their vacuoles.
 - may have water potentials that are lower than those of other plants.
 - only accumulate sodium.
 - have low root-to-shoot ratios.
 - rarely accumulate sodium.
- Which of the following is *not* true of the general immunity response of a plant to a pathogen?
 - It can result in changes in gene expression.
 - It can result in the production of plant hormones.
 - It is a weak response in comparison with specific immunity.
 - It involves sealing off damaged tissues to contain the infection.
 - It is produced when a plant receptor recognizes a molecular pattern in the pathogen.

UNDERSTANDING & APPLYING

7. How might the adaptations of herbivores affect plant evolution? How might plant adaptations affect the evolution of herbivores?
8. A tomato plant can be infected with the fungus *Cladosporium*. The host plant and pathogen can have various genes involved in the hypersensitive response. Fill in the table that describes the fungal strains and the results of infection of plants:

Tomato genotype	<i>Cladosporium</i> genotype		
	R1R2	R3R4	R1R4
Avr1Avr2	Healthy 	Diseased 	Healthy 
Avr2Avr3			
Avr1Avr4			

ANALYZING & EVALUATING

9. In the coming decades, climate change may have significant effects on the growth and productivity of plants, in particular the crops on which we depend for our food. Discuss the physiological effects, and possible genetic responses in terms of plant breeding, of the following:
- a. In Pakistan, reduced rainfall causes a reduction in wheat yields.
 - b. In the Mekong Delta of Vietnam, rising sea level inundates rice fields, causing a drastic reduction in yields.
 - c. Increased temperature and humidity in western Canada causes an increase in wheat rust.
10. The tobacco hornworm (*Manduca sexta*) is adapted to feeding on nicotine-producing plants. Using the genetically modified tobacco plants described in Figure 39.6, how might you test the hypothesis that dietary nicotine protects the tobacco hornworm against its parasite *Cotesia congregata*?

PART NINE Animals: Form and Function

Physiology, Homeostasis, and Temperature Regulation

CHAPTER OUTLINE

- 40.1** How Do Multicellular Animals Supply the Needs of Their Cells?
- 40.2** What Are the Relationships between Cells, Tissues, and Organs?
- 40.3** How Does Temperature Affect Living Systems?
- 40.4** How Do Animals Alter Their Heat Exchange with the Environment?
- 40.5** How Do Endotherms Regulate Their Body Temperatures?

Limits to Performance Paula Radcliffe, photographed here during her winning performance at the 2008 New York City Marathon, collapsed from heat stress during the 2004 Olympic marathon. When the body is subjected to extreme heat, its homeostatic mechanisms may fail.

THE 2008 NEW YORK CITY MARATHON took place on a cold, clear, windy day in November. For the third time, the first-place woman in this 41-km race was world record holder Paula Radcliffe. Radcliffe had also been expected to win the women's marathon in the 2004 Olympics. But that race took place on an extremely hot (a high of 34°C), humid day in Athens. Overcome by heat stress, Radcliffe collapsed 6 km from the finish line. In contrast, the average temperature for the three New York marathons Radcliffe won was 7°C.

Based on a survey of many marathons, elite runners have their best times when temperatures are below 10°C; higher temperatures can mean serious problems. The 2012 Boston Marathon coincided with an unseasonable April heat wave, with temperatures exceeding 27°C. During the course of the race, 120 runners were rushed to hospitals with severe heat stress.

When a person's internal body temperature rises above 40°C, major organs begin to fail, a condition known as heat stroke. Every year some athletes suffer heat stroke, which leads to death in a high percentage of cases. Soldiers in desert environments are at extreme risk of heat stroke, as are workers in many occupations, including firefighting, agriculture, and construction.

Why is heat stroke a particular danger for those who must be active in the heat? The short answer is that working muscles generate heat. That heat leaves the muscles in the blood and is circulated around the body, raising the temperature of the body's internal tissues. Although some of the heated blood flows to the skin, where heat can be lost to the environment, humans are subject to the problems faced by all mammals in losing excess heat. First, their normal internal temperatures are not far from the environmental temperatures that cause heat stress, so they don't have much of a safety zone. Second, most mammalian skin surfaces are covered with an insulating layer of fur—great for conserving body heat in cold environments, but an impediment to heat loss in warm ones.

Evolutionary adaptation in mammals has resulted in the efficient heat-loss portals of non-furred areas such as the nose, tongue, and footpads. In these areas, specialized blood vessels can open up and act like radiators to disperse heat (conversely, these portals can close down to conserve heat). Humans are not furred, but our evolutionary ancestors were, and we retain these general mammalian blood vessel adaptations in our hands, feet, and face (which is why we blush).

Can we increase heat loss from our natural heat portals to protect against heat stress?

See answer on p. 831.

40.1 How Do Multicellular Animals Supply the Needs of Their Cells?

All animal cells must obtain nutrients and oxygen from the environment and must eliminate carbon dioxide and other waste products of metabolism to the environment. The cells of very small or very thin aquatic animals meet these needs by direct exchanges with the external environment. In such animals, no cell is far from direct contact with the water it lives in; the water contains nutrients, absorbs wastes, and provides a relatively unchanging physical environment. Most cells of larger animals do not have direct contact with the external environment, and their needs must be served by an environment that is wholly internal to the animal.

An internal environment makes complex multicellular animals possible

The cells of multicellular animals exist within an **internal environment** of extracellular fluid. A human, for example, is about 60 percent water. Two-thirds of that water is contained within our cells, while one-third is the extracellular fluid (ECF) that is our internal environment. About 20 percent of the ECF (about 3 liters) is the **plasma** that circulates in our blood vessels. The remaining 80 percent (about 11 liters) is the **interstitial fluid** that bathes every cell of the body (**Figure 40.1**). Individual cells get their nutrients from this interstitial fluid and dump their waste products into it. As long as conditions in the body's internal environment are held within certain limits, cells are protected from the changes and harsh conditions of the external environment. A stable internal environment makes it possible for an animal to occupy habitats that would kill its cells if they were directly exposed to the external conditions. How is the internal environment kept constant?

As multicellular organisms evolved, cells became specialized for maintaining specific aspects of the internal environment. In turn, the internal environment enabled these specializations, since each cell no longer had to provide for all of its own needs. Some cells evolved to be the body's interface between the internal and the external environments and to provide the necessary transport functions to get nutrients in and move wastes out. Other cells became specialized for internal functions such as circulation of the extracellular fluids, energy storage, movement, and information processing. The evolution of physiological systems to maintain the internal environment made it possible for multicellular animals to become larger, thicker, and more complex, and allowed them to occupy many different habitats.

The composition of the internal environment is constantly being challenged by the external environment and by the metabolic activity of the cells of the body. Organisms must maintain their internal environment in a state of **homeostasis**—a narrow range of stable physical and biochemical conditions under which the body functions optimally. If a physiological system fails to function properly, homeostasis is compromised, and cells are damaged and can die. To avoid the loss of homeostasis, physiological systems must be controlled and regulated in response to changes in both the external and internal environments. The maintenance of homeostasis is a central theme of physiology.

40.1 The Internal Environment The “internal environment” is the extracellular fluid, or ECF, which accounts for about one-third of total body water. The ECF is made up of the blood plasma and the interstitial fluid. The physiological state of the ECF must remain stable within narrow limits, and maintaining that stability is the job of the body's organ systems.

Physiological systems are regulated to maintain homeostasis

The activities of physiological systems are *controlled*—speeded up or slowed down—by actions of the nervous and endocrine systems. But to *regulate* these systems and maintain homeostasis, information is required. As an analogy, think of the thermostat that controls the furnace or air conditioner to regulate the temperature of a house (**Figure 40.2**). The desired temperature is a **set point**, or reference point on the thermostat. The thermostat sensor responds to the temperature of the air, providing **feedback**—information that is compared with the set point. Any difference between the set point and the air temperature is an **error signal**. The error signal is converted into a corrective action—turning the air conditioner or furnace on or off.

Some components of physiological systems are called **effectors** because they *effect* changes in the internal environment. Muscles are a notable example of effectors. Another example are cells in the stomach that secrete digestive juices. Effectors are **controlled systems** because their activities are controlled by neural or hormonal signals from regulatory systems. **Regulatory systems** obtain, process, and integrate information, then issue commands to controlled systems. Important components of any regulatory system are the **sensors** (e.g., light-, temperature-, and pressure-sensitive cells) that provide feedback information to be compared with the internal set point.

Negative feedback is information used to counteract the influence that created an error signal. Whatever force is pushing the system away from its set point must be “negated.” In our thermostat analogy, an air temperature below the set point causes the furnace to be turned on, which then reverses the direction of change in the air temperature.

Although not as common as negative feedback, **positive feedback** also exists in physiological systems. Rather than returning a system to a set point, positive feedback amplifies a response (i.e., it increases the deviation from the set point). An

40.2 Thermostat Regulates Temperature A thermostat regulates the temperature of a room by turning the furnace or air conditioner on or off in response to the difference between feedback information (room temperature) and set points that are programmed into the thermostat.

example is sexual behavior, in which a little stimulation causes more behavior, which causes more stimulation, and so on. Positive feedback responses tend to reach a limit and terminate rapidly. The birth process is a good example. Contractions of the uterus stretch the birth canal, and that stretching stimulates more and stronger contractions until the baby is delivered, at which time contractions cease.

Feedforward information is another feature of regulatory systems. Its function is to change the set point in anticipation of a change in conditions. The timer on a thermostat provides feedforward information by changing the system's temperature set point, usually lowering it in the evening and raising it in the morning. Hearing the words "on your mark" before a race is feedforward information that raises your heart rate in anticipation of running. Feedforward information anticipates a change in the internal environment before that change occurs.

RECAP 40.1

The internal environment provides for the needs of all the cells that make up a complex multicellular animal. Organs and organ systems control the composition of the internal environment so as to maintain homeostasis.

- What are the three water-containing compartments in the human body? Why is the ECF crucial to survival in multicellular animals? **See p. 816 and Figure 40.1**
- Explain the difference between negative and positive feedback control mechanisms. **See pp. 816–817**
- Thinking about the thermoregulatory system in your own home, what is the set point, what is the feedback, and what would be feedforward information? **See pp. 816–817 and Figure 40.2**

Principles of control and regulation help organize our thinking about physiological systems. Once we understand how a system works, we can then ask how it is regulated. Part 9 of this book describes various physiological systems, how they function, and how they are regulated. But first we summarize some important structural features of the physiological systems that link the functioning of individual cells with the systemic functioning of multicellular animals.

40.2 What Are the Relationships between Cells, Tissues, and Organs?

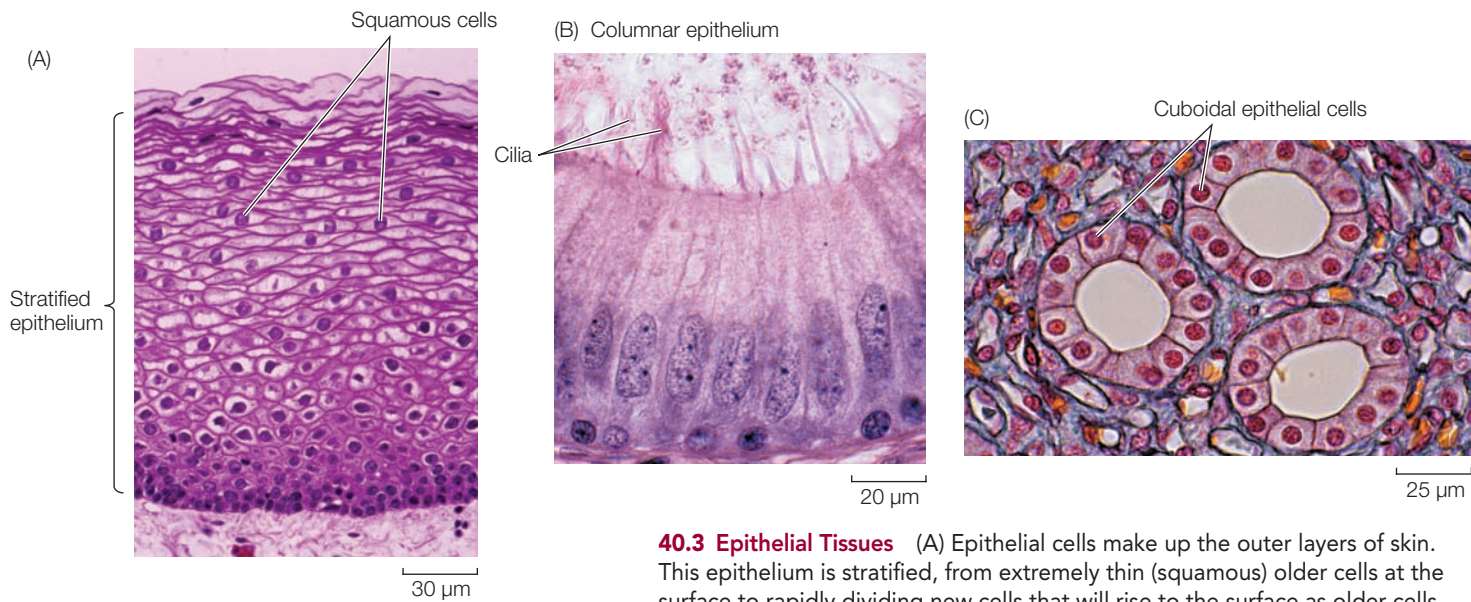

Control, regulation, and the resulting maintenance of homeostasis is the work of a hierarchy of interacting physiological systems that make up a multicellular animal (see Figure 1.9A). Each system is composed of discrete **organs**, such as the stomach, heart, lungs, and kidneys. Organs are made up of assemblages of similar cells called **tissues**; tissues in turn are made up of cells of different types. There are many specialized cell types, but there are only four kinds of tissues: epithelial, muscle, connective, and nervous tissues. The word "tissue" is often used in a general way to refer to a piece of an organ, such as "lung tissue" or "kidney tissue." An organ, however, always consists of more than one of the four tissue types. Here we will provide only brief descriptions of the four tissues types because each will be dealt with in more detail in the context of an organ or organ system in which it plays a major role.

Epithelial tissues are sheets of densely packed, tightly connected cells

Epithelial tissues are formed by sheets of cells, creating boundaries between the inside and the outside of the body and between body compartments. Epithelial tissues comprise the outer layer of the skin, line the blood vessels, and make up various ducts and tubules (**Figure 40.3**). They control which molecules and ions can move between different body compartments, such as the blood and the interstitial fluid. They selectively transport ions and molecules from one side of an epithelial membrane to the other; for example, the gut epithelium absorbs nutrients from the gut and secretes digestive juices into the gut.

The cells that make up epithelial tissues are of different types and configurations. The multilayered epithelial tissues of the skin are subject to a lot of wear and tear. Accordingly, epithelial cells in the deepest layer of the skin have a high rate of cell division, producing new cells that move progressively to the skin surface, die, and are shed (see Figure 40.3A). In contrast, gut epithelium consists of a single layer of tall, closely packed cells.

Epithelial cells have many specialized roles. Some secrete hormones, milk, mucus, digestive enzymes, or sweat. Others have cilia that move substances over surfaces or through tubes (see Figure 40.3B). Epithelial cells can also provide information to the nervous system. Smell- and taste-sensitive cells, for example, are epithelial cells that detect specific chemicals.

40.3 Epithelial Tissues (A) Epithelial cells make up the outer layers of skin. This epithelium is stratified, from extremely thin (squamous) older cells at the surface to rapidly dividing new cells that will rise to the surface as older cells are shed. (B) Ciliated columnar epithelium from the male reproductive duct (the vas deferens). (C) A single layer of cuboidal epithelial cells forms a tubule in the kidney. These cells have many molecular transport functions.

Muscle tissues generate force and movement

Muscle tissues are the most abundant tissues in the animal body. They are the most prominent example of effectors (see p. 816).

The cells that make up muscle tissues contain long filaments of proteins called actin and myosin, which interact to cause muscle cells to contract and exert force. There are three types of muscle tissues (**Figure 40.4**):

- *Skeletal muscle* (so named because most of it is attached to bone) is responsible for locomotion and other body movements such as facial expressions, shivering, and breathing.
- *Cardiac muscle* makes up the heart and is responsible for the beating of the heart and the pumping of blood.
- *Smooth muscle* makes up the walls of many hollow internal organs such as the gut, bladder, and blood vessels.

Connective tissues include bone, blood, and fat

The cells that make up connective tissues are generally dispersed in an extracellular matrix that these cells themselves secrete. The composition and properties of the matrix differ among the different types of connective tissues, but protein fibers are always an important component of the matrix. The dominant protein in the extracellular matrix is collagen (see Figure 5.22), which makes up about 25 percent of total body protein. Collagen fibers are strong and resistant to stretch, giving strength to the skin and to the connections between bones and between bones and muscles. These fibers also provide a netlike framework for organs, giving them shape and structural strength. Elastin is another protein fiber found in the extracellular matrix of connective tissues. It recoils after

(A) Skeletal muscle

(B) Cardiac muscle

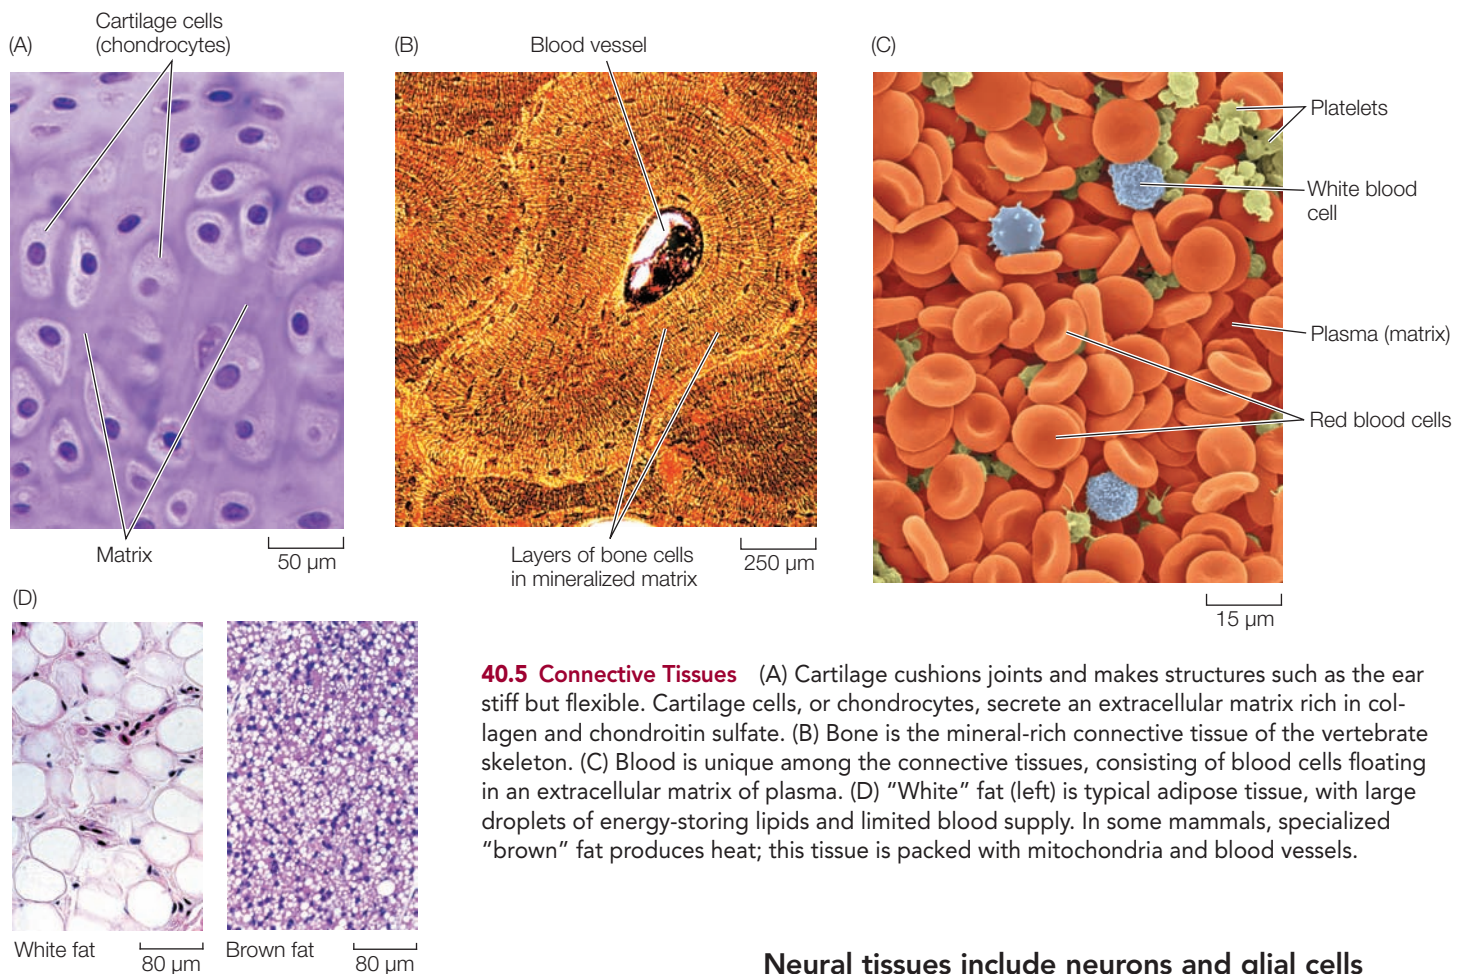

(C) Smooth muscle

40.4 Muscle Cells Contain Protein Filaments Filaments of two specific proteins—actin and myosin—interact to cause contraction and generate force in muscle tissue. (A) The regular arrangement of actin and myosin filaments results in the striated (striped) appearance of skeletal muscle. (B) The individual cells of cardiac muscle are branched and form a strong structural meshwork. (C) The actin and myosin filaments of smooth muscle are not regularly arranged and thus it does not have a striated appearance.

ance of skeletal muscle. (B) The individual cells of cardiac muscle are branched and form a strong structural meshwork. (C) The actin and myosin filaments of smooth muscle are not regularly arranged and thus it does not have a striated appearance.

being stretched, so elastin fibers are abundant in tissues that are regularly stretched, such as the walls of the lungs and the large arteries.

- *Cartilage* and *bone* (**Figure 40.5A,B**) are connective tissues that provide firm structural support.
- *Blood* (**Figure 40.5C**) is a connective tissue consisting of cells dispersed in an extensive liquid extracellular matrix, the blood plasma.
- *Adipose* cells (**Figure 40.5D**) form loose connective tissue that stores lipids. Adipose tissue, or "fat," is a major source of stored energy. It also cushions organs, and layers of adipose tissue under the skin can provide a barrier to heat loss.

40.6 Neural Tissue Includes Neurons and Glial Cells (A) This human neuron consists of a cell body, several processes that receive input from other neurons, and one long axon that sends information to other cells. (B) A section through human brain tissue shows astrocytes, a type of glial cell.

Neural tissues include neurons and glial cells

The many different cells of neural tissues are specialized for processing information. Nerve cells fall into one of two categories, neurons or glial cells.

- *Neurons* (**Figure 40.6A**) come in many shapes and sizes, but all neurons encode and conduct information as electrical signals. Most neurons release chemical signals that are received by target cells; the target cells can be other neurons,

muscle cells, or cells that secrete hormones and other molecules and substances, such as saliva.

- *Glial cells*, or *glia*, provide a variety of support functions for neurons (**Figure 40.6B**). One class of glia creates a barrier between the blood vessels and the neural tissue that protects the nervous system from potentially harmful chemicals circulating in the blood. Although glia do not generate electrical signals, they can communicate information through the release of chemical signals, and their roles in regulatory processes are becoming increasingly known. Chapters 45, 46, and 47 detail the properties of nervous tissues.

Organs consist of multiple tissues

Organs are composed of an epithelium and one or more other kinds of tissue. Indeed, most organs include all four tissue types. The wall of the gut is a good example (**Figure 40.7**). Its inner surface is lined with a sheet of columnar epithelial cells. Different types of epithelial cells in this lining secrete hormones or digestive juices or absorb nutrients from the gut. Beneath the epithelial lining is a layer of connective tissue called the mucosa. Within this connective tissue are blood vessels, neurons, and glands (clusters of secretory epithelial cells). Concentric layers of smooth muscle tissue

enable the gut to contract to mix food with digestive juices. A network of neurons between the muscle layers controls these movements.

An individual organ is usually part of an **organ system**, a group of organs that work together to carry out certain functions. The stomach, small intestine, liver, and pancreas, for example, are parts of the digestive system. Thus we see an organizational hierarchy, with cells forming tissues that become part of organs, which in turn are organized in the functioning physiological systems of an individual organism.

RECAP 40.2

There are four tissue types in the animal body: epithelial, connective, nervous, and muscle. Individual organs include tissues of multiple types and are part of organ systems

- Why is it crucial that the cells of epithelial tissue be densely packed into tight sheets? **See p. 817 and Figure 40.3**
- What is the key difference between neurons and glia, the two cell types that make up nervous tissue? **See pp. 819–820**
- What is meant by the hierarchical organization of physiological function? **See p. 820 and Figure 40.7**

Subsequent chapters will describe each of the organ systems mentioned above in much greater detail. The remainder of this chapter focuses on the mechanisms of homeostasis, using one important variable of the internal environment—temperature—as our example.

40.3 How Does Temperature Affect Living Systems?

Temperatures where organisms live vary enormously, from the boiling hot springs of Yellowstone National Park to the interior of Antarctica, where the temperature can fall below -80°C . Cells can function over only a narrow range of temperatures. If cells cool below 0°C , ice crystals form and damage cell structures. Some animals have adaptations, such as antifreeze molecules in their blood that help them resist freezing; others can survive freezing. Generally, however, cells must remain above 0°C to stay alive. The upper temperature limit for survival in most cells is about 45°C (although some specialized algae can grow in hot springs at 70°C , and some archaea live at near 100°C).

In general, proteins begin to denature and lose their function as temperatures rise above 40°C . Most cellular functions are limited to the range between 0°C and 40°C , which approximates the thermal limits for most organisms. Most species, however, have much narrower thermal limits. To stay within those limits in spite of environmental conditions, animals have evolved thermoregulatory adaptations. Those adaptations give them certain thermal tolerances, which determine their geographic ranges. When environments change rapidly, as may be happening as the global climate warms, animals may find themselves in situations that exceed their thermal tolerances.

40.7 Tissues Form Organs The organs of the human digestive system, such as the stomach and small intestine, are made up of all four tissue types.

Q_{10} is a measure of temperature sensitivity

Even between 0°C and 40°C, changes in tissue temperature create problems for animals. Most physiological processes, like the biochemical reactions that constitute them, are temperature-sensitive, going faster at higher temperatures (see Figure 8.20). The temperature sensitivity of a reaction or process is described in terms of Q_{10} , a factor calculated by dividing the rate of a process or reaction at a certain temperature, R_T , by that rate at a temperature 10°C lower, R_{T-10} :

$$Q_{10} = \frac{R_T}{R_{T-10}}$$

Q_{10} can be measured for a simple enzymatic reaction or for a complex physiological process, such as rate of oxygen consumption. If a reaction or process is not temperature-sensitive, it has a Q_{10} of 1. Most biological Q_{10} values are between 2 and 3. A Q_{10} of 2 means that the reaction rate doubles as temperature increases by 10°C, and a Q_{10} of 3 indicates a tripling of the rate over a 10°C temperature range (Figure 40.8).

You will notice that the Q_{10} values (except for $Q_{10} = 1$) plotted in Figure 40.8 produce curves rather than straight lines. This is because the temperatures increase in additive intervals (10, 20, 30, etc.) but the reaction rates increase in a multiplicative fashion (2, 4, 8, 16, 32, etc.). Such curvilinear plots are common in biological data.

Changes in body temperature can disrupt an animal's physiology because not all of the biochemical reactions that constitute the metabolism of an animal have the same Q_{10} . These biochemical reactions are linked together in complex networks: the products of one reaction are the reactants for other reactions. Because different reactions have different Q_{10} 's, changes in tissue temperature will shift the rates of some reactions more

40.8 Q_{10} and Reaction Rate The larger the Q_{10} of a reaction or process, the faster its rate rises in response to an increase in temperature.

40.9 Metabolic Compensation In its natural environment, a fish's metabolic rate readjusts, or acclimatizes, to compensate for seasonal changes in temperature.

than others, disrupting the overall network. Therefore, to maintain homeostasis, organisms must be able to compensate for or prevent changes in body temperature.

Animals acclimatize to seasonal temperatures

The body temperature of some animals (especially aquatic animals) is coupled to environmental temperature. The body temperature of a fish in a pond, for example, will be the same as the water temperature, which might range from 4°C in winter to 24°C in summer. If we bring that fish into the laboratory in the summer and measure the rates of any of its physiological or biochemical processes such as oxygen consumption, we will demonstrate a Q_{10} relationship. On the basis of that relationship, we can predict what the fish's metabolic rate will be in its pond in the winter. However, if we bring that fish back into the laboratory in the winter and measure its metabolic rate at winter pond temperature, we will find that rate to be higher than we predicted. The fish's biochemistry and physiology will have **acclimatized** to the seasonal change in water temperature so that it can remain active at winter temperatures (Figure 40.9). What could be the mechanism of this acclimatization? One possibility is that the fish may express isozymes with different temperature optima in summer and in winter. The ability of animals to acclimatize means that their metabolic functions are less sensitive to long-term changes in temperature than to short-term changes.

RECAP 40.3

Cells can survive only within a narrow range of temperatures, but even changes within that range can be disruptive because different physiological processes have different temperature sensitivities.

- Plot a $Q_{10} = 2.5$ curve for a physiological process. **See Figure 40.8**
- Explain how a change in body temperature can disrupt physiological processes. **See p. 821**

Now that we have seen how animals are affected by the temperature of their environments, we next take a look at the adaptations that allow animals to control and regulate their body temperatures.

40.4 How Do Animals Alter Their Heat Exchange with the Environment?

Animals have different ways of dealing with changes in environmental temperature. Many of us learned to think of animals as being either “cold-blooded” or “warm-blooded,” which implies a comparison with our own body temperature and sets mammals and birds apart from other animals. This simple classification breaks down when we realize that mammals that hibernate become cold, and that many reptiles and insects can have body temperatures similar to ours when they are active. Physiologists sometimes classify animals according to whether they have a constant body temperature (homeotherms) or a variable body temperature (poikilotherms). But there are situations where applications of these descriptive terms also lead to strange conclusions. A deep-sea fish has a constant body temperature. Should it be classified with mammals? And the hibernator’s body temperature in winter varies between a typical high mammalian level and a level that is close to environmental temperatures.

Another classification system is based on the source of heat that predominantly influences the body temperature of the animal. **Ectotherms** are animals whose body temperatures are determined primarily by external sources of heat. **Endotherms** can regulate their body temperatures by producing heat metabolically. Mammals and birds are endotherms—most of the time; other animals are ectotherms—most of the time. Therefore we have a third category: a **heterotherm** is an animal that sometimes behaves as an endotherm and at other times as an ectotherm. For example, a mammal that hibernates is an endotherm over the summer, but during its winter bouts of hibernation its internal heat production falls and it behaves much like an ectotherm. And some ectotherms can produce substantial amounts of metabolic heat, thus behaving like endotherms.

Endotherms produce substantial amounts of metabolic heat

Transfers of energy in biological systems are always inefficient, as Section 8.1 explained. With every transfer of energy—from food molecules to ATP, from ATP to biological work—some of the energy is lost as heat. This is true for both ectotherms and endotherms. In both cases, working muscles produce heat, as do the metabolic activities of all tissues. So why do endotherms produce more heat? The answer is that the cells of endotherms are less efficient at using energy than are the cells of ectotherms.

The cells of endotherms are more “leaky” to ions than are the cells of ectotherms. Therefore Na^+ ions are constantly diffusing into the cells, and K^+ ions are constantly diffusing out. Even an endotherm at rest must spend considerable amounts of energy to transport Na^+ out of the cells and transport K^+ back in. Because of their leaky membranes, endotherms expend more energy (and thus release more heat) than do ectotherms

just to maintain the ion concentration gradients across their cell membranes. This situation is analogous to a leaky rowboat: the faster water comes in (i.e., the faster ions leak), the more metabolic energy has to be expended to bail the water out (i.e., pump ions) just to remain afloat.

We can speculate that a mutation resulting in seemingly faulty or leaky ion channels may underlie the evolution of endothermy. Such a mutation in a small ectotherm would have increased its energy expenditure and therefore its heat production. Increased heat production would allow the animal to be active for a longer time after sunset. Being active in the evening would open up a new world of ecological opportunities—a world in which there was less competition from similar-sized ectotherms.

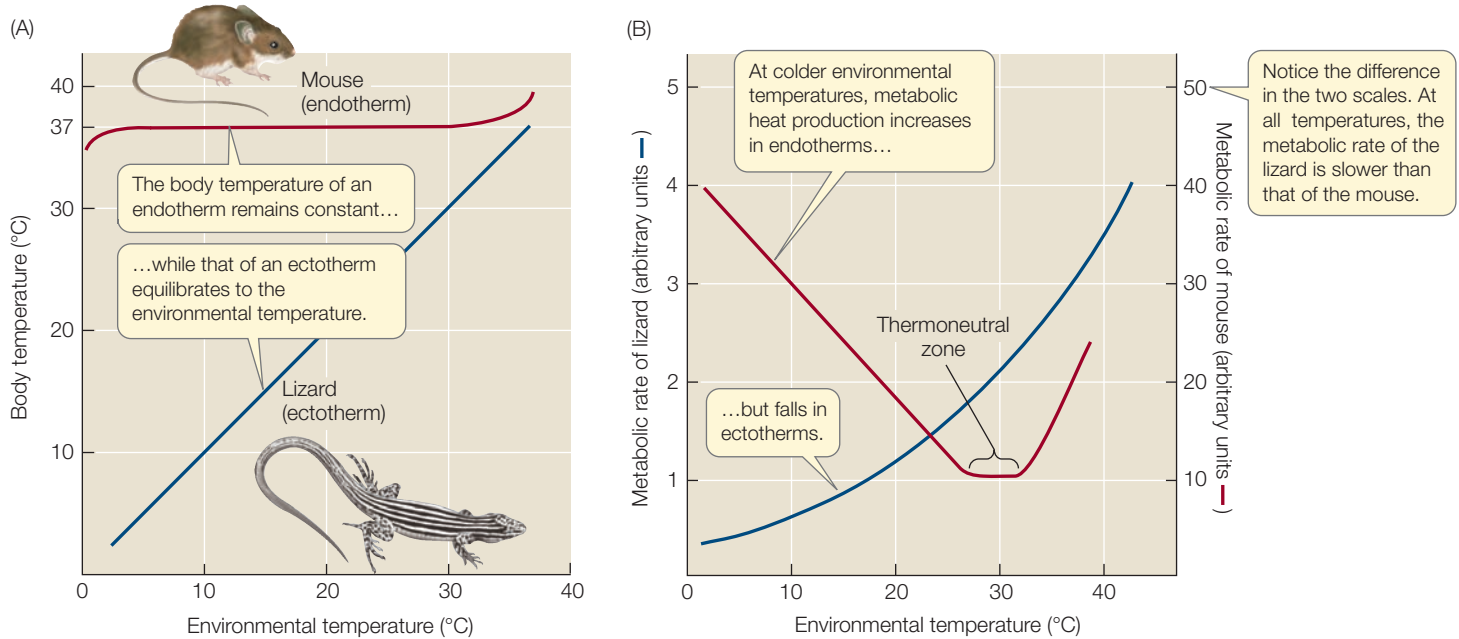

Two major differences between endotherms and ectotherms are their resting metabolic rates—the sum total of all energy expenditures in their bodies when at rest—and their responses to changes in environmental temperature.

Ectotherms and endotherms respond differently to changes in environmental temperature

How do two similar-size animals, a lizard (an ectotherm) and a mouse (an endotherm), respond to changes in environmental temperature? We put each animal in a closed chamber and measure its body temperature and its resting metabolic rate as we change the temperature of the chamber from 37°C to 0°C . The body temperature of the lizard equilibrates with that of the chamber, whereas the body temperature of the mouse remains stable (**Figure 40.10A**). The metabolic rate of the lizard (already lower than that of the mouse) decreases as the temperature drops (**Figure 40.10B**). In contrast, the mouse’s metabolic rate increases as the chamber temperature falls below 25°C . This increase in metabolism produces enough heat to prevent the mouse’s body temperature from falling. In other words, the mouse can regulate its body temperature by increasing its metabolic rate; the lizard cannot.

This experiment might lead us to conclude that the ectotherm cannot regulate its body temperature, but observations of the lizard in nature do not support this conclusion. In nature, unlike in the laboratory, the lizard’s body temperature is sometimes considerably different than the environmental temperature. Air temperature in the desert can fluctuate by 40°C in a few hours; the lizard, however, maintains a fairly stable body temperature by using behavior to alter its heat exchange with the environment (**Figure 40.11**). Its behavioral strategies include spending time in a burrow, basking in the sun, seeking shade, climbing vegetation, and changing its orientation with respect to the sun. Thus the lizard can regulate its body temperature quite well, although it does so by behavioral mechanisms rather than by altering its internal metabolic heat production.

Behavioral thermoregulation is not the exclusive domain of ectotherms. Endotherms usually select the most comfortable thermal environment possible. They may change posture, orient to the sun, move between sun and shade, and move between still air and moving air. Examples of more complex thermoregulatory behaviors include nest construction and social behaviors such as huddling. Humans put on or remove clothing and burn fossil fuels to generate the energy to heat or cool buildings.

40.10 Ectotherms and Endotherms React Differently to Environmental Temperatures (A) At the same environmental temperature, an ectotherm and an endotherm of approximately the same body size (here, a lizard and a mouse) have different body temperatures. (B) The metabolic rates of the lizard and mouse react in opposite ways to cooler temperatures. (The mouse's metabolic rate rises again at higher temperatures because, after a certain point, it takes metabolic energy to dissipate heat by sweating or panting.)

Energy budgets reflect adaptations for regulating body temperature

Both ectotherms and endotherms can influence their body temperatures by altering four avenues of heat exchange between their bodies and the environment (**Figure 40.12**):

- **Radiation** Heat moves from warmer objects to cooler ones via the exchange of infrared radiation (what you feel when you stand in front of a fire).

- **Convection** Heat transfers to a surrounding medium such as air or water as that medium flows over a surface (the wind-chill factor).
- **Conduction** Heat transfers directly between two objects at different temperatures when they come into contact (e.g., an icepack on a sprained ankle).
- **Evaporation** Heat transfers away from a surface when water evaporates on that surface (the effect of sweating).

The total balance of heat production and heat exchange can be expressed as an **energy budget**, based on the simple fact that if the body temperature of an animal is to remain constant, the heat entering the animal must equal the heat leaving it. The heat coming in is usually from metabolism and radiation (R_{abs} , for radiation absorbed). Heat leaves the body via the four mechanisms listed above—radiation emitted (R_{out}), convection, conduction, and evaporation. The energy budget takes the mathematical form

$$\underbrace{\text{heat}_{\text{in}}}_{\text{metabolism} + R_{\text{abs}}} = \underbrace{\text{heat}_{\text{out}}}_{R_{\text{out}} + \text{convection} + \text{conduction} + \text{evaporation}}$$

40.11 Using Behavior to Regulate Body Temperature The body temperature of a lizard (an ectotherm) depends on environmental temperature, but the lizard can regulate its temperature by moving from place to place within its environment.

40.12 Animals Exchange Heat with the Environment An animal's body temperature is determined by the balance between internal heat production and four avenues of heat exchange with the environment: radiation, convection, conduction, and evaporation.

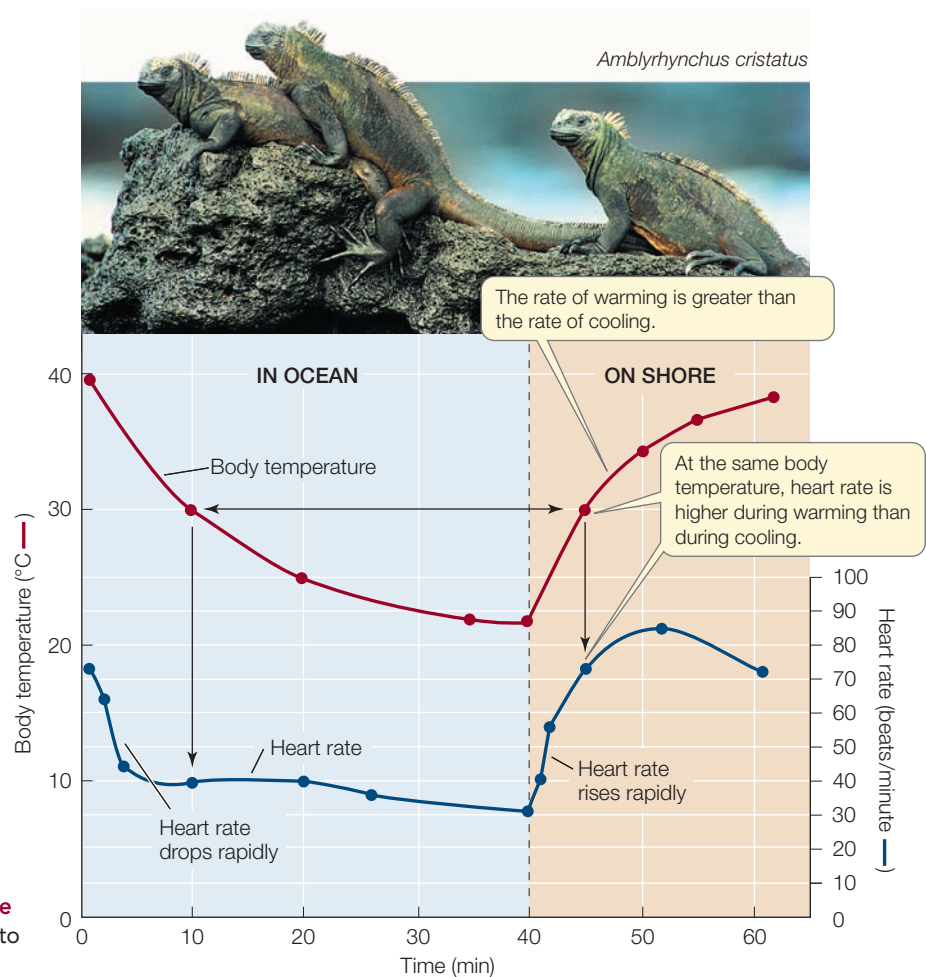

The energy budget is a useful concept because any adaptation that influences the ability of an animal to deal with its thermal environment must affect one or more components of the budget. So the energy budget gives us the ability to quantify and compare the thermal adaptations of animals. One interesting observation is that all of the components on the right side of the energy budget equation—that is, the heat-loss side—depend on the surface temperature of the animal. One way surface temperature can be controlled is by altering the flow of blood to the skin.

Both ectotherms and endotherms control blood flow to the skin

Heat exchange between the internal environment and the skin occurs largely through blood flow. As described at the beginning of this chapter, when body temperature rises because of exercise, blood flow to the skin increases, and the skin surface becomes warm. The heat that the blood brings from the body core to the skin is lost to the environment through the four avenues listed above, which helps bring the body temperature back to normal. In contrast, when body temperature is too low or the environment is too cold, the blood vessels supplying the skin constrict, reducing heat loss to the environment.

The ability to control blood flow to the skin can be an important adaptation for an ectotherm such as the marine iguana (a reptile) of the Galápagos archipelago (**Figure 40.13**). The Galápagos are volcanic islands that lie on the equator but are bathed by cold ocean currents. The iguanas bask on hot black lava rocks on the shore, but periodically they enter the cold ocean water to feed on seaweed. While the iguanas are feeding, they cool to the temperature of the sea. This cooling lowers their metabolism, making them slower, more vulnerable to predators, and incapable of efficient digestion. They therefore alternate between feeding in the cold seawater and basking on the hot rocks. It is advantageous for iguanas to retain body heat as long as possible while swimming and to warm up as fast as possible when basking. They can accomplish these results by changing their heart rate and thus the rate of blood flow to their skin.

40.13 Some Ectotherms Regulate Blood Flow to the Skin Galápagos marine iguanas control blood flow to the skin to alter their heating and cooling rates.

40.14 "Cold" and "Hot" Fish (A) In most fish species, the circulatory system conducts cool, oxygenated blood (red) from the gills through a large dorsal aorta to the rest of the body. By the time it returns to the heart, deoxygenated venous blood (blue) has been warmed by the metabolism of the muscles. (B) The anatomy of "hot" fish species includes a mechanism that allows heat to pass into cold arterial blood from the warmed venous blood so that both are at the same temperature. (C) The principle of this countercurrent heat exchange allows heat (orange) to be transferred with maximum efficiency.

What about furred mammals? Fur acts as insulation to keep body heat in, making it possible for mammals to function in cold environments. When they are active, however, mammals still must get rid of excess heat, and it does little good to transport that heat to the skin under the fur. Thus, as mentioned at the opening of this chapter, mammals have specialized blood vessels for transporting heat to their hairless skin surfaces. Heat loss from these areas is tightly controlled by the opening and closing of these blood vessels. When you are cold, the blood flow to your hands and feet decreases and they feel cold, but when you exercise, these same surfaces can get hot quickly.

Thermoregulation in Animals
Life10e.com/mc40.1

Some fish conserve metabolic heat

The muscles of active fish produce substantial amounts of metabolic heat, but they have difficulty retaining any of that heat. Blood pumped from the fish heart goes directly to the gills, where it must come very close to the surrounding water to exchange respiratory gases. So any heat that the blood picks up from metabolically active muscles is lost to the water flowing across its gills. It is thus surprising that some large, rapidly swimming fish, such as giant bluefin tuna and great white sharks, can maintain temperature differences as great as 10°C to 15°C between their bodies and the surrounding water. The heat comes from their powerful swimming muscles, and the ability of these "hot" fish to conserve that heat is based on the remarkable arrangement of their blood vessels.

In the typical ("cold") fish circulatory system, oxygenated blood from the gills collects in a large dorsal vessel, the aorta, and travels through the center of the fish, distributing blood to all organs and muscles (**Figure 40.14A**). "Hot" fish have a smaller central dorsal aorta; most of their oxygenated blood is transported in large side vessels just under their skin (**Figure 40.14B**). The cold blood leaving the gills is thus kept close to the surface of the fish as the blood flows posteriorly to the swimming muscles. Smaller vessels transport this cold blood into the muscle mass, and these small vessels run parallel to the vessels carrying warm blood from the swimming muscles back toward the heart. Because the vessels carrying the cold blood into the muscles are in close contact with the vessels carrying warm blood away, heat flows from the warm to the cold blood by conduction and is therefore retained in the muscle mass.

Because heat is exchanged between blood vessels carrying blood in opposite directions, this adaptation is called **countercurrent heat exchange** (**Figure 40.14C**). It keeps the heat within the muscles, enabling these fish to have an internal body temperature considerably higher than the water temperature. Each 10°C rise in muscle temperature increases the fish's sustainable power output almost threefold, giving it a faster swimming capability.

Some ectotherms regulate metabolic heat production

Some ectotherms raise their body temperature by producing metabolic heat. For example, the powerful flight muscles of many insects must reach 35°C to 40°C before the insects can fly, and they must maintain these high temperatures during flight. Such insects warm up to fly by contracting their flight

40.15 Bees Keep Warm in Winter Honey bee colonies survive winter cold because workers generate metabolic heat. In this infrared photograph of the center of an overwintering hive, individual bees are discernible by the heat their bodies produce as they cluster around their queen.

muscles in a manner analogous to shivering in mammals. The heat-producing ability of insects can be quite remarkable. Probably the most impressive case is a species of scarab beetle that lives mostly underground in mountains north of Los Angeles, California. These beetles come aboveground to mate, with the males flying in search of females. They undertake this mating ritual at night, in winter, and only during snowstorms.

Honey bees regulate temperature as a group. They live in large colonies consisting mostly of female worker bees that maintain the hive and rear the larval offspring of the single queen bee. During winter, worker bees cluster around the brood (eggs and larvae). They adjust their individual metabolic heat production and density of clustering so that the brood temperature remains remarkably constant, at about 34°C, even as the outside air temperature drops below freezing (**Figure 40.15**).

RECAP 40.4

Animals that can maintain constant high body temperatures because of their metabolic heat production are called endotherms. Those whose body temperatures are determined primarily by environmental sources of heat are called ectotherms. Heat exchange between an animal and its environment occurs via radiation, convection, conduction, and evaporation.

- Explain why the two curves in Figure 40.10A are different from the two curves in Figure 40.10B. **See p. 822**
- In terms of the energy budget, why is the control of blood flow to the skin so important for thermoregulation? **See pp. 823–824**
- Explain how countercurrent heat exchange makes it possible for some fish to have a body temperature higher than that of the surrounding water. **See p. 825 and Figure 40.14**

Endotherms respond to changes in environmental temperature by changing their rates of metabolic heat production. They also have other adaptations for controlling their rates of heat exchange with their environments. How do they regulate these various avenues of heat exchange to achieve a constant internal body temperature?

40.5 How Do Endotherms Regulate Their Body Temperatures?

Physiologists can determine an animal's metabolic rate by measuring its consumption of O_2 or production of CO_2 . Within a narrow range of environmental temperatures, called the **thermoneutral zone** (see Figure 40.10B), the metabolic rates of endotherms (birds and mammals) are at low levels and independent of temperature. The metabolic rate of a resting animal at a temperature within the thermoneutral zone is known as the **basal metabolic rate**, or **BMR**. It is usually measured in animals that are quiet but awake and not using energy for digestion, reproduction, or growth. Thus the BMR is the rate at which a resting animal is consuming just enough energy to carry out its minimal body functions.

Basal metabolic rates correlate with body size

As you might expect, the BMR of an elephant is greater than that of a mouse. After all, the elephant is more than 100,000 times larger than the mouse. However, the BMR of the elephant is only about 7,000 times greater than that of the mouse. That means that a gram of mouse tissue uses energy at a rate 15 times greater than a gram of elephant tissue (**Figure 40.16**). Across all of the endotherms, BMR per gram of tissue increases as animals get smaller.

40.16 The Mouse-to-Elephant Curve On a weight-specific basis, the metabolic rate of small endotherms is much greater than that of larger endotherms. This classic illustration originally published in the 1930s, plots O_2 consumption per kilogram of body mass (a measure of metabolic rate) against a logarithmic plot of body mass.

WORKING WITH DATA:

A Mammal's BMR Is Proportional to Its Body Size

Original Paper

White, C. R. and R. S. Seymour. 2003. Mammalian basal metabolic rate is proportional to body mass. *Proceedings of the National Academy of Sciences USA* 100: 4046–4049.

Analyze the Data

Studies conducted in the late 1800s concluded that BMR varied as a function of body mass to the $\frac{2}{3}$ power. This conclusion made sense because metabolism is a function of body mass (a cube function of a linear dimension), whereas heat loss is a function of body surface area (a square function of a linear dimension). Thus, because of this limitation on heat loss, BMR would have to decrease as body size increased.

Subsequent studies in the early 1900s, however, concluded that BMR varies as a function of body mass to the $\frac{3}{4}$ power. Recent theoretical considerations of fractal geometry led to support for this $\frac{3}{4}$ power function. The table at right gives a small subset of the data from ten species presented in the paper cited above.

QUESTION 1

Do you think these data support the $\frac{2}{3}$ power function or the $\frac{3}{4}$ power function?

QUESTION 2

You know from the “mouse-to-elephant curve” in Figure 40.16 that these data relate to each other as an exponential function and therefore produce a curvilinear plot. You can linearize the presentation of these data by conducting a logarithmic transformation. Using a calculator, create a new data table that

expresses the values below as \log_{10} values. Plot these values with body size (\log_{10} body mass) on the x axis and metabolic rate (\log_{10} BMR) on the y axis. Then, using a linear regression program on your calculator or computer, determine the equation that describes the graph you created in Question 2.

QUESTION 3

Remember that you transformed your data into logarithmic values, so in your equation, $y = \log_{10}$ BMR and $x = \log_{10}$ body mass. Convert your equation to a non-logarithmic form. Does your answer support the conclusion expressed in the title of the paper listed above?

Species	Body size (g)	BMR (ml O ₂ /hr)
Bat	16	40
Mouse	30	63
Rat	400	146
Muskrat	1,000	640
Marmot	4,000	1,550
Beaver	10,000	4,500
Coyote	10,000	2,690
Baboon	17,000	5,150
Antelope	37,800	9,300
Moose	325,000	51,400

Go to **BioPortal** for all **WORKING WITH DATA** exercises

Why should this disproportionate difference exist? There are several possible reasons. As animals get bigger, they have a smaller ratio of surface area to volume (see Figure 5.2). Since heat production is related to the volume (i.e., mass) of the animal, but its capacity to dissipate heat is related to its surface area, it has been reasoned that larger animals evolved lower metabolic rates to avoid overheating. However, this explanation alone is insufficient because the relationship between body mass and metabolic rate holds for even very small organisms and for ectotherms, in which overheating is not a problem. Other hypotheses have also been proposed. For example, a larger animal has a greater proportion of support tissues (e.g., skin and bone), which are not as metabolically active as other tissue types. The real explanation is probably a mixture of different factors, but the relationship holds over a very broad range of species.

For an endotherm, a metabolic rate versus environmental temperature curve represents the integrated response of all the animal's thermoregulatory adaptations (**Figure 40.17**). The thermoneutral zone is bounded by a lower and an upper **critical temperature**. When the environmental temperature is within its thermoneutral zone, an endotherm's thermoregulatory responses do not require much energy and could be considered passive; such responses include changing

posture, fluffing fur, and controlling blood flow to the skin. Outside its thermoneutral zone, however, an endotherm's thermoregulatory responses are active and require considerable metabolic energy.

Endotherms respond to cold by producing heat and adapt to cold by reducing heat loss

When environmental temperatures fall below the lower critical temperature, endotherms must produce heat to compensate for the heat they lose to the environment. Mammals can accomplish this by shivering and/or nonshivering heat production. Birds use only shivering heat production. Shivering uses the contractile machinery of skeletal muscles to convert ATP to ADP, with the energy from this process released as heat. Shivering muscles pull against each other so that little movement other than a tremor results. “Shivering heat production” is perhaps too narrow a term, however; increased muscle tone and increased body movements also contribute to increased heat production in cold environments.

Most nonshivering heat production occurs in specialized adipose tissue called **brown fat** (see Figure 40.5D). This tissue looks brown because of its abundant mitochondria and rich blood supply. In brown fat cells, a protein called thermogenin uncouples proton movement from ATP production,

40.17 Environmental Temperature and Mammalian Metabolic Rates A plot of an endotherm's metabolic rate versus environmental temperature represents the integrated response of all of its thermoregulatory mechanisms. Outside the thermoneutral zone, maintaining a constant body temperature requires expending energy. Outside extreme limits (0°C and 40°C in this instance), the animal cannot maintain its body temperature and dies.

allowing protons to leak across the inner mitochondrial membrane rather than having to pass through the ATP synthase and generate ATP (review the discussion of brown fat and the chemiosmotic mechanism in Chapter 9). As a result, metabolic fuels are consumed without producing ATP, but heat is still released. Pads of brown fat are found in newborns of many mammalian species (including humans), in some adult mammals that are small and acclimatized to cold, and in mammals that hibernate. Recently it has been discovered that adult humans have small amounts of brown fat distributed around the body and that its metabolic activity is stimulated by cold exposure. One study found less brown fat activity in obese than in lean individuals, leading to the hypothesis that individual differences in propensity for weight gain may be related to the amount of brown fat in an individual, as described in the opening stories of Chapters 9 and 41.

In addition to their ability to produce heat, endotherms that live in cold climates have evolved adaptations to reduce their heat loss. Heat is lost from the body surface, and cold-climate species have anatomical adaptations that give them smaller surface-to-volume ratios than their warm-climate relatives (Figure 40.18). These adaptations include rounder body shapes and shorter appendages.

The most common and important means of decreasing heat loss is to increase thermal insulation. Animals adapted to cold climates have much thicker layers of fur, feathers, or fat than do their warm-climate relatives. Fur and feathers are good insulators because they trap a layer of still, warm air close to the skin surface. If that air is displaced by water, insulation is drastically reduced. In many species, oil secretions spread through fur or feathers by grooming are critical for resisting wetting and maintaining a high level of insulation.

The ability to decrease blood flow to the skin is an important thermoregulatory adaptation for cold-climate endotherms. Constriction of blood vessels in the skin, and especially in the appendages, greatly improves an animal's ability to conserve heat. Countercurrent heat exchange like that we saw in "hot" fish is also an important adaptation in the appendages of endotherms. Blood flowing out to the paw of a wolf, the hoof of a caribou, or the foot of a bird parallels the flow of the blood returning to the body core. Heat is transferred from the outgoing to the returning blood, thus retaining heat in the animal's core.

Go to Activity 40.1 Thermoregulation in an Endotherm
Life10e.com/ac40.1

40.18 Adaptations to Cold and Hot Climates (A) The antelope jackrabbit is found in the Sonoran Desert of Arizona. Its large ears serve as heat exchangers, passing heat from the animal's blood to the surrounding air. (B) The thick fur of the Arctic hare provides insulation and its rounded body shape lowers its surface-to-volume ratio. The ears and extremities are smaller than those of its warm-climate relatives so less heat is lost to the environment.

Evaporation of water can dissipate heat, but at a cost

As environmental temperature rises within an endotherm's thermoneutral zone, the animal dissipates more of its metabolic heat by increasing blood flow to the skin, seeking shade and cool breezes, and decreasing activity. When the temperature exceeds the upper critical temperature, however, overheating becomes a problem. For exercising animals (including athletes), overheating can occur even at low environmental temperatures. Large mammals, especially those in hot habitats such as elephants, rhinoceroses, and water buffaloes, have little or no insulating fur and seek out water to wallow in when the air temperature is high. Having water in contact with the skin greatly increases heat loss because the heat-absorbing capacity of water is much greater than that of air.

Evaporation from external or internal body surfaces through sweating or panting can also cool an endotherm. A gram of water absorbs about 580 calories of heat when it evaporates. If this evaporation occurs on the skin, most of the heat comes from the skin. However, sweat or saliva that falls off the body provides no cooling. Thus when the need for heat loss is greatest, water from the internal environment can be squandered with no cooling benefit. Water is heavy, so animals do not carry an excess supply of it, and many hot environments are also arid. In habitats that are both hot and dry, sweating and panting are cooling adaptations of last resort.

Sweating and panting are *active* processes that require expending metabolic energy. That is why the metabolic rate increases when the upper critical temperature is exceeded (see Figure 40.17). A sweating or panting animal is generating heat in the process of dissipating heat, which can be a losing battle.

The mammalian thermostat uses feedback information

The thermoregulatory mechanisms and adaptations of endotherms that we have just discussed are controlled by neural regulatory systems that integrate information from environmental and physiological sources and then issue commands to the effectors that alter the heat content of the body. These regulatory systems are similar in principle in birds and mammals but differ in many details. Here we focus on the nervous system thermostats of mammals.

The major thermoregulatory integrative center of mammals is at the base of the brain in a structure called the **hypothalamus**. As we will see in upcoming chapters, the hypothalamus is a key player in many animal regulatory systems. Experiments demonstrating its role have shown that slight cooling of the hypothalamus stimulates constriction of skin blood vessels and that stronger cooling increases metabolic heat production. As a result, cooling of the hypothalamus in an unchanging, thermoneutral environment will cause body temperature to rise. Conversely, hypothalamic heating causes the overall body temperature to fall (Figure 40.19).

In mammals, the temperature of the hypothalamus itself is the major feedback signal. The hypothalamus generates set points for thermoregulatory responses. When the temperature

INVESTIGATINGLIFE

40.19 The Hypothalamus Regulates Body Temperature

A mammal's hypothalamus was subjected directly to temperature manipulation. The body's responses to the manipulations were as expected if the hypothalamus is the mammalian "thermostat."^a

HYPOTHESIS Heating or cooling the mammalian hypothalamus results in predictable changes in body temperature.

Method

1. Implant a probe into the hypothalamus of a living ground squirrel's brain. Use the probe to heat or cool the hypothalamus directly (i.e., without affecting the ambient temperature).
2. Manipulate the hypothalamic temperature T_H .

3. Measure the animal's metabolic rate and body temperature throughout the period of hypothalamic manipulation.

Results

- 1 When the hypothalamus was cooled, metabolic heat production increased and the animal's body temperature rose.
- 2 When the hypothalamus was heated, the squirrel's metabolic rate and body temperature fell.

CONCLUSION The ground squirrel's hypothalamus acts as a thermostat. When cooled it activates metabolic heat production; when warmed, it suppresses metabolic heat production and favors heat loss.

Go to **BioPortal** for discussion and relevant links for all INVESTIGATINGLIFE figures.

^aHeller, H. C. and G. W. Collier. 1974. *American Journal of Physiology* 227: 583–589.

of the hypothalamus exceeds or drops below those set points, thermoregulatory responses are activated to reverse the direction of temperature change (Figure 40.20). The system integrates other sources of information in addition to hypothalamic temperature. For example, temperature sensors in the skin register environmental temperature. A change in skin temperature is feedforward information that shifts hypothalamic set points; the set point for metabolic heat production is higher when the skin is cold and lower when the skin is warm.

40.20 The Mammalian Thermostat Like the home thermostat in Figure 40.2, the mammalian hypothalamus is the regulatory system that controls the body's heating and cooling mechanisms.

Go to Animated Tutorial 40.1
The Hypothalamus
Life10e.com/at40.1

Hypothalamic set points are higher during wakefulness than during sleep, and they are higher during the active part of the daily cycle than the inactive part, even if the animal is awake at both times. Even when an endotherm is kept under constant environmental conditions, its body temperature displays a daily cycle of changes in set point. This kind of cycle is controlled by an internal biological clock, as we will discuss in Chapter 53.

Fever helps the body fight infections

Fever is an adaptive response that helps the body fight pathogens. A fever is a rise in body temperature in response to molecules called **pyrogens**. Pyrogens can be exogenous, such as foreign proteins produced by bacteria or viruses that invade the body, or endogenous, including substances produced by cells of the immune system in response to infection.

The presence of a pyrogen causes a rise in the body's hypothalamic set point for metabolic heat production. As a result, you shiver, put on a sweater, or crawl under a blanket, and your body temperature rises until it matches the new set point. At the higher body temperature you no longer feel

cold, and you may not feel hot, but someone touching your forehead will say that you are "burning up." Taking aspirin lowers your set point to normal. Now you feel hot, take off clothes, and even sweat until your elevated body temperature returns to normal. Although modest fevers help the body fight infections, extreme fevers can be dangerous and must be controlled, usually with fever-reducing drugs.

Some animals conserve energy by turning down the thermostat

Hypothermia is a below-normal body temperature. It can result from starvation (lack of metabolic fuel), exposure to extreme cold, serious illness, or anesthesia. In each of these cases, the drop in body temperature is unregulated. However, many birds and mammals undergo *regulated* hypothermia to survive periods of cold and food scarcity.

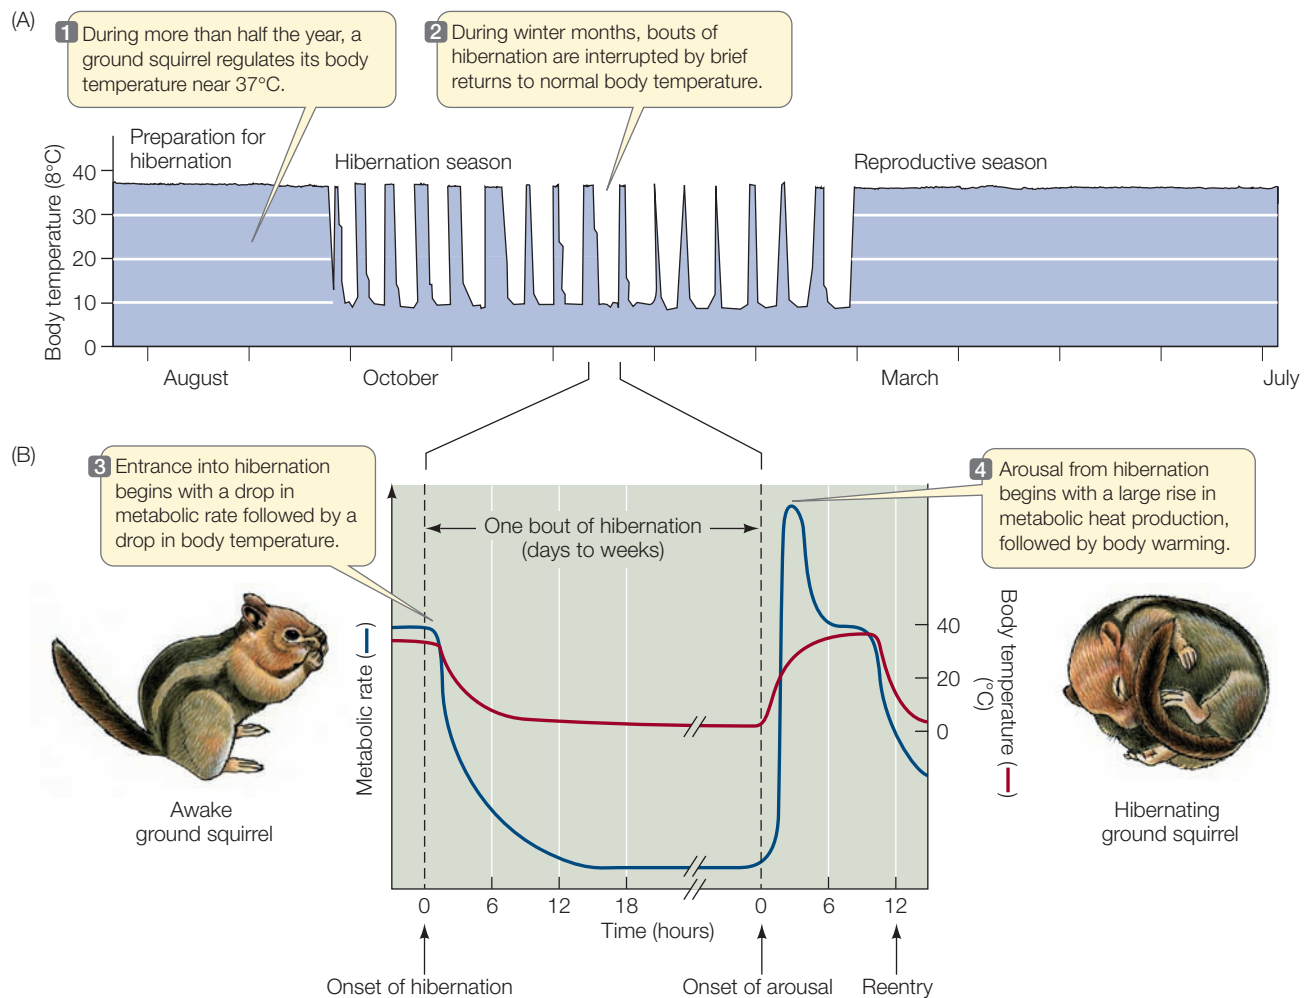

Hummingbirds, for example, are very small endotherms with a high metabolic rate, and going even a single day without food could exhaust their metabolic reserves. Hummingbirds and other small endotherms can extend the period over which they can survive without food by dropping their body temperature 10°C to 20°C during the portion of day or night when they are normally inactive, thus lowering their metabolic rate and conserving energy. This adaptive hypothermia is called **daily torpor**.

Regulated hypothermia that lasts for days or even weeks, during which the body temperature falls close to the ambient temperature, is called **hibernation** (Figure 40.21). Many species of mammals, including bats, bears, marmots, and ground squirrels, hibernate, but only one species of bird (the poorwill) has been shown to hibernate. The metabolic rate needed to sustain a hibernating animal may be only one-fiftieth its basal metabolic rate, and many hibernating animals maintain body temperatures close to the freezing point. Arousal from hibernation occurs when the hypothalamic set point returns to the normal level. The ability of animals to enter daily torpor or deep hibernation to reduce their thermoregulatory set point so dramatically probably evolved as an extension of the set point decrease that accompanies sleep in all mammals and birds.

RECAP 40.5

Within the thermoneutral zone, an endotherm controls its body temperature principally by passive means. Above or below the thermoneutral zone, an endotherm must expend considerable metabolic energy to control its body temperature. Thermoregulatory responses in mammals are regulated by the hypothalamus.

- Describe how endotherms produce heat. [See pp. 827–828 and Figure 40.17](#)
- Why is dependence on evaporative water loss a dangerous strategy for dealing with hot environments? [See p. 829](#)
- What is the nature of the negative feedback information and feedforward information used by the mammalian thermostat? [See pp. 829–830 and Figure 40.20](#)

40.21 Hibernation Patterns in a Ground Squirrel During most of the year, the ground squirrel regulates its body temperature around 37°C. During winter months, however, these animals hibernate in underground burrows, living off stored fuel (in the form of either fat or cached food). The metabolic demands for these stored fuels are decreased by bouts of torpor, during which body temperature drops close to that of the environment for long periods of time.

Can we increase heat loss from our natural heat portals to protect against heat stress?

ANSWER

Normally, blood flows from the heart through large arteries, through the tiny capillaries, and then into larger veins that carry the blood back to the heart. The evolutionary adaptations of the “heat portals” in non-hairy mammalian skin, however, includes gated shunts that can deliver arterial blood directly to veins, bypassing the slower flow of the capillaries. The veins in non-hairy skin form networks that can accommodate a large volume of blood when the shunts are open. Based on this knowledge, biologists at Stanford University developed a “rapid-cooling” technology that maximizes heat extraction from non-hairy skin. An area such as the palm of the hand is placed in contact with a cooled surface and a mild vacuum is used to pull more blood into the large, heat-exchanging blood vessels. When this device

is used, body temperature rises more slowly during exercise and cools more rapidly during rest after exercise.

An unexpected by-product of the Stanford discovery was enhanced athletic performance. Because muscle fatigue is partly due to increased muscle temperature, enhanced cooling can reduce fatigue and increase exercise capacity, which in turn can lead to conditioning gains. In one study, first-year college students in a conditioning program improved their push-up performance at a rate of 5 push-ups a day without cooling, but 9 push-ups a day with cooling. Some men and women in the study achieved more than 800 push-ups or hundreds of pull-ups in a 45-minute workout session.

CHAPTER SUMMARY 40

40.1 How Do Multicellular Animals Supply the Needs of Their Cells?

- Multicellular animals provide for the needs of all their cells by maintaining a stable **internal environment**. That environment consists of two extracellular fluid compartments: the **interstitial fluid** and the blood **plasma**. **Review Figure 40.1**
- Regulation of physiological systems is mostly through **negative feedback**. **Feedforward information** functions to change **set points**. **Review Figure 40.2**

40.2 What Are the Relationships between Cells, Tissues, and Organs?

- The cells of the body are organized into assemblages called **tissues**.
- Although there are many cell types, there are only four tissue types: **epithelial**, **muscle**, **connective**, and **neural** tissues.
- **Organs** are made up of tissues, and most organs contain all four types of tissues. Organs are grouped into **organ systems**. **Review Figure 40.7**

40.3 How Does Temperature Affect Living Systems?

- Life is possible only within a narrow range of environmental temperatures. Q_{10} is a measure of the sensitivity of a life process to temperature. A Q_{10} of 2 means that the reaction rate of that process doubles as temperature increases by 10°C. **Review Figure 40.8**
- Animals can acclimatize to seasonal changes in temperature through biochemical and physiological adaptations. **Review Figure 40.9**

40.4 How Do Animals Alter Their Heat Exchange with the Environment?

- The body temperatures of **ectotherms** are determined primarily by external sources of heat. **Endotherms** regulate their body temperatures by producing heat metabolically. **Review Figure 40.10**
- The four avenues of heat exchange with the environment are **radiation**, **convection**, **conduction**, and **evaporation**. The balance between heat production and heat exchange can be expressed as an **energy budget**. **Review Figure 40.12**
- Control of blood flow to the skin is an important means of temperature regulation. Circulatory system adaptations such as **countercurrent heat exchange** can conserve metabolic heat. **Review Figures 40.13, 40.14**

40.5 How Do Endotherms Regulate Their Body Temperatures?

- Within the **thermoneutral zone**, resting endotherms have a **basal metabolic rate (BMR)** that scales with body size. **Review Figures 40.16, 40.17, ACTIVITY 40.1**
- In mammals, control of body temperature relies on commands from a regulatory center in the **hypothalamus**. This thermostat uses its own temperature as negative feedback information and skin temperature as feedforward information. **Review Figure 40.20, ANIMATED TUTORIAL 40.1**

CHAPTER REVIEW

REMEMBERING

- Which of the following best describes the limits to life on earth?
 - The freezing point and the boiling point of water
 - The effects of temperature on biochemical rates of reaction
 - The freezing point of water and the temperature at which proteins denature
 - The ability of the organism to actively produce and dissipate heat
 - The effect of temperature on the oxygen content of the environment
- If the Q_{10} of an animal's metabolic rate is 2, then
 - the animal is better acclimatized to a cold environment than if its Q_{10} were 3.
 - the animal is an ectotherm.
 - the animal consumes half as much oxygen per hour at 20°C as it does at 30°C.
 - the animal's metabolic rate is not at basal levels.
 - the animal produces twice as much heat at 20°C as it does at 30°C.
- Which statement about brown fat is true?
 - It produces heat without producing much ATP.
 - It insulates animals acclimatized to cold.
 - It is a major source of heat production for birds.
 - It is found only in hibernators.
 - It provides fuel for muscle cells.
- Which of the following is the most important and most general characteristic of endotherms adapted to cold climates compared with endotherms adapted to warm climates?
 - Higher basal metabolic rates
 - Higher Q_{10} values
 - Brown fat
 - Greater insulation
 - Ability to hibernate

5. Which of the following would cause a decrease in the hypothalamic temperature set point for metabolic heat production?
- Entering a cold environment
 - Taking an aspirin when you have a fever
 - Arousing from hibernation
 - Getting an infection that causes a fever
 - Cooling the hypothalamus

UNDERSTANDING & APPLYING

6. What is the advantage of feedforward information for homeostasis? Can you suggest what some sources of feedforward information could be for regulation of breathing, blood pressure, and secretion of digestive juices?
7. Newton's law of cooling describes how a physical object comes into thermal equilibrium with its environment. This law can be expressed as

$$HL = K(T_o - T_a)$$

where HL is the rate of heat loss, K is the thermal conductance constant (how easily an object loses heat), T_o is the temperature of the object, and T_a is the ambient temperature. Apply this expression to the metabolic rate/environmental temperature curve for endotherms (see Figure 40.17). What would be the equivalent of HL ? In Newton's law of cooling, K is a constant reflecting the properties of the object. What would K represent for an endotherm? What would $1/K$ represent? Using a version of Newton's law that replaces T_o with T_b (body temperature), explain why the curve projects to zero at an ambient temperature that equals body temperature.

8. What do you expect to be the effect of temperature on the ability of a heart to pump blood and the ability of skeletal muscle to contract? How does this create a physiological challenge for a great white shark or a giant bluefin tuna?

ANALYZING & EVALUATING

The following data from the White and Seymour paper cited in the Working with Data exercise (p. 827) should be used to answer Questions 9 and 10.

Species	Body mass (kg)	Heart size (g)	BMR (ml O ₂ /hr)
Mouse	0.03	0.2	63
Rat	0.4	1.5	146
Muskrat	1.0	8	640
Marmot	4	24	1,550
Coyote	10	60	2,690
Baboon	17	100	5,150

9. Plot the data for (1) BMR versus body mass and (2) heart mass versus body size. Describe the differences between these two curves.
10. The BMR is supported by the amount of blood pumped by the heart, and the amount of blood the heart can pump depends on its size (volume). What other factor would you propose to explain the differences between these two curves?
11. The observations on the Galápagos marine iguana in Figure 40.13 showed that this animal's body temperature rose faster in air than it fell in water. The inference was that the iguana was influencing its gain or loss of heat by altering the blood flow to its skin. However, the thermal properties of air and water are different, and the animal was breathing when in air, but not while swimming. In terms of the energy budget

$$\underbrace{\text{heat}_{\text{in}}}_{\text{metabolism} + R_{\text{abs}}} = \underbrace{\text{heat}_{\text{out}}}_{R_{\text{out}} + \text{convection} + \text{conduction} + \text{evaporation}}$$

what factors other than blood flow to the skin could influence these rates of heat exchange, and what experiment could you do to strengthen the argument that changes in blood flow to the skin were critical variables?

Animal Hormones

CHAPTER OUTLINE

- 41.1** What Are Hormones and How Do They Work?
- 41.2** What Have Experiments Revealed about Hormones and Their Action?
- 41.3** How Do the Nervous and Endocrine Systems Interact?
- 41.4** What Are the Major Endocrine Glands and Hormones?
- 41.5** How Do We Study Mechanisms of Hormone Action?

IF YOU ARE a person who eats a lot but never puts on weight, it is likely that you also exercise regularly. But do you stay thin simply because exercising burns the excess calories that would otherwise be stored as fat? We learned in earlier chapters that typical adipose tissue, or “white” fat, stores lipids, whereas “brown” fat metabolizes lipids to produce heat without producing ATP. Brown fat is known to be present in cold-acclimated rodents, hibernators, and newborn humans, but it was not thought to be present in adult humans. Recently, however, imaging techniques revealed brown fat activity in cold-exposed adults. What was interesting was that the amount of brown fat was inversely proportional to total body mass—lean people had more brown fat and obese people had less. It was suggested that the excess calories burned by the brown fat were responsible for low body mass.

A recently discovered signaling molecule may explain the difference in individual propensity to put on weight. The molecule has been classified as a hormone and given the name *irisin*, after the mythological character Iris. *Irisin* was discovered in a strain of mice bred for increased exercise endurance capacity, and it was shown that the molecule is released from muscles. It has been well documented that exercise training causes numerous structural and metabolic changes in muscle. But exercise training also improves many other aspects of health. How are these changes mediated? Analysis of fat tissue from the super athletic mice showed a remarkable finding: their white fat had properties of brown fat. It was then shown

Exercised Muscles Secrete a Hormone Research on mice has shown that *irisin*, a hormone produced by exercising muscles, travels to fat cells in the body, where it stimulates molecular changes that make the adipose tissue more metabolically active.

that this “browning” of the white fat was triggered by a blood-borne chemical signal produced by the exercising muscles. Thus the muscle is telling the white fat to change its properties to a tissue that is more metabolically active, burns more calories, and produces more heat. So exercise improves the condition of muscles, and it also causes the muscles to talk to adipose tissues, telling them to “shape up.”

Why did the scientists call their signaling molecule a hormone and choose to name it after Iris? As we will discuss in this chapter, a hormone is a chemical message that circulates in the blood and activates distant target cells. In Greek mythology, Iris was a messenger of the gods, traveling the world with the speed of the wind.

How can we demonstrate that a molecule found in the blood is a hormone?

See answer on p. 853.

41.1 What Are Hormones and How Do They Work?

In multicellular animals, physiological regulatory systems require information and cell-to-cell communication. Most intercellular communication is by means of chemical signals that bind to receptors, as described in Chapter 7. Examples of chemical signals include hormones, growth factors and morphogens, cytokines, and neurotransmitters. These signals operate in different contexts—the endocrine system, growth and development, the immune system, and the nervous system—but the principles of their function are the same: one cell releases a chemical signal that travels to and binds to a receptor on a second cell (the “target”), causing a response in the target cell.

Not all signaling is chemical; keep in mind that there are receptors in the nervous system that encode information from external physical sources, such as temperature, pressure, and light. And the nervous system uses electric signals called action potentials to get information from place to place in the body. Regardless of the system, the processing of information depends on which cells have receptors for the signals and how those target cells respond to the signals.

Some analogies might help distinguish how the immune, nervous, and endocrine informational systems operate. The immune system (the topic of Chapter 42) operates like an army of private security guards. The various cellular agents make their rounds of the body, and if they detect a security breach, they sound their alarms—cytokines—that activate the body’s defenses. The nervous system (see Chapters 45–47) operates like a landline telephone system, with a central integration and command center that sends signals along specific wires to specific receivers. This chapter focuses on the endocrine system, which is more like a radio or television network, broadcasting signals that can be picked up by anyone who has an appropriate receiver that is turned on and tuned in.

Endocrine signaling can act locally or at a distance

The many and varied types of **endocrine cells** produce and release chemical signals directly into the extracellular fluid (ECF). These molecules may then diffuse through the ECF and enter the bloodstream. Endocrine signals that enter the blood are called **hormones**, and hormones activate target cells far from their site of release (**Figure 41.1A**). Irisin is an example of a hormone. You probably are familiar with several other hormones, such as testosterone, estrogen, adrenaline, and insulin.

Some endocrine signals are released in such tiny quantities, or are so rapidly inactivated by enzymes, or are taken up so efficiently by local cells that they never diffuse into the blood in sufficient amounts to act on distant cells (**Figure 41.1B**). Because these signals affect only target cells near their release site, they are called **paracrine** (*para*, “near”). An example of a paracrine signal is histamine, one of the mediators of inflammation. The most local action an endocrine signal can have is when it binds to receptors on or in the same cell that secreted it. When a chemical signal influences the cell that secreted it, it is called an **autocrine**. Hormones and paracrine

41.1 Chemical Signaling Systems (A) Hormones are distributed throughout the body in the bloodstream. (B) Paracrine and autocrine signals do not enter the blood. Paracrine signals simply diffuse to nearby cells, and autocrine signals influence the same cells that release them.

autocrine functions as a means of providing negative feedback to control their own rates of secretion.

Some endocrine cells exist as single cells within a tissue. Hormones of the digestive tract, for example, are secreted by isolated endocrine cells in the walls of the stomach and small intestine. Many hormones are secreted by aggregations of endocrine cells in secretory organs called **endocrine glands**. A single endocrine gland may secrete multiple hormones.

The name “endocrine” (Greek, “separated within”) reflects the fact that the substances secreted by these cells are secreted directly into the “internal environment,” the extracellular fluid (see Section 40.1). From the ECF they can diffuse locally or enter the bloodstream. **Exocrine glands**, in contrast, have ducts through which the products of exocrine cells are carried to an *external* environment such as the surface of the skin or a body cavity such as the gut (sweat and salivary glands are examples).

(A) Protein hormones

41.2 Three Classes of Hormones (A) The largest hormone molecules are peptides and proteins. This class includes insulin and growth hormone. (B) Steroid hormones are modified from cholesterol molecules. They include the corticosteroids produced by the adrenal gland and the sex steroids produced primarily by the gonads. (C) Amine hormones are tiny molecules synthesized from a single amino acid. Both epinephrine and thyroxine are synthesized from tyrosine units, but thyroxine is lipid-soluble and epinephrine is water-soluble. Their modes of release and transport and the locations of their receptors differ accordingly.

To complete our overview of intercellular chemical communication, we must mention neurotransmitters, which we will discuss in detail in Chapters 45 through 47. Neurons, the cells of the nervous system, conduct information over long distances as electric signals, but where a neuron communicates that information to another cell, it does so by releasing chemical signals called neurotransmitters. Most neurotransmitters act very locally (frequently on the same neuron that released them). Some, however, diffuse into the blood and act on distant targets; neurotransmitters that act in this manner are referred to as **neurohormones**.

Hormones can be divided into three chemical groups

There is enormous diversity in the chemical structure of hormones, but by and large they can be classified into three groups:

- The majority of hormones are peptides or proteins. These hormones (insulin is an example; **Figure 41.2A**) are water-soluble and thus easily transported in the blood without carrier molecules. Peptide and protein hormones can be packaged in vesicles within the cells that make them, and then released by exocytosis. Their receptors are on cell surfaces.
- **Steroid hormones** (such as estrogen and testosterone) are synthesized from the steroid cholesterol (**Figure 41.2B**), are lipid-soluble, and pass easily through cell membranes. Steroid hormones diffuse out of the cells that make them and

(B) Steroid hormones

(C) Amine hormones

are usually bound to carrier molecules in the blood. Their receptors are mostly intracellular.

- **Amine hormones** are mostly synthesized from the amino acid tyrosine (thyroxine is one example; **Figure 41.2C**). Some amine hormones are water-soluble and others are lipid-soluble; their modes of release differ accordingly.

Hormone action is mediated by receptors on or within their target cells

Water-soluble hormones cannot pass readily through plasma membranes, so their receptors must be located on the surfaces

of target cells. These receptors are large transmembrane glycoprotein complexes with three domains: a binding domain that projects outside the plasma membrane, a transmembrane domain that anchors the receptor in the membrane, and a cytoplasmic domain that extends into the cytoplasm of the cell. When a hormone binds to the binding domain, the cytoplasmic domain initiates the target cell's response. Second messengers activate a cascade of intracellular events, eventually activating protein kinases or protein phosphatases (see Figures 7.6 and 7.7). In most cases these protein kinases and phosphatases activate or inactivate enzymes in the cytoplasm that lead to the cell's response, but the signaling cascade initiated by the receptor can also generate signals that enter the nucleus and alter gene expression (see Figure 7.10).

Lipid-soluble hormones can diffuse through plasma membranes, and therefore their receptors are usually inside cells, in either the cytoplasm or the nucleus (although some membrane-bound receptors for lipid-soluble hormones have recently been described). In most cases, the complex formed by the lipid-soluble hormone and its receptor acts by altering gene expression in the cell's nucleus (see Figure 7.8).

Hormone action depends on the nature of the target cell and its receptors

Wherever a hormone encounters a cell with an appropriate receptor, it can bind to that receptor and trigger a response. The nature of the response depends on the responding cell and its receptors. Thus the same hormone can cause different responses in different types of cells.

Consider the amine hormone adrenaline, or **epinephrine**. Suppose you are walking in the forest and almost step on a rattlesnake. You jump back, your heart starts to thump, and protective reactions are set in motion. The jump and the heart thumping are driven by your rapidly responding nervous system. Simultaneously with these muscular responses, your nervous system stimulates endocrine cells in the adrenal glands just above your kidneys to secrete epinephrine. Within seconds, epinephrine is diffusing into your blood and circulating around your body to activate the many components of the **fight-or-flight response** (Figure 41.3).

Epinephrine binds to receptors in your heart, causing a faster and stronger heartbeat. Your heart is now pumping more blood. Epinephrine also binds to receptors in certain blood vessels. By causing constriction of blood vessels supplying your skin, kidneys, and digestive tract (digesting lunch can wait!), the hormone diverts more blood to the muscles needed for your escape from danger.

Epinephrine binds to cells in the liver, stimulating them to break down glycogen and release its glucose units into the blood as a quick energy supply (see Figure 7.18). In fatty tissue, epinephrine stimulates the breakdown of fats to yield fatty acids—another source of energy. These are just some of the actions triggered by one hormone. In each case the cellular response depends on the cell's receptors and associated intracellular signaling cascade, but they all contribute to increasing your chances of surviving a dangerous situation.

41.3 The Fight-or-Flight Response The brain of a person suddenly faced with a threatening situation sends a signal to the adrenal glands, which almost instantaneously release the hormone epinephrine. Epinephrine circulates around the body and induces the various components of the fight-or-flight response in different tissues.

RECAP 41.1

Hormones are chemical signals released by endocrine cells into the extracellular fluid, where they can diffuse into the blood and travel to distant target cells. The receptors for water-soluble hormones are on the surfaces of target cells; receptors for most lipid-soluble hormones are inside the target cells.

- What are the three general chemical categories of hormones? [See p. 836 and Figure 41.2](#)
- Describe the different methods by which water-soluble and lipid-soluble hormones reach their receptors. [See p. 837](#)
- How can a single hormone have diverse effects in the body? [See p. 837 and Figure 41.3](#)

Scientists discovered and elucidated the transformative actions of many hormones before their specific molecular structures were known. Ingenious experimental approaches have been used to show that a chemical released by one cell has effects on other distant cells. Subsequent studies have focused on the nature of the signal and the mechanisms of its actions.

41.2

What Have Experiments Revealed about Hormones and Their Action?

Intercellular chemical signaling was critical for the evolution of multicellularity. A protist, the slime mold *Dictyostelium*, uses a chemical signal (cAMP) to coordinate the aggregation of individual cells to form a multicellular fruiting structure (see Figure 27.18). The least complex of the multicellular animals—the sponges—do not have nervous systems, but they do have intercellular chemical communication. Molecules that diffuse between cells and communicate information have a long evolutionary history in the multicellular lineages. As we discussed in Chapter 37, plant growth is regulated by a variety of hormones, and hormones are identifiable throughout the animal kingdom.

Studying the evolution of hormonal signaling reveals an interesting generalization: the signal molecules themselves are highly conserved. We find the same chemical compounds over broad groups of organisms, although their functions may differ. As organisms have evolved to occupy different environments and have different lifestyles, the same hormone–receptor systems have diversified to serve different functions. A good example of this evolutionary diversification is seen in the hormone prolactin, described in **Figure 41.4**.

The existence and functions of hormones were experimentally demonstrated many years before specific molecules were isolated and identified chemically. That is not surprising when you consider their small size and the tiny amounts of certain hormones that exist in an organism.

The first hormone discovered was the gut hormone secretin

Secretin, a protein released from cells in the gut, stimulates the pancreas to secrete digestive fluids into the gut. At the start of the twentieth century, the prevailing view was that the secretion of digestive juices was controlled by the nervous system. This view was in part the result of the famous work of the Russian physiologist Ivan Pavlov, who discovered the neural control of salivary secretions of the mouth (see Figure 53.1). Pavlov failed, however, when he tried similar experiments with the secretions of the pancreas.

In 1902 William Bayliss and Ernest Starling, working on anesthetized dogs, surgically removed all of the nerves to the

The structure of prolactin is similar in all vertebrate groups.

Fish

Required for osmoregulation in freshwater species. In saltwater species that return to fresh water to spawn (e.g., salmon), prolactin production in adults may play a role in generating the drive to return to natal streams.

Birds

In some species, stimulates nesting activity, incubation behavior, and parental care in both sexes. Stimulates the epithelial cells of the upper GI tract to proliferate and slough off to form “crop milk” to nourish the young.

Amphibians

In some species, creates a “water drive” that returns adults to breeding locations. Stimulates oviduct development and production of egg jelly in females. In some species, controls development of sexual characteristics.

Mammals

In females, stimulates growth of the mammary glands and milk production. In humans, it is responsible for the sensation of sexual gratification as well as the male refractory period following sexual intercourse.

41.4 Prolactin's Structure Is Conserved, but Its Functions Have Evolved The hormone prolactin is found in all vertebrate groups and has a long evolutionary history. Its probable function in early vertebrates was in regulating the body's salt and water balance (osmoregulation). It maintains this function in some species, and has evolved in others to control a number of physiological processes, most of which are associated with reproduction.

pancreas. They then showed that the denervated pancreas still produced secretions when stomach acid was injected into the gut. Then they took tissue from the gut, ground it up, and injected an extract from this preparation into the bloodstream; this injected fluid stimulated pancreatic secretions. Bayliss and Starling's work proved that a chemical extracted from one tissue could travel in the blood to cause a reaction in a different tissue. They called this type of chemical a “hormone,” from the Greek word for “impetus.”

INVESTIGATING LIFE

41.5 Muscle Cells Can Produce a Hormone One effect of exercise is the “browning” of white fat (see Figure 40.5D), which increases the fat’s metabolic activity and leads to other health benefits. Bruce Spiegelman and his colleagues investigated the possibility that exercised muscles secrete a hormone that changes the characteristics of white fat.^a

HYPOTHESIS Exercised muscle cells produce a hormone that stimulates browning of fat cells.

Method

- Two types of muscle cell cultures were prepared. One culture received a treatment that mimicked the effects of exercise on muscle cells.
- After culture, the muscle cells were removed and their used media (the culture fluid) was added to cultures of developing fat cells.

Results

Fat cells treated with media from control muscle cells retained the characteristics of white fat cells.

Fat cells treated with media from “exercised” cells developed properties of brown fat.

CONCLUSION A substance secreted by exercised muscle cells stimulates “browning” of cultured fat.

^aBoström, P. et al. 2012. *Nature* 481: 463–469.

The discovery of irisin described at the start of this chapter was achieved using modern methods that did not rely on animal subjects (**Figure 41.5**). However, these experiments were similar in principle to those of Bayliss and Starling.

Early experiments on insects illuminated hormonal signaling systems

The British physiologist Sir Vincent Wigglesworth was a pioneer in the study of hormonal action and control in insects. Insects, like all arthropods, have rigid exoskeletons (see Chapter 32). Their growth is therefore episodic, punctuated with molts (shedding of the exoskeleton). Each growth stage between

WORKING WITH DATA:

Identifying a Hormone Secreted by Exercised Muscles

Original Paper

Boström, P. and 17 others. 2012. A PGC1- α -dependent myokine that drives brown-fat-like development of white fat and thermogenesis. *Nature* 481: 463–469.

Analyze the Data

Over the course of many experiments, Bruce Spiegelman and his colleagues demonstrated that exercising mammalian muscle cells secrete a substance (identified as irisin) that they hypothesized was a hormonal signal stimulating white fat cells to develop some of the characteristics of brown fat cells. They cultured muscle cells from wild-type mice (the equivalent of sedentary mice) and from transgenic mice that overexpress irisin (the equivalent of exercising mice). They then took the fluid media from the two culture types and added that media to cultures of white fat cells (see Figure 41.5). They compared the properties of the white fat cells exposed to “exercised” muscle cell media and to “sedentary” muscle cell media.

QUESTION 1

In Experiment 1 (left-hand bars in the figure below), the investigators measured the expression of uncoupling protein 1 (UCP1), a mitochondrial inner membrane protein abundant in brown fat that allows the energy in fat to be converted to heat (see Chapter 9). They then extracted mRNA from treated fat cells and quantified the amount of UCP1 mRNA. Looking at the results, what effect did the “exercised” muscle cell media have on the amount of UCP1 mRNA? Why does this support the idea that exercised muscle cells stimulate “browning” of white fat? In testing the hypothesis that a hormone was involved in stimulating UCP1 expression, why was it important to remove the muscle cells from the conditioned media before adding the media to the fat cells? (See Figure 41.5.)

QUESTION 2

In a second experiment (right-hand bars in the figure), the investigators repeated the procedure in Figure 41.5 but pretreated the culture media with an antibody that recognizes and *inactivates* the molecule of interest (i.e., irisin). What was the effect of pretreating the culture media with antibody? What additional information did this experiment provide?

Go to **BioPortal** for all **WORKING WITH DATA** exercises

two molts is called an instar. In the 1930s and 1940s Wigglesworth studied the phenomenon of insect molting in a series of experiments on the bloodsucking bug *Rhodnius prolixus*. Newly hatched *Rhodnius* look like miniature adults but lack certain adult features. A juvenile bug molts five times before

developing into a mature adult; a blood meal triggers each episode of molting and growth.

Rhodnius is an amazingly hardy experimental animal—it survives for quite a long time after its head is cut off. Wigglesworth's studies revealed that, if decapitated within an hour after a blood meal, *Rhodnius* can survive for up to a year, but it never molts. If decapitated a week after its blood meal, however, it does molt. Wigglesworth hypothesized that the time lag meant that the substance that triggers molting diffuses slowly from the head. He tested this hypothesis with the experiment described in **Figure 41.6**, which showed that molting was triggered by a substance that diffused throughout the body from a point of origin in the bug's head.

Wigglesworth's experiments yielded another curious result. Regardless of which instar was used, decapitated *Rhodnius* that molted always molted directly into adults, bypassing the usual juvenile instars. Additional experiments demonstrated that a different substance (distinct from that identified by the experiment in Figure 41.6) determines whether a bug molts into another juvenile instar or into an adult.

Because the head of *Rhodnius* is long, it is possible to remove just the front part of it, which contains the brain, while leaving the rear part intact. When fourth-instar bugs that had had a blood meal a week earlier were partly decapitated in this way, they molted into fifth-instar juveniles, not into adults.

This experiment was followed by more experiments in which Wigglesworth used glass tubes to connect individual bugs. When an unfed, completely decapitated fifth-instar bug was connected to a blood-fed, partly decapitated fourth-instar bug (i.e., with only the front part of its head removed), both bugs molted into juvenile forms. A substance from the rear part of the head of the fourth-instar bug prevented both bugs from molting into adults.

Three hormones regulate molting and maturation in arthropods

An arthropod's nervous system receives various types of information about the environment (e.g., day length, temperature, social cues, and nutrition) that help determine the optimal timing for the stages of growth and development. When conditions are right, the brain signals the prothoracic gland to produce the hormones that orchestrate physiological processes involved in development and molting.

PTTH AND ECDYSONE We now know that two hormones, prothoracicotropic hormone (PTTH) and ecdysone, work in sequence to regulate molting in arthropods. Cells in the brain produce PTTH, which is why it has also been called “brain hormone.” PTTH is transported to and stored in paired structures called the corpora cardiaca attached to the brain (see Figure 41.7) After appropriate stimulation (which for *Rhodnius* is a blood meal), PTTH is released and diffuses through the extracellular fluid to an endocrine gland, the prothoracic gland. PTTH stimulates the prothoracic gland to secrete the hormone ecdysone. Ecdysone diffuses to target tissues and stimulates molting.

Ecdysone is a steroid hormone (see Figure 41.2B) and thus is related to the vertebrate hormones estrogen and testosterone

INVESTIGATINGLIFE

41.6 A Diffusible Substance Triggers Molting The blood-sucking bug *Rhodnius prolixus* develops from hatchling to adult in a series of five molts (instars) that are triggered by ingesting blood. Sir Vincent Wigglesworth's experiments demonstrated that a blood meal stimulates production of some molt-inducing substance in the insect's head.^a

HYPOTHESIS The substance that controls molting in *R. prolixus* is produced in the head segment and diffuses slowly through the body.

Observation

Method

Results

CONCLUSION A blood meal stimulates production of some substance within the insect's head that then diffuses slowly through the body, triggering a molt.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

epidermis). In the target cells, ecdysone binds to a receptor that is probably related to the vertebrate testosterone receptor. The resulting hormone–receptor complex induces expression of the genes encoding enzymes involved in digesting the old cuticle and secreting a new one.

JUVENILE HORMONE What about the other substance noted in Wigglesworth’s experiments—the one that produced sequential juvenile instars rather than adults? The substance responsible for preventing maturation is now known to be **juvenile hormone**, a molecule that is released continuously from the corpora allata (structures that are attached to the corpora cardiaca, which release PTTH). As long as juvenile hormone is present, *Rhodnius* molts into another juvenile instar. Normally *Rhodnius* stops producing juvenile hormone during the fifth instar, then molts into an adult, a life cycle called incomplete metamorphosis (see Section 32.4).

The role of juvenile hormone is more complex in insects that undergo complete metamorphosis (such as butterflies). These animals undergo dramatic developmental changes in their life cycles. The fertilized egg hatches into a larva, which feeds and molts several times, becoming bigger each time. After a fixed number of molts, it enters an inactive stage called pupation. The pupa undergoes major body reorganization and finally emerges as an adult.

An example of complete metamorphosis is provided by the silkworm moth *Hyalophora cecropia* (Figure 41.7). As long as juvenile hormone is present in high concentrations, larvae molt into larger larvae. When the level of juvenile hormone falls, larvae spin cocoons and molt into pupae. Because no juvenile hormone is produced in pupae, they molt into adults. Many modern pesticides use juvenile hormone analogs to prevent larvae developing into adults.

RECAP 41.2

The chemical structure of hormones is highly conserved across many organisms. Early experiments identifying secretin as a hormone defined the characteristics of hormonal signaling in mammals. Early studies on insects revealed much about the nature of hormone action, although the chemical structures of the signaling molecules involved were not established until much later.

- What is meant when we say that hormone molecules are highly conserved? See p. 838 and Figure 41.4
- Why did decapitation of *Rhodnius* prevent molting when done 1 day after feeding but not when done 1 week after feeding? See pp. 840–841 and Figure 41.6
- What is the role of juvenile hormone in metamorphosis? See p. 841 and Figure 41.7

The hormonal control of molting and maturation described above is a general arthropod hormonal control mechanism and exemplifies how the endocrine system works with the nervous system to integrate information and induce long-term effects. The next section will describe similar links between the nervous system and endocrine glands in mammals.

41.8 The Endocrine System of Humans Cells that produce and secrete hormones may be organized into discrete endocrine glands, or they may be embedded in the tissues of other organs, such as the digestive tract or kidneys. The hypothalamus is part of the brain, but it includes cells that secrete neurohormones into the extracellular fluid.

Go to Activity 41.1 The Human Endocrine Glands

Life10e.com/ac41.1

41.3

How Do the Nervous and Endocrine Systems Interact?

The list of hormones known to exist is long and growing longer (as shown by the recent identification of irisin). To make the subject manageable, we will focus primarily on information about the endocrine system of humans (Figure 41.8), much of which is applicable to other mammals. We will begin by considering the hormones involved in the integration of nervous system and endocrine system functions.

The pituitary is an interface between the nervous and endocrine systems

The **pituitary gland** sits in a depression at the bottom of the skull, just over the back of the roof of the mouth (Figure

41.9A). It is attached by a stalk to the hypothalamus, which is involved in many physiological regulatory systems (we detailed its role in thermoregulation in Section 40.5). Through its close connection with the hypothalamus, the pituitary serves as the interface between the nervous system and the endocrine system and is involved in the hormonal control of many physiological processes.

The pituitary has two parts with different developmental origins. The **anterior pituitary** originates as an outpocketing of the roof of the embryonic mouth cavity, whereas the **posterior pituitary** originates as an outpocketing of the floor of the developing brain. Thus the anterior pituitary originates from gut epithelial tissue and the posterior pituitary from neural tissue. Both parts interact with the nervous system but in different ways. The anterior pituitary contains endocrine cells controlled

by neurohormones secreted by the hypothalamus. The posterior pituitary contains axons from hypothalamic neurons.

Go to Animated Tutorial 41.2
The Hypothalamic–Pituitary–Endocrine Axis
Life10e.com/at41.2

THE POSTERIOR PITUITARY Long axons extend into the posterior pituitary from neurons in the hypothalamus. The ends, or terminals, of those axons release two neurohormones, antidiuretic hormone and oxytocin (**Figure 41.9B**). These neurohormones are packaged in vesicles that are transported down the axons. The vesicles are stored in the nerve terminals until an action potential stimulates their release.

The main action of **antidiuretic hormone (ADH)** in mammals and birds is to increase the amount of water conserved by the kidneys. When ADH secretion is high, the kidneys produce only a small volume of highly concentrated urine. When ADH secretion is low, the kidneys produce a large volume of dilute urine. The posterior pituitary increases its release of ADH when blood pressure falls or the blood becomes too salty. ADH is also known as **vasopressin** because at high concentrations it causes the constriction of peripheral blood vessels as a means of elevating blood pressure.

When a woman is about to give birth, her posterior pituitary releases **oxytocin**, which stimulates the uterine contractions that deliver the baby. Oxytocin also brings about the flow of milk from the mother's breasts. The baby's suckling stimulates neurons in the mother's brain that cause the secretion of oxytocin. Even the sound of a baby can cause a nursing mother to secrete oxytocin and release breast milk—a good example of how the nervous system integrates information that regulates hormonally mediated processes.

Hormones, in turn, can influence the nervous system. Oxytocin, for example, promotes bonding (see the story that opens Chapter 7). If oxytocin release is experimentally blocked, mammalian mothers, from rats to sheep, will reject their newborn offspring, but if a virgin rat is given a dose of oxytocin, she will adopt strange pups as if they were her own. Oxytocin promotes pair bonding and trust in a variety of animals. In humans its secretion rises with intimate sexual contact, and it has been nicknamed the “cuddle hormone.”

THE ANTERIOR PITUITARY The anterior pituitary produces and releases four peptide and protein hormones that act as **tropic hormones**, meaning they control the activities of other endocrine glands. These four tropic hormones are thyrotropin (thyroid-stimulating hormone), luteinizing hormone, follicle-stimulating hormone, and corticotropin. Each is produced by a different type of pituitary cell. We will say more about the tropic hormones when we describe their target glands—the thyroid, testes, ovaries, and adrenal cortex—later in this chapter and in Chapter 43. Other peptide and protein hormones produced by the anterior pituitary are prolactin (see Figure 41.4), growth hormone, enkephalins, and endorphins.

Growth hormone (GH) acts on a wide variety of tissues to promote growth. One of its important effects is to stimulate

41.9 The Posterior Pituitary Releases Neurohormones Neurons in the hypothalamus produce two peptide neurohormones, which are stored and released by the posterior pituitary.

cells to take up amino acids. Growth hormone also promotes growth by stimulating the liver to produce chemical signals that stimulate the growth of bone and cartilage. Overproduction of growth hormone in children causes gigantism, in which affected individuals may grow to nearly 8 feet tall. Underproduction causes pituitary dwarfism, in which individuals fail to reach normal adult height.

Endorphins and **enkephalins** are the body's natural painkillers. In the brain, these molecules act as neurotransmitters in pathways that control pain. Their production in the anterior pituitary is normally quite small and probably has little significant effect.

The anterior pituitary is controlled by hypothalamic neurohormones

In contrast to the posterior pituitary, the anterior pituitary makes and secretes its own hormones, but its secretion of these hormones is controlled by the hypothalamus. The hypothalamus senses and receives information about conditions in the body and in the external environment and communicates that information to the anterior pituitary by releasing neurohormones. If the connection between the hypothalamus and the pituitary is experimentally cut, the release of pituitary hormones no longer changes when conditions in the internal or external environment change.

Hypothalamic neurons do not extend into the anterior pituitary as they do into the posterior pituitary. Remember that the posterior pituitary develops from neural tissue, whereas the anterior pituitary develops from gut tissue. Instead, a special set of **portal blood vessels** bridges the gap between the hypothalamus and the anterior pituitary (**Figure 41.10**). Secretions from neurons in the hypothalamus enter the blood and are conducted down the portal vessels to the anterior pituitary, where they stimulate the release of anterior pituitary hormones.

In the 1960s two large teams of scientists led by Roger Guillemin and Andrew Schally initiated the search for these hypothalamic secretions. Because the amounts of such neurohormones in any individual mammal would be tiny, massive numbers of hypothalami from pigs and sheep were collected from slaughterhouses and shipped to laboratories. One extraction effort began with the hypothalami from 270,000 sheep and yielded only 1 milligram of purified **thyrotropin-releasing hormone (TRH)**. TRH was the first hypothalamic release-stimulating hormone to be isolated and characterized. It turned out to be a simple tripeptide consisting of glutamine, histidine, and proline. It causes certain anterior pituitary cells to release the tropic hormone thyrotropin, which in turn stimulates the activity of the thyroid gland.

Soon after discovering TRH, Guillemin's and Schally's teams identified **gonadotropin-releasing hormone (GnRH)**, which stimulates certain anterior pituitary cells to release the tropic hormones that control the activity of the gonads (the ovaries and the testes). For these discoveries, Guillemin and Schally shared the 1977 Nobel Prize in Medicine with Rosalyn Yalow, who invented a technique that allows measurement of miniscule amounts of specific molecules (see Figure 41.19).

Many other hypothalamic neurohormones, including both releasing and release-inhibiting hormones, are now known. The major hypothalamic neurohormones that control anterior pituitary function are:

- Thyrotropin-releasing hormone
- Gonadotropin-releasing hormone
- Prolactin-releasing and release-inhibiting hormones

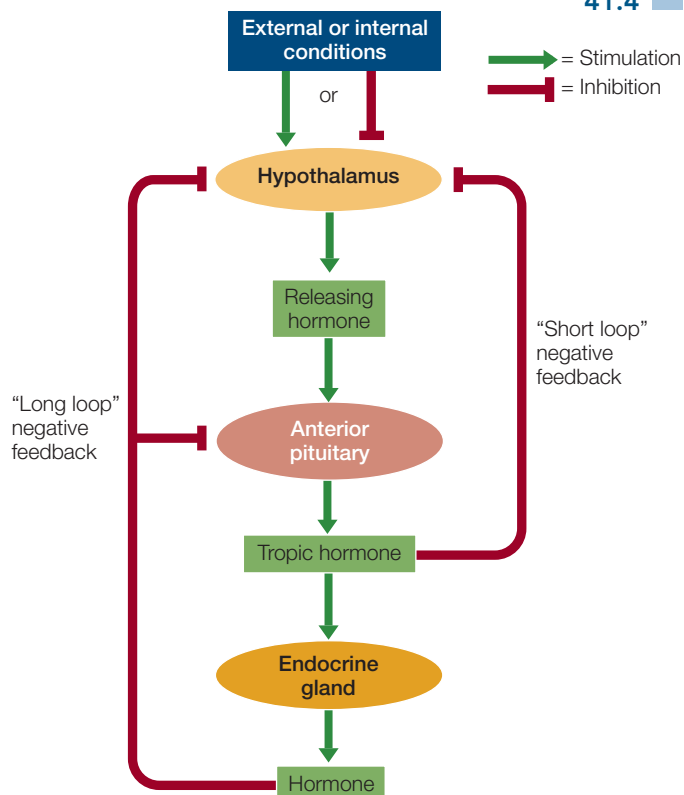

41.10 The Anterior Pituitary Is Controlled by the Hypothalamus Cells of the anterior pituitary produce four tropic hormones that control other endocrine glands, as well as several other peptide and protein hormones. These cells are controlled by neurohormones produced in the hypothalamus and delivered through portal blood vessels that run between the hypothalamus and the anterior pituitary through the pituitary stalk.

- Growth hormone-releasing hormone and growth hormone release-inhibiting hormone (somatostatin)
- Corticotropin-releasing hormone

Negative feedback loops regulate hormone secretion

In addition to being controlled by hypothalamic releasing and release-inhibiting hormones, the endocrine cells of the anterior pituitary are also under direct and indirect negative feedback control by the hormones of the target glands they stimulate (**Figure 41.11**). For example, cortisol, produced by the adrenal gland in response to corticotropin secreted by the anterior pituitary, reaches the pituitary in the circulating blood and inhibits further release of corticotropin. Cortisol also acts as a negative feedback signal to the hypothalamus, inhibiting the release of corticotropin-releasing hormone. In some cases a tropic hormone also exerts negative feedback control on the hypothalamic cells that produce the corresponding releasing hormone.

41.11 Multiple Feedback Loops Control Hormone Secretion

Multiple negative feedback loops regulate the chain of command from hypothalamus to anterior pituitary to endocrine glands.

RECAP 41.3

The pituitary is the interface between the nervous system and the endocrine system. The posterior pituitary releases two neurohormones. The anterior pituitary, under the control of other neurohormones from the hypothalamus, releases hormones that control other endocrine glands.

- Describe the anatomical and functional relationships between the brain and the two parts of the pituitary. [See pp. 842–843](#)
- Describe the role of hypothalamic neurohormones and the portal blood vessels in the secretion of hormones from the anterior pituitary. [See p. 844 and Figure 41.10](#)

Now that we have described some of the mechanisms by which endocrine systems are controlled, we will take a more detailed look at the functions of the major endocrine glands of mammals, as exemplified by humans.

41.4

What Are the Major Endocrine Glands and Hormones?

Hormones help regulate functions in all mammalian physiological systems. In this section we will examine a few major examples of hormonal action in physiological processes. Although we will focus on humans, these systems are very similar in all mammals. Be aware that these are only a few

examples; hormonal actions play an important role in virtually all the physiological systems that will be described in the chapters that follow.

The thyroid gland secretes thyroxine

The **thyroid gland** wraps around the front of the windpipe (trachea) and expands into a lobe on either side (see Figures 41.8 and 41.14). There are two cell types in the thyroid gland, each of which produces a specific hormone. **Thyroxine** is produced by epithelial cells that make up round, colloid-containing structures called follicles (**Figure 41.12A**). **Calcitonin** is produced by cells in the spaces between the follicles and is involved in blood calcium regulation (which we will describe shortly).

Thyroxine, a crucial signal in the regulation of cellular energy metabolism, begins as the glycoprotein thyroglobulin, which is synthesized by the follicle cells and packaged in secretory vesicles. The follicle cells actively take up iodide from the blood and move it into the lumen of the follicle. Each thyroglobulin molecule contains about 100 tyrosine units. When the secretory vesicles release thyroglobulin into the lumen of the follicle, they also release an enzyme that catalyzes the iodination of the tyrosine units in the thyroglobulin. When the thyroid gland is stimulated to release thyroxine, the follicle cells take up thyroglobulin from the follicle by endocytosis. These bits of thyroglobulin are then cleaved to form smaller molecules consisting of only two tyrosine units, and these molecules leave the follicle cells and enter the blood (**Figure 41.12B**). If these molecules are iodinated at the maximum of four sites on the tyrosine units, the hormone is tetraiodothyronine, or T_4 :

and if they are iodinated at only three sites, they are triiodothyronine, or T_3 :

The thyroid usually releases about ten times as much T_4 as T_3 . However, T_3 is a much more active hormone than T_4 is, so when you read about the effects of thyroxine, keep in mind that the actions discussed are primarily those of T_3 . The difference in the activities of T_3 and T_4 makes it possible to control the effects of thyroxine in different tissues. Within target cells, T_4 can be converted to T_3 by an enzyme called a deiodinase. Another deiodinase can convert T_4 into an inactive hormone called reverse T_3 . Deiodinase can also inactivate T_3 by converting it into T_2 or T_1 . Thus each target cell can set a unique sensitivity to thyroid hormones using these enzymes to control the conversion of T_4 to T_3 or to reverse T_3 .

41.12 The Thyroid Gland Consists of Many Follicles (A) Cross section through a thyroid gland, showing numerous follicles bounded by epithelial cells. Calcitonin-secreting cells are located in the spaces between the follicles. (B) The epithelial cells of the follicle synthesize thyroglobulin and secrete it into the lumen of the follicle, where it is iodinated and stored until it is processed by the epithelial cells to generate T_3 and T_4 .

TSH AND TRH REGULATE THYROXINE PRODUCTION The tropic hormone **thyroid-stimulating hormone (TSH, also known as thyrotropin)**, produced by the anterior pituitary, activates the thyroxine-producing follicle cells in the thyroid. Thyrotropin-releasing hormone (TRH), produced in the hypothalamus and transported to the anterior pituitary through the portal blood vessels, activates the TSH-producing pituitary cells. The hypothalamus uses environmental information, such as temperature or day length, to determine whether to increase or decrease its secretion of TRH. This sequence of steps is regulated by a negative feedback loop (see Figure 41.11). Circulating thyroxine inhibits the response of pituitary cells to TRH, so less TSH is released when thyroxine levels are high, and more TSH is released when thyroxine levels are low. Circulating thyroxine

41.13 A Hypothyroid Goiter In this condition, dietary iodide deficiency leads to a lack of functional thyroxine, resulting in the oversynthesis of thyroglobulin and subsequent enlarged follicles.

also exerts negative feedback on the production and release of TRH by the hypothalamus.

Because thyroxine is lipid-soluble, it enters cells readily and binds to receptors in the nucleus. When combined with thyroxine, these receptors (which are found in most cells of the body) stimulate the transcription of numerous genes whose products are transport proteins, structural proteins, and enzymes involved in metabolic pathways; thus thyroxine elevates the metabolic rates of most cells and tissues. Exposure to cold for several days leads to an increased release of thyroxine, an increased conversion of T_4 to T_3 , and therefore an increased basal metabolic rate (see Section 40.5).

During development and growth, thyroxine promotes amino acid uptake and protein synthesis. Insufficient thyroxine in a human fetus or growing child greatly retards physical and mental development, resulting in a condition known as cretinism.

GOITER A **goiter** is an enlarged thyroid gland (Figure 41.13) that can be associated with either hyperthyroidism (excess production of thyroxine) or hypothyroidism (thyroxine deficiency). The negative feedback loop whereby thyroxine controls TSH release helps explain how two seemingly opposite conditions can result in the same symptom.

- The most common cause of *hyperthyroid* goiter is Graves' disease, an autoimmune disease involving an antibody to the TSH receptor. This antibody binds to and activates the TSH receptors on the follicle cells, causing uncontrolled

production and release of thyroxine. Blood levels of TSH are low due to negative feedback from high levels of thyroxine, but the thyroid remains maximally stimulated and grows bigger. People with hyperthyroidism have high metabolic rates, usually feel hot, and may develop a buildup of fat behind the eyeballs that causes their eyes to bulge.

- **Hypothyroid** goiter results when there is not enough circulating thyroxine to turn off TSH production. The most common cause is a deficiency of dietary iodide, without which the follicle cells cannot make thyroxine. Without sufficient thyroxine, TSH levels remain high and the thyroid continues to produce large amounts of thyroglobulin. Because sufficient iodine is not available, however, the thyroglobulin is poorly iodinated. When it is broken down by the follicle cells, it produces little functional T_3 or T_4 . TSH levels remain high and stimulate more and more synthesis of thyroglobulin, and the thyroid gets bigger. The symptoms of hypothyroidism are low metabolism, intolerance of cold, and general physical and mental sluggishness.

Goiter affects about 5 percent of the world's population. The addition of iodide to table salt has greatly reduced the incidence of hypothyroid goiter in industrialized nations, but the condition is still common in the other parts of the world and is a leading cause of intellectual impairment.

Three hormones regulate blood calcium concentrations

The regulation of calcium concentration in the blood is crucial, and shifts in blood calcium concentration above or below a narrow range can cause serious problems. When blood calcium falls below this range, the nervous system becomes overly excited, resulting in muscle spasms and even seizures. When blood calcium rises above this range, the nervous system becomes depressed and muscles—including the heart—weaken. Regulation of blood calcium is difficult because only about 0.1 percent of the calcium in the body is located in the extracellular fluid. About 1 percent is in cells, and almost 99 percent is in the bones. Therefore the body must maintain a tiny pool of calcium in the blood at a precise concentration, and that tiny pool can be influenced greatly by relatively small shifts in the much larger pools of calcium in the cells and bones.

The body has multiple mechanisms for changing blood calcium levels, including:

- Deposition or absorption of bone
- Excretion or retention of calcium by the kidneys
- Absorption of calcium from the digestive tract

These mechanisms are controlled by three hormones: calcitonin, parathyroid hormone, and calcitriol (synthesized from vitamin D).

CALCITONIN REDUCES BLOOD CALCIUM Calcitonin is released by the thyroid and lowers the concentration of calcium in the blood, mainly by regulating bone turnover (**Figure 41.14**). Bone is continuously remodeled through a dynamic process that involves both resorption of old bone and synthesis of new bone, as we will discuss in Section 48.3. Cells called osteoclasts break down bone and release calcium into the blood, and cells called osteoblasts take up calcium from the blood and deposit it in new bone. Calcitonin decreases the activity of osteoclasts and thereby favors removal of calcium from the blood and its deposition in bone by osteoblasts. The turnover of bone in adult humans is not very high, so calcitonin does not play a major role in calcium homeostasis in adults. It is probably more important in young individuals whose bones are actively growing.

PARATHYROID HORMONE INCREASES BLOOD CALCIUM The **parathyroid glands** are four tiny structures embedded in the

Go to Animated Tutorial 41.3
Hormonal Regulation of Calcium
Life10e.com/at41.3

41.14 Hormonal Regulation of Calcium Calcitonin, parathyroid hormone (PTH), and calcitriol (the active form of calciferol, or vitamin D) regulate Ca^{2+} levels in the blood.

posterior surface of the thyroid gland (see Figure 41.14). Their single hormone product, **parathyroid hormone (PTH)**, also called parathormone), is the most important hormone in the regulation of blood calcium levels. Circulating calcium activates receptors in the plasma membrane of the parathyroid cells. When these receptors are active, they inhibit the synthesis and release of PTH. A fall in blood calcium removes this inhibition and triggers the synthesis and release of PTH. PTH stimulates bone turnover by actions on both osteoclasts and osteoblasts. The end result of these actions of PTH is a net increase of calcium in the blood. PTH also raises blood concentration of calcium by stimulating the kidneys to reabsorb it rather than excrete it in the urine.

CALCITRIOL INCREASES BLOOD CALCIUM It had long been known that fragile bones were common among people living at high latitudes, where winter days are short and the winter diet often lacks fish, dairy products, and fresh vegetables. Since the condition could be reversed by taking cod-liver oil, it was assumed that a vitamin deficiency was involved. That vitamin was vitamin D, but when its chemical identity was established, this molecule turned out not to be a vitamin at all.

A vitamin is a substance that the body requires in small quantities but cannot synthesize for itself and must therefore obtain from food (or from supplements such as vitamin pills). However, vitamin D—now more accurately named calciferol—is synthesized naturally from cholesterol when skin cells receive ultraviolet light. Calciferol is not an active hormone, but through actions of the liver and kidneys it is converted into the active form called **calcitriol**, which circulates in the blood and acts on distant cells (and therefore *is* a hormone). The conversion of calciferol to calcitriol is activated by PTH. Calcitriol promotes the absorption of calcium from food in the gut. Thus the combined actions of PTH and calcitriol raise blood calcium levels.

PTH lowers blood phosphate levels

Bones are made of phosphate as well as calcium, and when PTH stimulates the release of calcium from bone it also releases phosphate. Normal blood concentrations of calcium and phosphate are just below the levels at which they precipitate out of solution as calcium phosphate salts. Even a small rise may cause such precipitation, leading to maladies such as kidney stones and calcium deposits in the arteries (hardening of the arteries). To reduce this risk, PTH acts on the kidneys to increase the elimination of phosphate via the urine.

Insulin and glucagon regulate blood glucose concentrations

Before the 1920s, the disease diabetes mellitus was fatal. Characterized by weakness, lethargy, and a dramatic loss of body mass, this condition was known to be connected somehow with the pancreas—a large gland located just below the stomach (see Figure 41.8)—and with abnormal glucose metabolism. The exact links, however, were not clear.

Today we know that diabetes mellitus is caused by a lack of the protein hormone **insulin** (in type I diabetes) or by a lack of insulin responsiveness in target tissues (in type II diabetes).

Glucose enters cells by diffusion, but cell membranes are not very permeable to glucose. Glucose transporter proteins in cell membranes facilitate the movement of glucose into cells, and the glucose transporters most common in muscle and adipose tissue are controlled by insulin. When insulin binds to its receptor on the cell membrane, it causes these glucose transporters to move from cytoplasmic vesicles to the cell membrane, thus making the cell more permeable to glucose. When insulin is not present, these transporters are returned to the cytoplasmic pool through endocytosis.

In the absence of insulin or insulin responsiveness, glucose entry into cells is impaired, resulting in so much glucose accumulating in the blood that it starts to spill over into the urine. A high concentration of glucose in the blood increases urine output by two mechanisms. First, it causes water to move from cells into the blood by osmosis, and this increase in blood volume results in increased urine production. Second, the increased glucose in the tubules of the kidneys pulls more water into the urine by osmosis. Diabetic individuals thus can become dehydrated, but more importantly they suffer from a lack of metabolic fuel. Because glucose uptake by muscle and adipose tissue is impaired in the absence of insulin, muscle cells must depend on fat and protein for fuel and adipose tissue cannot replenish its stores of triglycerides. If the condition is not treated, the body can waste away.

For centuries, the prospects for people suffering with diabetes were bleak. A change came almost overnight in 1921, when the physician Frederick Banting and a medical student, Charles Best, at the University of Toronto, discovered they could reduce the symptoms of diabetes by injecting an extract prepared from pancreatic tissue. The active component of this extract was found to be insulin, a small protein consisting of just 51 amino acids. In the United States today, insulin replacement therapy using manufactured insulin allows more than 1.5 million people with type I diabetes to lead almost normal lives.

ISLETS OF LANGERHANS Insulin is produced in clusters of endocrine cells in the pancreas. These clusters are called **islets of Langerhans** after the German medical student who discovered them. They contain three types of cells, each of which produces a specific hormone:

- Beta (β) cells produce and secrete insulin.
- Alpha (α) cells produce and secrete **glucagon**, a hormone that has effects mostly opposite from those of insulin.
- Delta (δ) cells produce the hormone **somatostatin**.

The rest of the pancreas is made up of exocrine tissue, which produces enzymes and other secretions that travel through ducts to the gut, where they participate in digestion.

After a meal, the concentration of glucose in the blood rises, stimulating the β cells of the islets to release insulin. Insulin causes target cells throughout the body to use circulating glucose as fuel and convert it into storage products such as glycogen and fat. When the gut is empty of food, blood glucose concentration falls and the islets stop releasing insulin. As a result, most cells shift to using glycogen and fat rather than glucose as fuel. If blood glucose concentration falls substantially below

normal, the islet α cells release glucagon, which stimulates the liver to break down stored glycogen and release glucose into the blood. These actions will be discussed in greater detail in Section 51.4.

SOMATOSTATIN Somatostatin is released from the δ cells of the pancreas in response to rapid increases of glucose and amino acids in the blood. This hormone has paracrine functions within the islets, where it inhibits the release of both insulin and glucagon. Outside the pancreas it acts as a hormone, slowing the digestive activities of the gut and extending the period during which nutrients are absorbed. Somatostatin is also produced in very small amounts by cells in the hypothalamus. Hypothalamic somatostatin is transported in the portal blood vessels to the anterior pituitary, where it acts as a neurohormone to inhibit the release of growth hormone and thyrotropin.

The adrenal gland is two glands in one

An **adrenal gland** sits above each kidney, just below the middle of your back. Functionally and anatomically, each adrenal gland consists of a gland within a gland (**Figure 41.15**). The core, or **adrenal medulla**, produces: **epinephrine** (also known as adrenaline) and, to a lesser degree, **norepinephrine** (noradrenaline). The medulla develops from nervous tissue and is under the control of the nervous system. Surrounding the medulla is the **adrenal cortex**, which produces steroid hormones. The cortex is under hormonal control, largely by corticotropin produced by the anterior pituitary.

41.15 The Adrenal Is Really Two Glands An adrenal gland, consisting of an outer cortex and an inner medulla, sits above each kidney. The medulla and the cortex produce different hormones.

THE ADRENAL CORTEX The cells of the adrenal cortex use cholesterol to produce three classes of steroid hormones (see Figure 41.2B), collectively called **corticosteroids**:

- **Mineralocorticoids** influence the salt and water balance of the extracellular fluid.
- **Glucocorticoids** influence blood glucose concentrations as well as other aspects of fat, protein, and carbohydrate metabolism.
- **Sex steroids** play roles in sexual development, sexual behavior, and anabolism (tissue-building).

In adult humans, the adrenal cortex secretes only negligible amounts of sex steroids. The major producers of sex steroids are the gonads, as we will see in the following section.

Aldosterone, the primary mineralocorticoid, stimulates the kidneys to conserve sodium and excrete potassium, as we will discuss in Chapter 51. If the adrenal glands are removed from an animal, sodium must be added to its diet, or its sodium will be depleted and it will die.

The main glucocorticoid in humans is **cortisol**, which is critical for mediating the body's metabolic responses to stress. Within minutes of a stressful stimulus (one provoking fear or anger, for example), blood cortisol levels begin to rise. This response is much slower than the neurally mediated epinephrine and norepinephrine response to stress, but it lasts longer. Cells not critical for a sustained stress response are stimulated by cortisol to decrease their use of blood glucose and shift instead to using fats and proteins for energy. Cortisol also inhibits the immune system (because dealing with the immediate stressor is more important than feeling sick, having allergic reactions, or healing wounds). This explains why cortisol and drugs that mimic its action are useful for reducing inflammation and allergic responses.

Cortisol release is controlled from the anterior pituitary by **corticotropin** (also called **adrenocorticotrophic hormone**, or **ACTH**), whose release is controlled in turn by **corticotropin-releasing hormone (CRH)** from the hypothalamus. The action of ACTH on the adrenal cortex is to stimulate the synthesis of cortisol. Like other steroid hormones, cortisol is not stored in vesicles and therefore is available for immediate release. As cortisol or other steroid hormones diffuse into the blood, they combine with carrier proteins, and their release from these proteins can have a long time course, thus stretching out their actions. Also, many of their actions stimulate gene expression in target cells, which also takes time but has a long-lasting effect.

Turning off the stress responses activated by cortisol is as important as turning them on. A study of stress in rats showed that old rats could turn on these stress responses as effectively as young rats, but they had lost the ability to turn them off as rapidly. As a result, they suffered from the well-known consequences of stress seen in humans: digestive system problems, cardiovascular problems, strokes, impaired immune system function, and increased susceptibility to cancers and other diseases. Acute stress responses are controlled by negative feedback from cortisol on both the ACTH-secreting cells of the anterior pituitary and CRH-secreting cells of the hypothalamus. With chronic or prolonged stress, these control mechanisms

(A) Epinephrine

41.16 Hormones Can Activate a Variety of Signal Transduction Pathways Epinephrine and norepinephrine bind to G protein-linked adrenergic receptors that act through different signal transduction pathways. Epinephrine (A) acts equally on both α - and β -adrenergic receptors; norepinephrine (B) acts mostly on α -adrenergic receptors.

become insufficient and cortisol must exert negative feedback through another brain region, the hippocampus. Prolonged exposure to cortisol, however, causes trauma to and loss of hippocampal cells, resulting in the decreased ability to turn off the stress response.

THE ADRENAL MEDULLA The adrenal medulla produces epinephrine and norepinephrine in response to stressful situations, arousing the body to action. As we saw earlier in this chapter, epinephrine increases heart rate and blood pressure and diverts blood flow to active muscles and away from the gut and skin. Norepinephrine has similar functions, but since it is also a neurotransmitter involved in many physiological regulatory processes, it has many ongoing functions in addition to its involvement in flight-or-fight reactions.

Epinephrine and norepinephrine are both water-soluble, and both bind to the same set of receptors on the surfaces of target cells. These **adrenergic receptors** are of two general types, α -adrenergic and β -adrenergic (Figure 41.16). The α -adrenergic receptors respond more strongly to norepinephrine than to epinephrine, whereas β -adrenergic receptors respond about equally to both epinephrine and norepinephrine. Because of this difference in receptor affinities, it is possible for drugs to blunt the flight-or-fight responses without disrupting physiological regulatory processes. Such drugs are called “beta blockers” because, by inhibiting β -adrenergic receptors, they can reduce the fight-or-flight response to epinephrine without disrupting the physiological regulatory functions of norepinephrine mediated through the α -adrenergic receptors. Beta blockers are commonly prescribed to reduce symptoms of anxiety such as dry mouth and elevated heart rate (palpitations).

Sex steroids are produced by the gonads

The **gonads**—the testes of the male and the ovaries of the female—produce hormones as well as sperm and ova. The male steroid hormones are collectively called **androgens**, and the dominant hormone is testosterone. The female steroids are

(B) Norepinephrine

estrogens and progesterone. The dominant estrogen is estradiol, which is synthesized from testosterone. Males and females both synthesize testosterone, but females have an enzyme (aromatase) that converts testosterone to estradiol.

Go to Media Clip 41.1
The Testosterone Factor
Life10e.com/mc41.1

PHENOTYPIC SEX DETERMINATION The sex steroids determine whether a mammalian embryo develops into a phenotypic female or male. In humans, the gonads of an early embryo are undifferentiated. Beginning in about the seventh week of development, the expression of genes on the Y chromosome of an XY individual normally causes the undifferentiated gonads to produce androgens. In response to androgens, the reproductive system develops the male phenotype. If no Y chromosome is present (i.e., the individual is genotype XX), androgens are not produced at this time and female structures develop (Figure 41.17). After birth, the sex steroids control the maturation of the reproductive organs and the development and maintenance of secondary sexual characteristics, such as breasts and facial hair.

PUBERTY In humans, the sex steroids are produced at low levels by juvenile gonads, but their production increases rapidly at puberty (around age of 12 or 13). Why does this sudden increase occur? In both juvenile and adult humans, the activities of the gonads are controlled by the tropic hormones luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which

41.17 Sex Steroids Direct the Development of Human Sex Organs

The sex organs of early human embryos are undifferentiated. Androgens promote the development of male sex organs. In the absence of androgens, female sex organs form.

together are the **gonadotropins**. The production of gonadotropins by the anterior pituitary is under the control of gonadotropin-releasing hormone (GnRH) produced by the hypothalamus. Before puberty, the hypothalamus produces only low levels of GnRH. Puberty is initiated by a reduction in the sensitivity of hypothalamic GnRH-producing cells to negative feedback from sex steroids and from gonadotropins. As a result, GnRH production increases, stimulating increased production of gonadotropins and hence increased production of sex steroids.

In females, increasing levels of LH and FSH at puberty stimulate the ovaries to increase their production of the female sex hormones. The increased circulating levels of these hormones initiate the development of the traits of a sexually mature woman: enlarged breasts, vagina, and uterus; broadened hips; increased subcutaneous fat; pubic hair; and initiation of the

menstrual and ovarian cycles (see Figure 43.13). In males, an increasing level of LH stimulates groups of cells in the testes to increase their synthesis of testosterone, which in turn initiates the physiological, anatomical, and psychological changes associated with adolescence. The voice deepens, hair begins to grow on the face and body, and the testes and penis grow larger. Testosterone also stimulates bone and skeletal muscle growth. FSH in males stimulates production of sperm.

The roles that sex steroids play in adult sexual behavior and reproduction will be described in Chapter 43.

Melatonin is involved in biological rhythms and photoperiodicity

The **pineal gland** is situated between the two hemispheres of the brain and is connected to the brain by a stalk. It synthesizes the amine hormone **melatonin** from the amino acid tryptophan. The pineal gland releases melatonin in the dark, and therefore melatonin levels indicate the length of the night. Exposure to light inhibits the release of melatonin.

In vertebrates, melatonin is involved in biological rhythms, including **photoperiodicity**—the phenomenon whereby seasonal changes in day length cause physiological changes. Many species, for example, come into reproductive condition when the days begin to lengthen (Figure 41.18). Humans are not strongly photoperiodic, but melatonin in humans may play a role in synchronizing daily biological rhythms to the daily cycle of light and dark.

Many chemicals may act as hormones

We have discussed the major mammalian endocrine glands and their hormones in this chapter, but many more hormones

(B) *Phodopus sungorus*

41.18 Melatonin Regulates Seasonal Changes (A) Melatonin release occurs in the dark and is inhibited by exposure to light. The duration of daily melatonin release thus changes as day length (photoperiod) changes, inducing dramatic seasonal physiological changes in some animals. (B) In winter, Siberian hamsters are white and do not reproduce. In summer, they are mottled brown and breed.

exist. As we discuss the organ systems of the body in the chapters that follow, we will frequently describe hormones that their tissues produce as well as hormones that control their functions.

RECAP 41.4

The major endocrine glands of mammals include the hypothalamus, pituitary gland, thyroid gland, parathyroid glands, pancreas, adrenal glands, gonads, and pineal gland. Each of these glands secretes and responds to hormones that play crucial roles in controlling physiology and development.

- Describe how thyroxine is produced and how its production and release are controlled. **See pp. 845–846 and Figure 41.12**
- How is the concentration of calcium in the blood regulated? **See pp. 847–848 and Figure 41.14**
- How does insulin control the rate of glucose uptake by cells? **See p. 848**
- What changes in the feedback control of sex steroids result in puberty? **See pp. 850–851**

Many hormones are released in very small quantities, and some disappear from the extracellular fluid rapidly. A hormone's receptors may be found on diverse cells around the body, and those cells can respond in different ways to the same hormone. How have we overcome these difficulties to learn how hormones work?

41.5

How Do We Study Mechanisms of Hormone Action?

In the current age of molecular biology, we can break the study of hormone actions into different sets of problems. First we must be able to detect, identify, and measure hormones. Next we must be able to identify and characterize hormone receptors. Finally, we must understand the signal transduction pathways activated by hormones in different tissues.

Hormones can be detected and measured with immunoassays

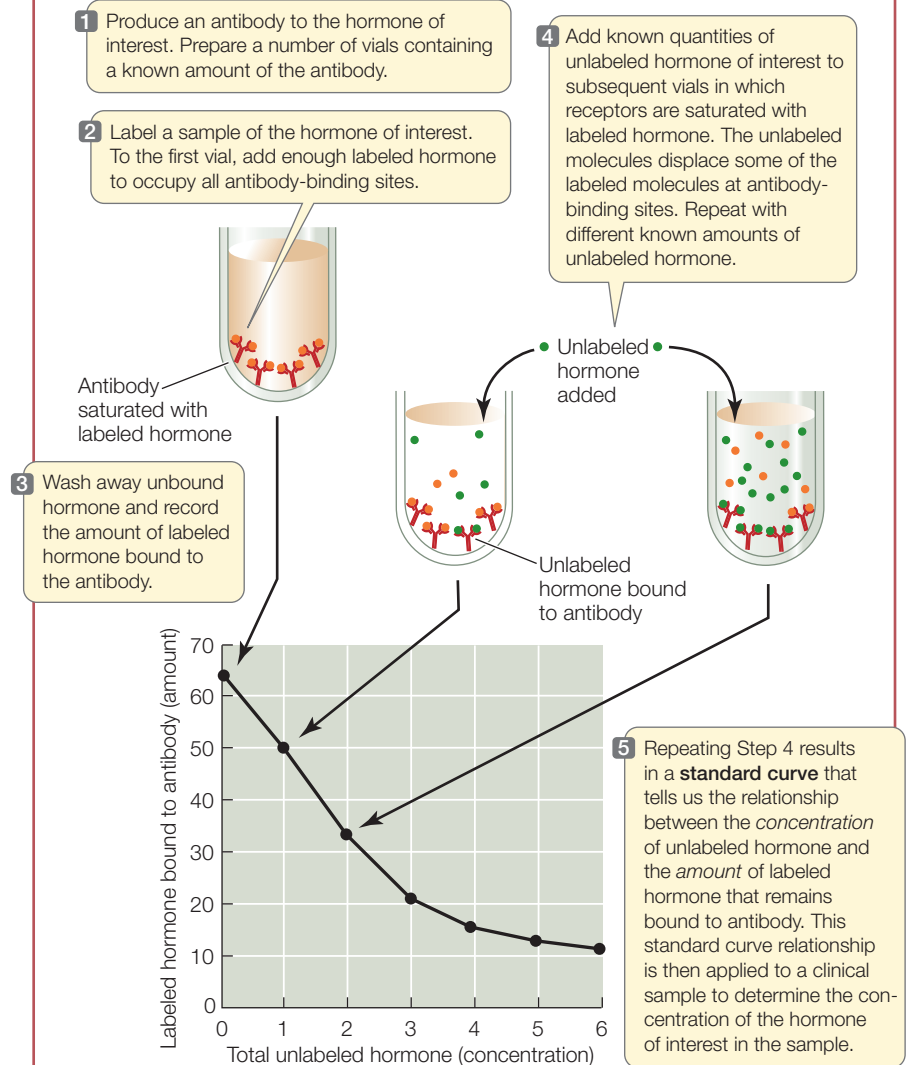

As we have seen, testosterone has many dramatic and diverse effects, yet its concentration in the blood of adult human males is only about 30 to 100 *billionths* of a gram per milliliter. Measuring hypothalamic neurohormones requires calibrations in the range of *trillionths* of a gram per milliliter.

The ability to detect and measure minute quantities of hormones was an important breakthrough. Rosalyn Yalow developed a method she named radioimmunoassay because it used

RESEARCH TOOLS

41.19 An Immunoassay Allows Measurement of Small Concentrations

An immunoassay uses labeled and unlabeled samples of a purified hormone (or other substance to be measured) and an antibody to that hormone to develop a standard curve against which a sample of unknown concentration can be measured.

radioactive labels (she used radioactive isotopes of iodine) to track interactions between an antigen (the hormone or other substance of interest to be measured) and an antibody made to that antigen. Today we are more likely to use nonradioactive labels, so the technique is called simply **immunoassay** (Figure 41.19). Being able to measure hormones in the blood made it possible to study many important hormonal mechanisms.

An important characteristic of a hormone is the time course over which it acts. This time course can be measured by the hormone's half-life in the blood (defined as the length of time it takes for one-half of the hormone molecules to disappear). Soon after endocrine cells are stimulated to secrete their hormone, the hormone reaches its maximum concentration in the blood. By examining a series of blood samples using immunoassays, researchers can determine how long it takes for the circulating hormone to drop to half its maximum concentration. The fight-or-flight response to epinephrine is fast both in its onset and its termination; the half-life of epinephrine in the

41.20 Dose-Response Curves Quantify the Body's Response to a Hormone Between the threshold and maximum doses, a dose-response curve frequently has an S shape. Anything that changes the responsiveness of a system—such as an increase or decrease in the number of receptors in target cells—affects the position of the curve.

blood is 1 to 3 minutes. The effects of other hormones, such as cortisol and thyroxine, are expressed over much longer periods, with half-lives measured in days.

Immunoassays have also facilitated the measurement of dose-response relationships. To evaluate a drug or a natural hormone for therapeutic use, it is critical to know the sensitivity of the body to that drug or hormone. Being able to measure the concentrations of drugs or hormones in the blood makes it possible to construct dose-response curves that help physicians adjust dosages appropriately (Figure 41.20).

A hormone can act through many receptors

Different receptors may be involved in mediating the actions of a single hormone. Because there are slight differences among the receptors for a particular hormone, it is possible to create drugs that are selective in blocking or stimulating specific responses. A number of receptors have been identified, isolated, and purified through biochemical separation techniques. For example, a hormone can be bound to a substrate such as resin beads packed into a glass column. When an extract of cells suspected of containing receptors to that hormone is added to the column, the receptors bind to the hormone molecules on the beads. The hormone-receptor complexes can then be washed off the beads and the receptors isolated. This technique is called **affinity chromatography**.

As more receptors are isolated and characterized, researchers discover that they frequently exist in families with common structural features. These common features result from common nucleotide sequences in the receptor genes. Genomic analyses have led to the discovery of many new receptors. Investigators “scan” the genome for sequences that bear homologies to known receptor gene sequences; when they get a “hit,” they have found a candidate gene for a new receptor. They can then identify the molecule to which that receptor binds (its ligand), describe where the receptor occurs within the body, and characterize the receptor’s physiological effects.

Knowing the molecular identity of a receptor and being able to measure its concentration makes it possible to study that receptor’s regulation. We saw above that the release of hormones can be under negative feedback control. Similarly,

the abundance of *receptors* for a hormone can be under feedback control. In some cases, continuous high concentrations of a hormone can decrease the number of its receptors, a process known as **downregulation**. An increased number of receptors can occur when hormone secretion is suppressed, resulting in **upregulation**. The regulation of receptor abundance is an important mechanism controlling the sensitivity of the body to hormonal signaling.

An example of downregulation occurs in type II diabetes, which is characterized by elevated insulin concentrations in the blood and a loss of insulin receptors. Although genetic factors are probably involved, a possible immediate cause of the disease is an overstimulation of pancreatic release of insulin by excessive carbohydrate intake, which leads to downregulation of the insulin receptors. An example of upregulation may be seen in people who have been on a regular dose of beta blockers (see p. 850). As the activity of the β -adrenergic receptors is blocked over time, more of these receptors are produced. If the person goes off the medication suddenly, the effects of the receptors are amplified, resulting in heightened anxiety. Changes in dosage in the long-term use of such medications thus are usually gradual and carefully supervised.

RECAP 41.5

Studying the mechanisms of hormone action requires the ability to measure hormone concentrations and to identify and characterize hormone receptors.

- Describe how an immunoassay is performed. [See p. 852 and Figure 41.19](#)
- How are receptors for a particular hormone identified? [See p. 853](#)

How can we demonstrate that a molecule found in the blood is a hormone?

ANSWER

In order for a molecule to be considered a hormone, we have to show that the molecule is released from cells in a certain tissue and that it has an effect on cells in another, distant tissue. We also have to show that the molecule is *necessary* to stimulate its presumed target cells and that it is *sufficient* to stimulate those target cells. In the experiment shown in Figure 41.6, when the bugs were decapitated soon after a blood meal, molting did not occur, but when they were decapitated a week after a blood meal, molting did occur. These results showed that some substance from the head, but not the head itself, was necessary for the molting response. Sufficiency was demonstrated by connecting two bugs with a glass tube allowing diffusion of substances between them. In this experiment, both bugs molted. In the irisin experiments (Figure 41.5), it was shown that the molecule came from muscle cells and acted on fat cells; that the molecule could stimulate “browning” of white fat cells in culture; (sufficiency); and that when the molecule was inactivated it blocked this “browning” of the white fat (necessity).

41.1 What Are Hormones and How Do They Work?

- **Endocrine cells** secrete chemical signals that induce responses in other cells that have receptors for those molecules. In some cases endocrine cells are aggregated into **endocrine glands**.
- **Hormones** are endocrine signals that are secreted from a cell, circulate in the blood, and bind to target cells distant from the secreting cell. **Review Figure 41.1**
- Hormones fall into three general categories: proteins and peptides, steroids, and amines. Peptide and protein hormones and some amines are water-soluble; steroids and some amines are lipid-soluble. **Review Figure 41.2**
- Receptors for water-soluble hormones are located on the cell surface. Receptors for most lipid-soluble hormones are inside the cell.
- Hormones can cause different responses in different target cells. **Review Figure 41.3**

41.2 What Have Experiments Revealed about Hormones and Their Action?

- The chemical structures of hormones are highly conserved. Through evolution, however, hormones acquire different functions in different animal groups. **Review Figure 41.4**
- Early experiments identifying secretin as a hormone defined the characteristics of hormonal signaling. Modern experiments demonstrate these characteristics in order to identify hormone molecules. **Review Figure 41.5**
- Pioneering experiments illustrating hormonal action showed that two hormones, PTH and ecdysone, control molting in arthropods. A third hormone, **juvenile hormone**, prevents maturation. **Review Figures 41.6, 41.7, ANIMATED TUTORIAL 41.1**

41.3 How Do the Nervous and Endocrine Systems Interact?

- In humans, the major endocrine glands are distributed around the body. **Review Figure 41.8, ACTIVITY 41.1**
- The **pituitary gland** is the interface between the nervous and endocrine systems. The **anterior pituitary** develops from embryonic mouth tissue; the **posterior pituitary** develops from the developing brain. **Review Figures 41.9, 41.10**
- The posterior pituitary secretes two **neurohormones**: **antidiuretic hormone (ADH)** and **oxytocin**. The anterior pituitary secretes **tropic hormones** (thyrotropin, corticotropin, luteinizing hormone, and follicle-stimulating hormone) as well as **growth hormone**, **prolactin**, **endorphins**, and **enkephalins**.
- The anterior pituitary is controlled by neurohormones produced by cells in the hypothalamus and transported through **portal blood vessels** to the anterior pituitary. **See ANIMATED TUTORIAL 41.2**

- Hormone release is controlled in part by negative feedback loops. **Review Figure 41.11**

41.4 What Are the Major Endocrine Glands and Hormones?

- The **thyroid gland** is controlled by **thyrotropin** and secretes **thyroxine**, which controls cell metabolism. **Review Figure 41.12**
- The level of calcium in the blood is regulated by three hormones. **Calcitonin** from the thyroid lowers blood calcium by promoting bone deposition. **Parathyroid hormone (PTH)** raises blood calcium by promoting bone turnover and decreasing calcium excretion. **Calcitriol** promotes calcium absorption from the digestive tract. **Review Figure 41.14, ANIMATED TUTORIAL 41.3**
- The pancreas secretes three hormones. **Insulin** stimulates glucose uptake by cells and lowers blood glucose, **glucagon** raises blood glucose, and **somatostatin** slows the rate of nutrient processing.
- The **adrenal gland** has two portions, one within the other. The inner portion, the **adrenal medulla**, releases **epinephrine** and **norepinephrine** in response to stress. The outer portion, the **adrenal cortex**, produces three classes of **corticosteroids**: glucocorticoids, mineralocorticoids, and small amounts of sex steroids. **Review Figure 41.15**
- **Aldosterone** is a mineralocorticoid that stimulates the kidneys to conserve sodium and excrete potassium. **Cortisol** is a glucocorticoid that is released in response to stressful stimuli but acts more slowly than the hormones of the adrenal medulla.
- Sex hormones (**androgens** in males, **estrogens** and **progesterone** in females) control sexual development, secondary sexual characteristics, and reproductive functions. **Review Figure 41.17**
- The **pineal gland** releases **melatonin**, a hormone involved in controlling biological rhythms. **Review Figure 41.18**

41.5 How Do We Study Mechanisms of Hormone Action?

- **Immunoassay** techniques are used to measure concentrations of hormones and other substances. **Review Figure 41.19**
- The body's sensitivity to a hormone is measured by a dose-response curve. **Review Figure 41.20**
- The sensitivity of a cell to a hormone can be altered by **down-regulation** or **upregulation** of the hormone's receptors in that cell.

CHAPTER REVIEW

REMEMBERING

1. Prior to puberty
 - a. the pituitary secretes luteinizing hormone and follicle-stimulating hormone, but the gonads are unresponsive.
 - b. the hypothalamus does not secrete much gonadotropin-releasing hormone.
 - c. males can stimulate massive muscle development through a vigorous training program.
 - d. testosterone plays no role in development of the male sex organs.
 - e. genetic females will develop male genitals unless estrogen is present.
2. Both epinephrine and cortisol are secreted in response to stress. Which of the following statements is also true for *both* of these hormones?
 - a. They act to increase blood glucose availability.
 - b. Their receptors are on the surfaces of target cells.
 - c. They are secreted by the adrenal cortex.
 - d. Their secretion is stimulated by corticotropin.
 - e. They are secreted into the blood within seconds of the onset of stress.
3. The posterior pituitary
 - a. synthesizes oxytocin.
 - b. is under the control of hypothalamic releasing hormones.
 - c. secretes tropic hormones.
 - d. secretes neurohormones.
 - e. is under feedback control by thyroxine.
4. PTH
 - a. stimulates osteoblasts to lay down new bone.
 - b. reduces blood calcium levels.
 - c. stimulates calcitonin release.
 - d. is produced by the thyroid gland.
 - e. is released when blood calcium levels fall.
5. Steroid hormones
 - a. are produced only by the adrenal cortex.
 - b. have only cell-surface receptors.
 - c. are water-soluble.
 - d. act by altering the activity of proteins in the target cell.
 - e. act by altering gene expression in the target cell.

UNDERSTANDING & APPLYING

6. Compare the characteristics you would expect of a hormone signaling system that controls a short-term process, such as digestion, with the characteristics you would expect of a hormone signaling system that controls a long-term process, such as embryonic development.
7. Some body builders, males and females, take high doses of synthetic male steroid hormones to enhance the growth of their muscles. Among other side effects, the ovarian cycles of the females stop and the males become sterile. Explain these consequences in terms of the hypothalamic/pituitary/gonadal hormonal axis.
8. Explain how both hyperthyroidism and hypothyroidism can both be associated with goiter.

ANALYZING & EVALUATING

9. Honey bees build honeycombs from beeswax that they produce. After extracting honey from the combs, beekeepers store the combs until they are needed again as the bees build up their honey reserves. Wax moths lay their eggs in honeycombs. The larvae eat the wax as they go through cycles of molting and growth until they metamorphose into adult moths. A beekeeper decided to store his honeycombs in a cold room. Months later when he went to get the spare combs out of the cold room, he found them full of large holes and gigantic moth larvae, but no adult moths. Hypothesize as to what aspect of the moth endocrine system was altered by the low temperature.
10. Neurons (the cells of the nervous system) do not require insulin. Why might this be so, and why is it important?

CHAPTER OUTLINE

- 42.1** What Are the Major Defense Systems of Animals?
- 42.2** What Are the Characteristics of the Innate Defenses?
- 42.3** How Does Adaptive Immunity Develop?
- 42.4** What Is the Humoral Immune Response?
- 42.5** What Is the Cellular Immune Response?
- 42.6** What Happens When the Immune System Malfunctions?

Fighting the Pox This 1905 illustration depicts Parisians being vaccinated against smallpox with serum from a cow infected with cowpox, a disease similar to smallpox that causes mild symptoms in humans.

TWO TINY VIALS IN DEEP FREEZERS, one in Atlanta and the other in Siberia, are all that is left of the smallpox virus, long a scourge of humanity. It last occurred as a human pathogen in 1978, after killing more than 300 million people in the twentieth century alone. Smallpox was eliminated by the human immune system with the help of vaccination. A vaccine is usually an inactive form of a pathogen or toxin that nevertheless provokes the immune system to produce antibodies: specific proteins directed against the target. The immune system destroys whatever is bound to the antibodies.

The eradication of smallpox was a spectacular international accomplishment. One might think that vaccination for other potentially lethal diseases such as the flu (influenza) would be widely accepted by the public. But in the U.S. and some other Western countries, this is not necessarily so. In fact, some surveys show that more than one-third of Americans refuse flu shots, and a significant number of parents refuse vaccination for their children.

Unfortunately, those who refuse vaccination may harm people other than themselves. A vaccination program can control or eradicate a disease only if a high percentage (typically above 80 percent) of people are vaccinated, thus disrupting the chain of infection from person to person. This level of vaccination results in "herd immunity," meaning that even those who cannot be vaccinated or who have weak immune systems are protected from infection. This protection is lost if the vaccination rate falls below the level needed for herd

immunity. Those who are old or sick, and infants whose immune systems have not yet fully developed, are most at risk.

The best way to develop herd immunity in a population is compulsory vaccination. In many countries, vaccination is a prerequisite for school enrollment and military enlistment and is required during epidemics. For example, in the periodic smallpox epidemics during the twentieth century in the U.S., doctors accompanied by police would go into neighborhoods where the disease raged, vaccinating all those who were uninfected and removing infected people to quarantine. You can imagine the reaction of parents whose children were taken away, often to die. When Henning Jacobson, a Swedish immigrant in Massachusetts, refused vaccination during a smallpox epidemic, he was arrested and took his case to the U.S. Supreme Court. It ruled in 1905 that while personal freedom is important, each state was entitled to protect its citizens. This provided a legal framework for compulsory vaccination that continues to this day. But opposition and court challenges continue. These cases of "freedom v. immunity" are a political dilemma.

Why do many people resist vaccination?

See answer on p. 877.

42.1 The Human Lymphatic System A network of ducts and vessels collects lymph from body tissues and carries it toward the heart, where it mixes with blood to be pumped back to the tissues. Other lymphoid tissues, including the thymus, spleen, and bone marrow, are also essential to the body's defense system.

Go to Activity 42.1 The Human Defense System
Life10e.com/ac42.1

42.1 What Are the Major Defense Systems of Animals?

Animals have several ways of defending themselves against **pathogens**—harmful organisms and viruses that can cause disease. These defense systems are based on the distinction between *self*—the animal's own molecules—and *nonself*, or foreign, molecules. The defensive response involves three phases:

- **Recognition phase.** The organism must be able to discriminate between self and nonself.
- **Activation phase.** The recognition event leads to a mobilization of cells and molecules to fight the invader.
- **Effector phase.** The mobilized cells and molecules destroy the invader.

There are two general types of defense mechanisms:

- **Innate defenses**, or nonspecific defenses, provide the first line of defense against pathogens. They typically act very rapidly and include barriers such as the skin, molecules that are toxic to invaders, and phagocytic cells that ingest invaders. (Recall from Section 6.5 that phagocytosis is a form of endocytosis, in which a cell engulfs a large particle or another cell.) This system recognizes broad classes of organisms or molecules and responds quickly, within minutes or hours. All animals have some level of innate

immunity, and certain innate immunity mechanisms are shared between animals and plants.

• **Adaptive defenses** are aimed at specific pathogens and are activated by the innate immune system. For example, an adaptive defense system can make an antibody protein that will recognize, bind to, and aid in the destruction of a specific virus, if that virus ever enters the body. Adaptive defenses are typically slower to develop than the innate response and longer-lasting. Adaptive immunity evolved in vertebrate animals.

Mammals have both kinds of defense mechanism and are the focus of this chapter. In mammals and other vertebrates, the innate and adaptive mechanisms operate together as a coordinated defense system. **Table 42.1** gives an overview of these processes during the course of an infection. Innate immunity is the body's first line of defense because the adaptive defenses often require days or even weeks to become effective.

Blood and lymph tissues play important roles in defense

The components of the mammalian defense system are dispersed throughout the body and interact with almost all of its other tissues and organs. The lymphoid tissues, which include the thymus, bone marrow, spleen, and lymph nodes, are essential parts of the defense system (**Figure 42.1**). The blood and lymph are complex systems with nondefensive functions that will be discussed in Chapter 50. They each have central roles in defense as well.

The blood and lymph both consist of liquids in which cells are suspended:

- **Blood plasma** is a yellowish solution containing ions, small molecule solutes, and soluble proteins. Suspended in the plasma are red blood cells, white blood cells, and platelets (cell fragments essential to blood clotting). Whereas red blood cells are normally confined to the closed circulatory system (the heart, arteries, capillaries, and veins), white blood cells and platelets are also found in the lymph.

TABLE 42.1
Innate and Adaptive Immune Responses to an Infection

Response (Time after Infection by a Pathogen)	System	Mechanisms
Early (0–4 hr)	Innate, nonspecific (first line)	Barrier (skin and lining of organs) Dryness, low pH Mucus Lysozyme, defensins
Middle (>4–96 hr)	Innate, nonspecific (second line)	Inflammation Phagocytosis Natural killer cells Complement system Interferons
Late (>96 hr)	Adaptive, specific	Humoral immunity (antibodies from B cells) Cellular immunity (T cells)

- **Lymph** is a fluid that is derived from the blood (but lacking red blood cells) and other tissues and accumulates in intercellular spaces throughout the body. From these spaces, the lymph moves slowly into the vessels of the lymphatic system. Tiny lymph capillaries conduct this fluid to larger ducts that eventually join together, forming one large vessel, the thoracic duct, which joins a major vein (the left subclavian vein) near the heart. By this system of vessels, the lymph is eventually returned to the blood and the circulatory system.

At many sites along the lymph vessels are small, roundish structures called **lymph nodes**, which contain a type of white blood cell called a **lymphocyte**. As lymph passes through a lymph node, the lymphocytes encounter foreign cells and molecules that have entered the body, and if they are recognized as nonself, an immune response is initiated.

White blood cells play many defensive roles

One milliliter of human blood typically contains about 5 billion red blood cells and 7 million of the larger **white blood cells** (also called leukocytes). All of these cells originate from multipotent stem cells (constantly dividing undifferentiated cells that can form several different cell types; see Section 19.2) in the bone marrow. There are two major families of white blood cells: lymphocytes and phagocytes (**Figure 42.2**). Lymphocytes include the B cells and T cells; they are smaller than other white blood cells and are not phagocytic. **Phagocytes** include most of the other cells shown in Figure 42.2, and as their name suggests, they are phagocytic. Each kind of white blood cell has specialized functions. Some phagocytes are also referred to collectively as granulocytes because they contain numerous granules (vesicles containing defensive molecules). Defensive proteins and signals play fundamental roles in the interactions and functioning of these cells.

Immune system proteins bind pathogens or signal other cells

The cells that defend mammalian bodies work together, interacting with one another and with the cells of invading pathogens. These cell–cell interactions are accomplished by a variety

of key proteins, including receptors, other cell surface proteins, and signaling molecules. Four of the major players are listed here, and will be discussed in more detail later in the chapter.

- **Antibodies** are proteins that bind specifically to certain substances identified by the immune system as nonself. They recognize and bind specific configurations of atoms. The molecules that bind antibodies are called **antigens**. This binding can directly inactivate viruses and toxins; on nonself cells, antibody–antigen complexes can act as tags, making the cells easier for the immune system cells to recognize and attack. Antibodies are produced by B cells.
- **Major histocompatibility complex (MHC)** proteins are used to display antigens on the surfaces of self cells, so that the antigens can be detected by antibodies and by cells of the immune system. MHC proteins also function as important self-identifying

	TYPE OF CELL	FUNCTION
	Basophils (I, A)	Release histamine; may promote development of T cells
	Eosinophils (A)	Kill antibody-coated parasites
	Neutrophils (I)	Stimulate inflammation; engulf and digest microorganisms
	Mast cells (I)	Release histamine when damaged
	Monocytes (I, A)	Develop into macrophages and dendritic cells
	Macrophages (I, A)	Engulf and digest microorganisms; activate T cells
	Dendritic cells (A)	Present antigens to T cells
	Natural killer cells (I)	Attack and lyse virus-infected or cancerous body cells
	B lymphocytes (A)	Differentiate to form antibody-producing cells and memory cells
	T lymphocytes (A)	Kill virus-infected cells or cancer cells; regulate activities of other white blood cells

42.2 White Blood Cells White blood cells have key roles in both innate (I) and adaptive (A) immunity. The lymphocytes are the B cells and T cells; the other cell types are phagocytes.

Go to Animated Tutorial 42.1
Cells of the Immune System
Life10e.com/at42.1

labels. There are two major classes of MHC proteins: MHC I proteins are found on the surfaces of most cells in the mammalian body, whereas MHC II proteins are found on immune system cells.

- **T cell receptors** are integral membrane proteins on the surfaces of T cells. They recognize and bind to antigens presented by the MHC proteins on the surfaces of other cells.
- **Cytokines** are soluble signaling proteins released by many cell types. They bind to cell surface receptors and alter the behavior of their target cells. Various cytokines activate or inactivate B cells, macrophages (see Figure 42.1), and T cells.

RECAP 42.1

All animals have innate defenses against pathogens, and vertebrates have innate and adaptive defenses. Both kinds of mechanisms are based on the ability to differentiate self from nonself. Innate defenses target a broad range of molecules and organisms, whereas adaptive defenses target specific pathogens.

- List the differences between innate and adaptive defenses. [See p. 857](#)
- What are the two classes of white blood cells, and how do they function in innate or adaptive immunity? [See p. 858 and Figure 42.2](#)

The outcome of a disease—the life or death of the host—often depends on the success of both rapid, innate responses and long-lasting, adaptive responses to invading pathogens. We will turn now to the innate defenses that protect vertebrates from disease.

42.2 What Are the Characteristics of the Innate Defenses?

Innate defenses are general protection mechanisms that attempt to stop pathogens from invading the body or to quickly eliminate those that do manage to invade. They are genetically programmed (innate) and “ready to go,” in contrast to adaptive responses, which take time to develop after a pathogen or toxin has been recognized as nonself. In mammals, innate defenses include physical barriers as well as cellular and chemical defenses (**Figure 42.3**).

Barriers and local agents defend the body against invaders

The first line of innate defense is encountered by a potential pathogen as soon as it lands on the surface of an animal. Consider a pathogenic bacterium that lands on human skin. The challenges faced by the bacterium just to reach its target are formidable:

- The *physical barrier of the skin*: Bacteria rarely penetrate intact skin; by the same token, broken skin increases the risk of infection.
- The *saltness and dryness of skin*: This environment may not be hospitable to the growth of the bacterium.
- The *presence of normal flora*: Bacteria and fungi that normally live and sometimes reproduce in great numbers on

42.3 Innate Immunity Physical barriers, cells, and proteins (complement and interferons) provide nonspecific defenses against invading pathogens.

Go to Media Clip 42.1

The Chase Is On: Phagocyte versus Bacteria

Life10e.com/mc42.1

our body surfaces without causing disease will compete with pathogens for space and nutrients.

If a pathogen lands inside the nose or another internal organ, it faces other innate defenses:

- **Mucus** is a slippery secretion produced by mucous membranes found at the inner surfaces of the nose (as well as the digestive, respiratory, and urogenital systems). Mucus traps microorganisms so they can be removed by the beating of cilia (see Figure 5.17), which continuously move the mucus and its trapped debris away.
- **Lysozyme** is an enzyme made by mucous membranes that attacks the cell walls of many bacteria, causing them to lyse (burst open).
- **Defensins**, also made by mucous membranes, are peptides of 18 to 45 amino acids that contain hydrophobic domains. They are toxic to a wide range of pathogens, including bacteria, microbial eukaryotes, and enveloped viruses. Defensins insert themselves into the plasma membranes of these organisms and make the membranes permeable, thus killing the invaders. Defensins are also produced in phagocytes, where they kill pathogens ingested by phagocytosis. Plants also produce defensins in response to pathogen exposure (see Chapter 39).

- Harsh conditions in an animal's internal environment can also kill pathogens. For example, gastric juice in the stomach is a deadly environment for many bacteria because of the hydrochloric acid and proteases that are secreted into it.

Cell signaling pathways stimulate the body's defenses

Pathogens that are able to penetrate the body's outer and inner surfaces encounter more complex innate defenses. These include the activation of defensive cells. Over the past 15 years, much has been learned about the innate cellular defense systems of both plants and animals. A critical feature is that the defense responses are triggered by nonself rather than self molecules. A class of receptors called **pattern recognition receptors (PRRs)** plays an important role in distinguishing self from nonself.

PRRs are present in cells that play roles in the innate immune systems of both plants and animals. In mammals these include macrophages, dendritic cells, and natural killer cells. The molecules recognized by PRRs are called **pathogen associated molecular patterns (PAMPs)**. As we described in Chapter 39, these are molecules that are unique to large classes of microbes, such as bacterial lipopolysaccharides, which are found in bacterial cell membranes.

An invading pathogen can be regarded as a signal. In response to that signal, the body produces molecules (complement proteins, interferons, and other cytokines) that regulate phagocytosis and other defense processes. Not surprisingly, the link between signal and response is a signal transduction pathway, similar to the ones we considered in Section 7.3. A key group of PRRs in mammals is the **toll-like receptors**, which activate signal transduction pathways involved in both innate and adaptive defenses (**Figure 42.4**). The toll protein was first identified in insects, where it is involved in development and in sensing infection. Comparative genomics has revealed at least ten similar receptors in humans. Bruce Beutler, the scientist who first described these receptors, won the Nobel Prize in 2011. Binding of a PAMP to the receptor sets in motion a cascade of molecular changes, including the activation of the transcription factor NF- κ B. (NF- κ B stands for *nuclear factor kappa light chain enhancer of activated B cells*.) The activated NF- κ B enters the nucleus, where it activates the transcription of genes encoding defensive proteins.

Specialized proteins and cells participate in innate immunity

Several proteins are produced by the body either before an infection occurs or in response to invasion by pathogens. Two important groups are the complement and interferon proteins.

COMPLEMENT PROTEINS Vertebrate blood contains more than 20 different proteins that make up the antimicrobial **complement system**. This system can be activated by various mechanisms, including both innate and adaptive defense responses. The proteins act in a characteristic sequence, or cascade, with each protein activating the next:

42.4 Cell Signaling and Defense Binding of a pathogenic molecule or fragment to the toll-like receptor initiates a signal transduction pathway that results in the transcription of genes whose products are involved in adaptive and innate defenses.

- First, the proteins attach to specific components on the surface of a microbe or to an antibody that has already bound to the microbe's surface. In either case, binding helps phagocytes recognize and destroy the microbe.
- Then, complement proteins activate the inflammatory response (see next page) and attract phagocytes to the site of infection.
- Finally, complement proteins lyse invading cells (such as bacteria).

INTERFERONS When a cell is infected by a pathogen, it produces small amounts of signaling proteins called **interferons** that increase the resistance of neighboring cells to infection. Interferons are a class of cytokines and have been found in many vertebrates. Various molecules, including double-stranded (viral) RNA, induce the production of interferons. Thus interferons are particularly important as a first line of defense against viruses. Interferons bind to receptors on the plasma membranes of uninfected cells, stimulating a signaling pathway that inhibits viral reproduction if the cells are subsequently infected. In addition, interferons stimulate the cells to hydrolyze bacterial or viral proteins to peptides, an initial step in adaptive immunity (see Section 42.3).

PHAGOCYTES Some phagocytes travel freely in the circulatory and lymphatic systems; others can move out of blood vessels and adhere to certain tissues. Pathogenic cells, viruses, or fragments of these invaders are recognized by phagocytes, which then ingest them by phagocytosis. Defensins, nitric oxide, and

reactive oxygen intermediates (see also Section 39.1) inside these phagocytes then kill the pathogens.

NATURAL KILLER CELLS One class of lymphocytes, known as **natural killer cells**, can distinguish virus-infected cells and some tumor cells from their normal counterparts and initiate the apoptosis of these target cells. In addition to this innate defense action, natural killer cells interact with the adaptive defense mechanisms by lysing antibody-labeled target cells.

DENDRITIC CELLS These phagocytes act as messengers between the innate and adaptive systems. They can endocytose microbes, viruses, and even virus-infected host cells. Once inside a dendritic cell, these particles are digested to fragments, and if fragments have PAMPs, the dendritic cell “presents” an antigenic fragment on its surface, along with class II MHC proteins. In addition, the dendritic cell secretes signals that activate cells of the adaptive immune system.

Inflammation is a coordinated response to infection or injury

When mammalian tissue is damaged because of infection or injury, the body responds with **inflammation**. This response can happen almost anywhere in the body, internally as well as on the surface. Inflammation is an important phenomenon: it isolates the damaged area to stop the spread of the damage; it recruits cells and molecules to the damaged location to kill the invader; and it promotes healing. The first responders to tissue damage are **mast cells**, which adhere to the skin and the linings of organs and release numerous chemical signals, including:

- **Tumor necrosis factor**, a cytokine protein that kills target cells and activates immune cells.
- **Prostaglandins**, fatty acid derivatives involved in various responses, including the widening of blood vessels. Prostaglandins interact with nerve endings and are partly responsible for the pain caused by inflammation.
- **Histamine**, an amino acid derivative that leads to itchy, watery eyes and rashes seen with some types of allergic reactions.

The redness and heat of inflammation result from the dilation and leakiness of blood vessels in the infected or injured area (**Figure 42.5**). Phagocytes enter the inflamed area, where they engulf the invaders and dead tissue cells. **Phagocytes are responsible for most of the healing associated with inflammation.** They produce several cytokines, which (among other functions) can signal the brain to produce a fever. This rise in body

temperature accelerates lymphocyte production and phagocytosis, thereby speeding the immune response. In some cases, pathogens are temperature-sensitive and their growth is inhibited. The pain of inflammation results from increased pressure due to swelling, the action of leaked enzymes on nerve endings, and the action of prostaglandins, which increase the sensitivity of the nerve endings to pain.

Following inflammation, pus may accumulate. **Pus is a mixture of leaked fluid and dead cells: bacteria, neutrophils (the most abundant white blood cells—see Figure 42.2), and damaged body cells.** Pus is a normal result of inflammation and is gradually consumed and further digested by **macrophages**.

Inflammation can cause medical problems

Although inflammation is generally a good thing, sometimes the inflammatory response is inappropriately strong, resulting in some allergies, cases of autoimmunity, and sepsis. In these cases the response causes more damage than was originally there. We will discuss allergy and autoimmune diseases in Section 42.6. In some cases of severe bacterial infection, the inflammatory response does not remain local. Instead it extends throughout the bloodstream in a condition called sepsis. As in a local infection or injury, blood vessels dilate, but they do so throughout the body. The lowering of blood pressure that results is a medical emergency and can be lethal.

The symptoms of swelling, pain, and fever caused by excessive inflammation can be bothersome to the point of incapacitation. Diseases such as rheumatoid arthritis and chronic obstructive pulmonary disease, and accidents such as athletic injuries, result in tissue damage and an inflammatory response. In order to manage excessive inflammation, drugs have been developed that act on the various cytokines and signal transduction pathways to reduce inflammation and its symptoms. For example, aspirin works by inhibiting an enzyme in the pathway for the synthesis of prostaglandins. **Other anti-inflammatory drugs act on the prostaglandin pathway, on the actions of tumor necrosis factor, and on the actions of histamine.**

RECAP 42.2

Innate immunity is the first line of defense against pathogens. Innate immunity includes physical barriers such as the skin, and cellular responses involving the recognition of self and nonself molecules. Recognition of nonself molecules by white blood cells leads to coordinated responses such as the production of defensive proteins and inflammation.

- How do complement proteins and interferons defend the body against microbes? **See p. 860**
- What are the roles of pathogen-associated patterns (PAMPs) and pattern recognition receptors (PRRs) in innate defenses? **See p. 860 and Figure 42.4**
- Describe the inflammatory response. **See pp. 861–862 and Figure 42.5**

Often the innate immune system, with its nonspecific defenses, is adequate to prevent or fight off a pathogenic infection. But in many cases this system works together with adaptive immunity, which detects and responds to specific

pathogens. We will now turn to the development and functioning of adaptive immunity.

42.3

How Does Adaptive Immunity Develop?

Before the twentieth century, scientists had long suspected that blood was somehow involved in immunity against pathogens. More than a century ago, Emil von Behring and Shibasaburo Kitasato at the University of Marburg in Germany performed a key experiment that pointed to blood as an important factor in immunity (**Figure 42.6**). They showed that guinea pigs injected with a sublethal dose of diphtheria toxin or bacteria developed in their blood serum (the noncellular fluid that remains after blood is clotted) a factor that protected other guinea pigs from a lethal dose of the same toxin. In other words, the recipients had developed **immunity**. Moreover, the immunity was specific: the immune factor made by the guinea pigs protected only against the specific toxin, from one strain of diphtheria-causing bacteria, with which they had been injected.

In this section we outline the main features of the adaptive immune system, much of which does indeed occur in blood serum. We will consider the two major types of adaptive responses: the humoral immune response, which produces antibodies; and the cellular immune response, which destroys infected cells.

Adaptive immunity has four key features

Four important features of the adaptive immune system are:

- specificity
- the ability to distinguish self from nonself
- the ability to respond to an enormous diversity of nonself molecules
- immunological memory

SPECIFICITY Lymphocytes (B and T cells) are crucial components of adaptive immunity. T cell receptors and the antibodies produced by B cells recognize and bind to specific nonself substances (antigens), and this interaction initiates an adaptive immune response. The specific sites on antigens that the immune system recognizes are called **antigenic determinants**, or **epitopes**:

An antigenic determinant is a specific portion of a large molecule, such as a certain **sequence of amino acids** that may be present in a protein. Antigens are usually proteins or

INVESTIGATINGLIFE

42.6 The Discovery of Adaptive Immunity Until the twentieth century, most people did not survive an attack of the bacterium that causes diphtheria, but a few did. Emil von Behring and Shibasaburo Kitasato performed a key experiment using an animal model, and demonstrated that the factor(s) responsible for immunity against diphtheria were in blood serum.^a

HYPOTHESIS Serum from guinea pigs injected with a sublethal dose of diphtheria toxin protects other guinea pigs that are exposed to a lethal dose of the same toxin.

Method

CONCLUSION Serum of toxin-exposed guinea pigs is protective against later exposure to a lethal dose of toxin from the same genetic strain of bacteria, but not a different strain.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

^aBehring, E. and S. Kitasato. 1890. *Deutsche medizinische Wochenschrift* 16: 1113–1114.

polysaccharides, and there can be multiple antigens on a single invading bacterium. A single antigenic molecule can have multiple, different antigenic determinants. The host animal responds to the presence of an antigen with highly specific defenses involving T cell receptors and antibodies. These receptors and soluble proteins bind to the antigenic determinants. Each T cell and each antibody is specific for a single antigenic determinant. For the remainder of the chapter, we will refer to antigenic determinants simply as “antigens.”

DISTINGUISHING SELF FROM NONSELF We have seen how the innate immune system distinguishes between self and non-self molecules. The adaptive immune system has another set of

mechanisms for distinguishing self from non-self. The human body contains tens of thousands of different proteins, each with a specific three-dimensional structure capable of generating immune responses. Thus every cell in the body bears a tremendous number of antigens. A crucial requirement of an individual’s adaptive immune system is that it recognize the body’s own antigens and not attack them. **This is accomplished by clonal deletion, negative selection, and the action of Treg cells (we will discuss these mechanisms later in the chapter.)**

DIVERSITY Challenges to the immune system are numerous. Pathogens take many forms: viruses, bacteria, protists, fungi, and multicellular parasites. Furthermore, each pathogenic species usually exists as many subtly different genetic strains, and each strain possesses multiple surface features. Estimates vary, but a reasonable guess is that humans can respond specifically to 10 million different antigens. Upon recognizing an antigen, the adaptive immune system responds by activating lymphocytes of the appropriate specificity. This capacity is accomplished by a special genetic recombination mechanism that we will describe in Section 42.4.

IMMUNOLOGICAL MEMORY After the innate immune system responds to a particular type of pathogen once, the adaptive immune system “remembers” that pathogen and can usually respond more rapidly and powerfully to the same threat in the future. This **immunological memory** usually saves us from repeats of childhood diseases such as chicken pox. Vaccination against specific diseases works because the adaptive immune system “remembers” the antigens that were introduced into the body.

All four of these features of adaptive immune defense characterize both the humoral immune response and the cellular immune response.

Two types of adaptive immune responses interact: an overview

The adaptive immune system mounts two types of responses against invaders: the humoral immune response and the cellular immune response. B cells that make antibodies are the workhorses of the humoral immune response, and cytotoxic (killer) T cells are the workhorses of the cellular immune response. These two responses operate simultaneously and cooperatively, sharing many mechanisms. A key event early in these two processes is the exposure of the nonself antigen’s three-dimensional structure to the immune system. This occurs

WORKING WITHDATA:

The Discovery of Adaptive Immunity

Original Paper

Behring, E. and S. Kitasato. 1890. Über das Zustandekommen der Diphtherie-Immunität und der Tetanus-Immunität bei thieren. *Deutsche medizinische Wochenschrift* 16: 1113–1114. In *Milestones in Microbiology: 1556–1940*, translated and edited by T. D. Brock, 1998, p. 138. ASM Press, Washington, D.C.

Analyze the Data

Until the early twentieth century, diphtheria, an infectious disease called the “strangling angel” for the way it disrupts breathing, exacted a terrible death toll, particularly on children. In the late 1800s a team of scientists led by Robert Koch, a leader in the then new field of microbiology, focused on diseases such as diphtheria and the equally lethal tetanus. Both diseases are caused by bacteria that kill their victims by secreting toxins into the bloodstream. A member of Koch’s team from Japan, Shibasaburo Kitasato isolated the bacteria that cause diphtheria, and a recent medical school graduate, Emil Behring, set out to see how the disease could be treated. They discovered that animals injected with the disease-causing bacteria had substances in their blood that could prevent productive infections in naïve (previously unexposed) animals and even increase survival of animals already infected (see Figure 42.6). They called these substances anti-toxins (we know them as antibodies) and soon found that they were not

species-specific: anti-toxin from a horse could be used to treat people. This and similar work on tetanus led quickly to the development of anti-diphtheria and anti-tetanus medicines. Behring shared the first Nobel Prize for Medicine in 1901. In their experiments, Behring and Kitasato used different doses of toxin to test the immunity of guinea pig #2 in each experiment (see Figure 42.6). The results are shown in the table.

QUESTION 1

What can you conclude from these data in terms of the level of protection afforded by the serum?

QUESTION 2

These experiments could be performed with the same results with either intact bacteria that cause diphtheria or a bacteria-free filtrate of a 10-day-old culture of the bacteria. Explain.

Experiment	Symptoms	
	0.5 ml dose	10 ml dose
A	Diphtheria	Diphtheria
B	No diphtheria	No diphtheria
C	Diphtheria	Diphtheria

Go to BioPortal for all WORKING WITHDATA exercises

when an antigenic molecule, or a fragment of the molecule, is displayed on the surface of a cell and the unique epitope structure protrudes from the cell, where it is exposed to nearby T or B cells. Cells that can “present” the antigen to the immune system in this way are collectively referred to as **antigen-presenting cells**. Dendritic cells play a key role as antigen-presenting cells, although other cells can also perform this function. Figure 42.7 provides a simplified overview of antigen presentation and the roles of T and B cells in the adaptive immune response.

The key player integrating the humoral and cellular immune responses is the T-helper (T_H) cell. By binding to the antigen on a presenting cell, the T_H cell stimulates events in both responses.

HUMORAL IMMUNE RESPONSE In the **humoral immune response** (from the Latin *humor*, “fluid”), antibodies react with antigens on pathogens in blood, lymph, and tissue fluids. An animal can produce a staggering diversity of antibodies capable of binding to almost any conceivable antigen the animal encounters. Antibodies are secreted by B cells and travel freely in the blood and lymph. A particular B cell also possesses receptors on its surface with the same specificity as the antibodies it produces.

The first time a specific antigen invades the body, it may be presented and then detected by binding to a T cell receptor. This binding activates a B cell with the appropriate antibody; this cell proliferates, and its daughter cells make and secrete multiple copies of the antibody.

Pregnancy Test
[Life10e.com/at42.2](https://life10e.com/at42.2)

CELLULAR IMMUNE RESPONSE The **cellular immune response** is directed against antigens that have become established within a cell of the host animal. It detects and destroys virus-infected or mutated cells, such as cancer cells expressing unique proteins caused by mutations.

T cells in the lymph nodes, bloodstream, and intercellular spaces carry out the cellular immune response. These T cells have integral membrane proteins—T cell receptors—that recognize and bind to antigens. T cell receptors are rather similar to antibodies in structure and function, each including specific molecular configurations that bind to specific antigens. Once a T cell is bound to an antigen, it initiates an immune response that typically results in the total destruction of the antigen-containing cell.

42.7 The Adaptive Immune System Humoral immunity involves the production of antibodies by B cells. Cellular immunity involves the activation of cytotoxic T cells that bind to cells expressing the antigen. For further details, see Figure 42.16.

Adaptive immunity develops as a result of clonal selection

Before the reactions just described for the humoral and cellular immune responses can take place, the body needs to generate a vast diversity of lymphocytes that have the ability to bind different antigens. How does this tremendous diversity arise? As we will discuss in Section 42.4, this diversity is generated primarily by DNA changes—chromosomal rearrangements and other mutations—that occur just after the B and T cells are formed in the bone marrow. Millions of different B cells develop, each of which can produce only one kind of antibody. Similarly, there are millions of different T cells, each with one specific kind of T cell receptor. Thus the adaptive immune system is “predeveloped”—*all of the machinery available to respond to an immense diversity of antigens is already there, even before the antigens are ever encountered.*

As we have described, when a pathogen enters the vertebrate body it stimulates the innate immune system. In addition to triggering its own defensive responses, the innate immune system triggers adaptive defensive responses via specific antigens that are presented on the surfaces of antigen-presenting cells, particularly dendritic cells. This triggers the proliferation of lymphocytes that are specific for those particular antigens. How does this proliferation occur? The answer lies in the process of **clonal selection**: *antigen binding “selects” a particular B or T cell for proliferation. When an antigen fits the surface receptor on a B or T cell and binds to it, that cell is activated. It divides to form a clone of cells (a genetically identical group derived from a single cell), all of which recognize and react to the same antigen.* This process is illustrated for B cells in Figure 42.8. Binding and activation select a particular lymphocyte, while proliferation generates the clone, hence the term “clonal selection.”

Clonal deletion helps the immune system distinguish self from nonself

Normally, the body is tolerant of its own molecules—the same molecules that would generate an immune response in another individual. One way that the immune system does this is through the process of **clonal deletion**. This occurs primarily in the thymus, during the early differentiation of T and B cells, when these cells encounter self antigens. *Any immature B or T cell that shows the potential to mount an immune response against self antigens undergoes programmed cell death (apoptosis) within a short time.*

Immunological memory results in a secondary immune response

The first time a vertebrate animal is exposed to a particular antigen there is a time lag (usually several days) before the B cell–produced antibody molecules and T cells specific to that antigen slowly increase. But for years afterward—sometimes for life—the immune system “remembers” that particular antigen, allowing the body to mount a faster response the next time it encounters the antigen. How does this happen?

The answer lies in the fact that activated lymphocytes divide and differentiate to produce *two types* of daughter cells: effector cells and memory cells.

- **Effector cells** carry out the attack on the antigen. Effector B cells, called **plasma cells**, secrete antibodies. Effector T cells release cytokines and other molecules that initiate reactions that destroy nonself or altered cells. Effector cells live only a few days.
- **Memory cells** (see Figure 42.8) are long-lived cells that retain the ability to start dividing on short notice to produce more effector and more memory cells. Memory B and T cells may survive in the body for decades, rarely dividing.

These two types of lymphocytes can respond to an antigen in two different ways:

42.8 Clonal Selection in B Cells The binding of an antigen to a specific receptor on the surface of a B cell stimulates that cell to divide, producing a clone of genetically identical cells to fight that invader. Plasma cells have extensive endoplasmic reticulum for synthesizing antibodies.

- When the body first encounters a particular antigen, a **primary immune response** is activated, in which the “naïve” (previously unexposed) lymphocytes that recognize that antigen proliferate to produce clones of effector and memory cells.
- After a primary immune response to a particular antigen, subsequent encounters with the same antigen will trigger a much more rapid and powerful **secondary immune response**. The memory cells that bind with that antigen proliferate, launching a huge army of plasma cells and effector T cells.

Vaccines are an application of immunological memory

You will recall Behring’s experiment on using the serum of diphtheria-exposed animals to protect other animals from the disease (see Figure 42.6). The animals that survived and donated serum had developed an adaptive immune response, including memory cells that lead to long-term protection.

Thanks to immunological memory, exposure to many diseases (including childhood diseases such as chicken pox) provides a natural immunity to those diseases. Furthermore, it is possible to provide artificial immunity against many life-threatening diseases by **vaccination**: the introduction of antigen into the body in a form that does not cause disease.

Vaccination initiates a primary immune response, generating memory cells without making the person ill. Later, if a pathogen carrying the same antigen attacks, specific memory cells already exist. They recognize the antigen and quickly overwhelm the invaders with a massive production of lymphocytes and antibodies (Figure 42.9).

Because the antigens used for immunization or vaccination are produced by pathogenic organisms, they must be altered so that they cannot cause disease but are still able to provoke an immune response. There are three principal ways to do this:

- **Inactivation** involves killing the pathogen with heat or chemicals.
- **Attenuation** involves reducing the virulence of a virus by repeatedly infecting cells with it in the laboratory; this results in mutations in the virus that render it nonpathogenic but still recognized as nonself.
- **Recombinant DNA technology** can be used to produce peptide fragments that bind to and activate lymphocytes but do not have the harmful part of a protein toxin.

For most of the 70 or so bacteria, viruses, fungi, and parasites known to cause serious human diseases, vaccines are already

available or will be in the next few years. As you saw in the opening story, vaccination has completely or almost completely wiped out some deadly diseases, including smallpox, diphtheria, and polio, in industrialized countries.

42.9 Vaccination Immunological memory from exposure to an antigen that does not cause disease can result in a massive response to the disease agent when it appears later.

RECAP 42.3

The adaptive immune system reacts against nonself or mutated self molecules called antigens. The system generates amazing diversity in both antibodies (produced by B cells) and in T cell receptors. In the primary immune response, B cells and T cells that recognize a particular pathogen proliferate by clonal selection. Immunological memory prepares the body for a much stronger secondary immune response.

- How does an antigen initiate an adaptive immune response? See pp. 864–865 and Figure 42.7
- Describe clonal selection. How does it contribute to immunological memory? See pp. 865–866 and Figure 42.8
- How do vaccines make use of immunological memory? See p. 866 and Figure 42.9

Now that we have discussed some general features of the adaptive immune system, let's focus in more detail on the B lymphocytes and the humoral immune response.

42.4 What Is the Humoral Immune Response?

Every day, billions of B cells survive the test of clonal deletion and are released from the bone marrow into the circulation. B cells are the basis for the humoral immune response.

Go to Animated Tutorial 42.3
Humoral Immune Response
Life10e.com/at42.3

Some B cells develop into plasma cells

A B cell begins by making a receptor protein on its cell surface. As we have seen, if a B cell is activated by antigen binding to this receptor, it gives rise to clones of plasma cells and memory cells. The plasma (effector B) cells secrete antibodies into the bloodstream (see Figure 42.8).

Usually, for a naïve B cell to develop into an antibody-secreting plasma cell, a T-helper (T_H) cell with the same specificity must also bind to the antigen (see Figure 42.7). The division and differentiation of the B cell is stimulated by chemical signals from the T_H cell.

As plasma cells develop, the number of ribosomes and the amount of endoplasmic reticulum in their cytoplasm increase greatly. These increases allow the cells to synthesize and secrete large amounts of antibody proteins—up to 2,000 molecules per second! *All the plasma cells arising from a given B cell produce antibodies that are specific for the antigen that originally bound to the parent B cell.* Thus antibody specificity is maintained as B cells proliferate.

Different antibodies share a common structure

Antibodies belong to a class of proteins called **immunoglobulins**. There are several types of immunoglobulins, but all

42.10 The Structure of an Immunoglobulin Four polypeptide chains (two light, two heavy) make up an immunoglobulin molecule. Both diagrammatic (A) and space-filling (B) representations of immunoglobulin are shown here.

Go to Activity 42.3 Immunoglobulin Structure
Life10e.com/ac42.3

contain a tetramer consisting of four polypeptide chains (**Figure 42.10**). In each immunoglobulin molecule, two of these polypeptides are identical light chains, and two are identical heavy chains. Disulfide bonds hold the chains together. Each polypeptide chain has a constant region and a variable region:

- The amino acid sequences of the **constant regions** are similar among the immunoglobulins. They determine the destination and function—the class—of each immunoglobulin.
- The amino acid sequences of the **variable regions** are different for each specific immunoglobulin. Their three-dimensional antigen-binding sites are determined by their secondary structures and are responsible for antibody specificity.

The two antigen-binding sites on each immunoglobulin molecule are identical, making the antibody bivalent (*bi*, “two”; *valent*, “binding”). This ability to bind two antigen molecules at once, along with the presence of multiple epitopes on the surfaces of many antigens (including large proteins, viruses, and bacteria) permits antibodies to form large complexes with the antigens. These complexes are easy targets for ingestion and breakdown by phagocytes.

There are five classes of immunoglobulins

While the variable regions are responsible for the specificity of an immunoglobulin, the constant regions of the heavy chain determine the class of the immunoglobulin—for example, whether it will be an integral membrane receptor (e.g., on the surface of a B cell) or a soluble antibody that is secreted into the bloodstream. The five immunoglobulin classes are described in **Table 42.2**. The most abundant class is IgG; these soluble antibody proteins make up about 80 percent of the total immunoglobulin content of the bloodstream. They are made in greatest quantity during a secondary immune response. IgG molecules defend the body in several ways. For example, after some IgG molecules bind to antigens, they become attached by

their heavy chains to macrophages. This attachment permits the macrophages to destroy the antigens by phagocytosis.

Immunoglobulin diversity results from DNA rearrangements and other mutations

Each mature B cell makes one—and only one—specific antibody targeted to a single epitope. As we have seen, there are millions of possible epitopes to which a human is exposed or can be exposed. A simple calculation using approximate numbers shows that it would be impossible to have a unique gene for each of these epitopes:

One antibody gene \approx 2,100 base pairs (bp) DNA

10 million different antibodies \approx 21 billion bp DNA

This is seven times the size of the entire human genome! There must be another way to generate antibody diversity.

It turns out that instead of a single gene encoding each immunoglobulin, the genome of the differentiating B cell has a limited number of alleles for each of several regions (domains) of the protein, and that combinations of these alleles generate

TABLE 42.2
Antibody Classes

Class	General Structure	Location	Function
IgG	Monomer 	Free in blood plasma; about 80 percent of circulating antibodies	Most abundant antibody in primary and secondary immune responses; crosses placenta and provides passive immunization to fetus
IgM	Pentamer 	Surface of B cell; free in blood plasma	Antigen receptor on B cell membrane; first class of antibodies released by B cells during primary response
IgD	Monomer 	Surface of B cell	Cell surface receptor of mature B cell; important in B cell activation
IgA	Dimer 	Saliva, tears, milk, and other body secretions	Protects mucosal surfaces; prevents attachment of pathogens to epithelial cells
IgE	Monomer 	Secreted by plasma cells in skin and tissues lining gastrointestinal and respiratory tracts	Binds to mast cells and basophils to sensitize them to subsequent binding of antigen, which triggers release of histamine that contributes to inflammation and some allergic responses

The **variable region** for the heavy chain of a specific antibody is encoded by one *V* gene, one *D* gene, and one *J* gene. Each of these genes is taken from a pool of like genes.

The **constant region** is selected from another pool of genes. The number of possible combinations to make an immunoglobulin heavy chain from these pools of genes is $(100 V)(30 D)(6 J)(8 C) = 144,000$.

42.11 Heavy-Chain Genes Mouse immunoglobulin heavy chains have four domains, each of which is coded for by one of several possible genes selected from a cluster of similar genes.

coding sequence (*VDJ*) of the heavy-chain variable region. So the number of different heavy chains that can be made through this random recombination process is quite large:

$$100 V \times 30 D \times 6 J = 18,000 \text{ possible combinations}$$

If we assume a similar amount of diversity in the light chain variable region, the number of possible combinations of light- and heavy-chain variable regions is:

$$18,000 \text{ different light chains} \times 18,000 \text{ different heavy chains} = 324 \text{ million possibilities!}$$

diversity. First let's look at the unusual process of shuffling this genetic deck to generate the enormous immunological diversity that characterizes each individual mammal. This process affects the variable region, the part of the immunoglobulin that recognizes a particular epitope. Next we will see how similar events involving the constant region produce the five classes of immunoglobulins, which have different cellular locations or functions in the body.

Each gene encoding an immunoglobulin chain is in reality a "supergene" assembled by means of genetic recombination from several clusters of smaller genes scattered along part of a chromosome. Such a region in the mouse genome is shown in **Figure 42.11**. Every cell in the body has hundreds of immunoglobulin genes located in separate clusters that are potentially capable of participating in the synthesis of both the variable and constant regions of immunoglobulin chains. In most body cells and tissues, these genes remain intact and separated from one another. But during B cell development, these genes are cut out, rearranged, and joined together in DNA recombination events. One gene from each cluster is chosen randomly for joining, and the others are deleted.

In this manner, a unique immunoglobulin supergene is assembled from randomly selected "parts." Each B cell precursor assembles two supergenes, one for a specific heavy chain and the other, assembled independently, for a specific light chain. In humans and mice, two families of genes encode the variable region of the light chain, and three families encode the variable region of the heavy chain. For example, in mice the variable region of the heavy chain is assembled from 100 *V*, 30 *D*, and 6 *J* genes (see Figure 42.11). Each B cell randomly selects one gene from each of these clusters to make the final

Even more diversity is generated by various kinds of mutation that occur during the recombination events. These mutations can occur through imprecise recombination and the high spontaneous mutation rates in immunoglobulin genes.

These genetic events are irreversible—once the final coding sequence has been assembled for the variable regions of a B cell's light and heavy chains, that B cell's epitope specificity cannot change. This remarkable example of irreversible cell differentiation generates an enormous diversity of immunoglobulins from the same starting genome. A similar process results in the diversity of T cell receptors, which we will discuss in more detail in Section 42.5.

Once the pre-transcriptional processing is completed, each supergene is transcribed and then translated to produce an immunoglobulin light chain or heavy chain. These combine to form an active immunoglobulin protein, as shown in **Figure 42.12**. This figure shows the variable region joining with a μ constant region segment, which forms a gene for an immunoglobulin in the IgM class (see below). However, this genetic system is capable of still other kinds of changes. The B cell or plasma cell can switch the immunoglobulin class it produces while retaining its antigen specificity.

Go to Animated Tutorial 42.4
A B Cell Builds an Antibody
Life10e.com/at42.4

The constant region is involved in immunoglobulin class switching

Table 42.2 describes the different classes of immunoglobulins and their functions. Generally, a B cell makes only one class

42.12 Heavy-Chain Gene Recombination and RNA Splicing

Two types of rearrangement in the heavy-chain gene clusters are required for antibody formation. (A) Prior to transcription, DNA is rearranged to join one each of the V, D, and J genes into a variable region supergene. (B) After transcription, RNA splicing joins the VDJ region to the constant region.

at a time. But **class switching** can occur, in which a B cell changes the immunoglobulin class it synthesizes. For example, a B cell making IgM can switch to making IgG.

Early in its life, a B cell produces IgM molecules, which are the receptors responsible for its recognition of a specific antigen. At this time, the constant region of the heavy chain is encoded by the first constant region gene, the μ gene (see Figures 42.11 and 42.12). If the B cell later becomes a plasma cell during a humoral immune response, another deletion occurs in the cell's DNA, positioning the variable region genes (consisting of the same V, D, and J genes) next to a constant region gene farther away on the original DNA molecule (Figure 42.13). Such a DNA deletion results in the production of a new immunoglobulin with a different constant region of the heavy chain, and therefore a different function (see Table 42.2). However, this immunoglobulin has the same variable regions—and therefore the same antigen specificity—as the IgM produced by the parent B cell. The new immunoglobulin protein falls into one of the other four classes (IgA, IgD, IgE, or IgG), depending on which of the constant region genes is placed adjacent to the variable region genes.

What triggers class switching? T_H cells direct the course of an immune response and determine the nature of the attack on the antigen. These T cells induce class switching by sending cytokine signals. The cytokines bind to receptors

42.13 Class Switching: Exchanging C Regions The supergene produced by joining V, D, J, and C genes (see Figure 42.12) may later be modified, causing a different C region to be transcribed. This modification, known as class switching, is accomplished by deletion of part of the constant region gene cluster. Shown here is class switching from IgM to IgG.

on the target B cells, generating signal transduction cascades that result in recombination and altered expression of the immunoglobulin genes.

Monoclonal antibodies have many uses

The specificity of antibodies suggested to scientists that they might be useful for detecting specific substances in the laboratory. However, the immune response to a complex antigen is polyclonal—that is, most antigens carry many different antigenic determinants and will produce a complex mixture of antibodies, each made by a different clone of B cells. Furthermore, as emphasized in our study of biochemistry, many biological molecules share regions of similar structure—all human steroid hormones, for example, have a similar multi-ring structure (see Figure 41.2). A polyclonal group of antibodies targeted to estrogen might be uninformative because some of the antibodies would bind to any steroid hormone present in the blood sample. More useful would be a clone of B cells that produce large amounts of an antibody that binds to only one specific epitope—a **monoclonal antibody**. Various methods can be used to produce monoclonal antibodies in the laboratory.

Monoclonal antibodies have many applications:

- *Immunoassays* involve the use of monoclonal antibodies to detect tiny amounts of molecules in tissues and fluids. For example, this technique is used in pregnancy tests to detect human chorionic gonadotropin, the hormone made by the developing embryo.
- *Immunotherapy* involves the use of monoclonal antibodies targeted against antigens on the surfaces of cancer cells. The coupling of a radioactive ligand or a toxin to the antibody makes it into a medical “smart bomb.” In a related approach, binding of the antibody itself is enough to trigger a cellular immune response that destroys the cancer. This is the case with trastuzumab (Herceptin), a monoclonal antibody that binds to a growth factor receptor on some breast cancer cells.

RECAP 42.4

The humoral immune response is based on the synthesis by B cells of specific immunoglobulins. The specificity of an immunoglobulin derives from the amino acid sequence of its variable regions. B cells can make millions of immunoglobulins with different specificities by rearranging the genes that encode the variable regions of the heavy and light chains. Monoclonal antibodies are specific to one epitope and can be produced artificially for use in diagnostics and therapy.

- How does a B cell respond to an antigen? **See p. 867**
- How is the structure of an antibody molecule related to its function? **See pp. 867–868 and Figure 42.10**
- How can millions of antibodies with different specificities be generated from a relatively small number of genes? **See pp. 869–870 and Figures 42.11 and 42.12**
- What is the role of the constant region of the immunoglobulin in class switching? **See p. 870 and Figure 42.13**
- What are monoclonal antibodies, and how are they used? **See p. 871**

By making antibodies, B cells are the major players in the humoral immune response. We will now turn to the cellular immune response, where T cells are active at all stages.

42.5 What Is the Cellular Immune Response?

Two types of effector T cells (T-helper cells and cytotoxic T cells) are involved in the cellular immune response. They work along with proteins of the major histocompatibility complex (the MHC proteins), which present antigens on the surfaces of cells and contribute to the immune system’s tolerance for the body’s own cells.

Go to Animated Tutorial 42.5
Cellular Immune Response
Life10e.com/at42.5

T cell receptors bind to antigens on cell surfaces

Like B cells, T cells possess specific membrane receptors. The T cell receptor is not an immunoglobulin, however, but a **glycoprotein** with a molecular weight of about half that of an IgG. It is made up of **two polypeptide chains, each encoded by a separate gene** (Figure 42.14). The two chains have distinct regions with constant and variable amino acid sequences. As in the immunoglobulins, the variable regions provide the site for specific binding to antigens. But there is one major difference: **whereas an antibody can bind to any antigen, whether it is present on the surface of a cell or not, a T cell receptor binds only to an antigen displayed by an MHC protein on the surface of an antigen-presenting or target cell.**

42.14 A T Cell Receptor The receptors on T lymphocytes are smaller than those on B lymphocytes, but their two polypeptides contain both variable and constant regions. As with the B cell receptors, the constant region fixes the receptor in the plasma membrane, while the variable regions establish the specificity for binding to antigen.

When a T cell is activated by contact with a specific antigen, it proliferates and forms a clone. Its descendants form clones of two types of effector T cells:

- **Cytotoxic T cells**, or **T_C cells**, recognize virus-infected or mutated cells and kill them by inducing lysis (see p. 874).
- **T-helper cells (T_H cells)**, also called helper T cells) assist both the cellular and the humoral immune responses.

MHC proteins present antigen to T cells

T cell receptors do not bind directly to antigens. Instead, they bind to antigens that are bound to a cell surface glycoprotein, an MHC protein. With several gene families and hundreds of alleles, the MHC protein is a cell surface marker of genetic individuality. The diversity of MHC proteins also means that there are many possibilities for presenting an antigen to the T cell receptor.

There are two classes of MHC proteins. Both function to present antigens to the different T lymphocytes:

- **Class I MHC** proteins are present on the surface of every nucleated cell in the vertebrate body. They enable T_C cells to recognize virus-infected cells and kill them. Viral protein fragments that are antigenic are complexed with MHC I inside the cell and then the complex is carried to the plasma membrane. A T_C cell with the appropriate T cell receptor then binds to the MHC–antigen complex. To ensure binding, the T_C cell also has a cell surface protein called CD8 that recognizes and binds to MHC I.
- **Class II MHC** proteins are found mostly on the surfaces of B cells, macrophages, and other antigen-presenting cells, including dendritic cells (see Figure 42.2). When one of these cells ingests a pathogen such as a bacterium, the bacterial antigens are broken down in a phagosome. An MHC II molecule may bind to one of the fragments and carry it to the cell surface, where it is presented to a T_H cell (Figure 42.15). T_H cells have a surface protein called CD4 that recognizes and binds to MHC II.

Table 42.3 summarizes the information on MHC proteins, the cellular origins of antigens, and T lymphocytes. To accomplish its role in antigen presentation, each kind of MHC protein has an antigen-binding site that can hold a peptide of about 10 to 20 amino acids. The T cell receptor recognizes not just the antigenic fragment but the MHC I or II protein to which the fragment is bound.

MHC proteins play a vital role in the selection of T cells during their development in the thymus gland:

- **Binding to MHC proteins.** A T cell receptor should bind not to an antigen alone but to an antigen–MHC complex, because T cells are activated by antigen presented on the surface of cells, not free antigen. Here there is positive selection for T cells that bind to MHC proteins. Any T cells that do not recognize MHC proteins (and thus would not bind to antigen-presenting cells) are eliminated soon after they develop; the rest of the T cells go on to the next selection step.
- **Binding to self peptides bound to self MHC proteins.** In this case there is negative selection of T cells that bind to self antigens presented on MHC proteins. This eliminates the further production of T cells that react to self antigens. Negative selection through clonal deletion (see p. 874) is

42.15 Macrophages Are Antigen-Presenting Cells A fragment of an antigen is displayed by MHC II on the surface of a macrophage. T cell receptors on a specific T-helper cell can then bind to and interact further with the antigen–MHC II complex.

a mechanism that prevents the adaptive immune system from reacting to self molecules.

T-helper cells and MHC II proteins contribute to the humoral immune response

When a T_H cell survives the selection processes and binds to an antigen-presenting cell, it releases cytokines that activate the T_H cell to proliferate, producing a clone of T_H cells with the same specificity. The steps to this point constitute the activation phase of the humoral immune response, and they occur in the lymphoid tissues. Next comes the effector phase, in which the T_H cells activate naïve B cells with the same specificity to produce antibodies.

B cells are also antigen-presenting cells. B cells take up antigens bound to their surface immunoglobulin receptors by endocytosis, break them down, and display antigenic fragments on class II MHC proteins. When a T_H cell binds to the displayed antigen–MHC II complex, it releases cytokines that cause the B cell to produce a clone of plasma cells (Figure 42.16A). Finally, the plasma cells secrete antibodies, completing the effector phase of the humoral immune response.

TABLE 42.3 The Interaction between T Cells and Antigen-Presenting Cells				
Presenting Cell Type	Antigen Presented	MHC Class	T Cell Type	T Cell Surface Protein
Any cell	Intracellular protein fragment	Class I	Cytotoxic T cell (T _C)	CD8
Macrophages, dendritic cells, and B cells	Fragments from extracellular proteins	Class II	Helper T cell (T _H)	CD4

(A)

(B)

**42.16 Phases of the Humoral and Cellular Immune Responses**

Both the humoral and the cellular immune responses have activation and effector phases, all of which involve T cells.

Cytotoxic T cells and MHC I proteins contribute to the cellular immune response

Class I MHC proteins play a role in the cellular immune response that is similar to the role played by class II MHC proteins in the humoral immune response. In a virus-infected or mutated cell, foreign or abnormal proteins or peptide fragments combine with MHC I molecules. The resulting complex is displayed on the cell surface and presented to T_C cells. When a T_C cell recognizes and binds to this antigen–MHC I complex, it is activated to proliferate (Figure 42.16B).

In the effector phase of the cellular immune response, T_C cells recognize and bind to cells bearing the same antigen–MHC I complex. These bound T_C cells produce a substance called perforin, which lyses the bound target cell. In addition, the T_C cells can bind to a specific receptor (called Fas) on the target cell that initiates apoptosis in that cell. These two mechanisms, cell lysis and programmed cell death, work in concert to eliminate the antigen-containing host cell. Because T_C cells recognize MHC proteins complexed with nonself antigens, they help rid the body of its own virus-infected or cancerous cells.

Regulatory T cells suppress the humoral and cellular immune responses

A third class of T cells called **regulatory T cells (Tregs)** ensures that the immune system does not attack self cells and molecules indiscriminately. Like T_H and T_C cells, Tregs mature in the thymus gland, carry T cell receptors, and become activated if they bind to antigen–MHC complexes. But Tregs are different in one important way: **the antigens that Tregs recognize are self antigens**. The activation of Tregs causes them to secrete the cytokine interleukin-10, which blocks T cell activation and leads to apoptosis of the T_C and T_H cells that are bound to the same antigen-presenting cell (Figure 42.17). Thus Tregs constitute another mechanism for distinguishing self from nonself. How do we know this? There are two lines of evidence for the role of Tregs. As in many other biological studies, the cause-and-effect relationships were worked out using experimental manipulations and genetics:

- If Tregs are experimentally destroyed in the thymus of a mouse, the mouse grows up with an out-of-control immune system, mounting strong immune responses to self antigens (autoimmunity—see Section 42.6).
- In humans, a rare X-linked hereditary disease occurs when a gene critical to Treg function is mutated. An infant with this disease, called IPEX (*immune dysregulation, polyendocrinopathy and enteropathy, X-linked*), mounts an immune response that attacks the pancreas, thyroid, and intestines. Most affected individuals die within the first few years of life.

MHC proteins are important in tissue transplants

In humans, one consequence of the major histocompatibility complex became important with the development of organ transplant surgery. Because the proteins produced by the MHC

42.17 Tregs and Tolerance A special class of T cells called regulatory T cells (Tregs) inhibits the activation of the immune system in response to self antigens.

are specific to each individual, they act as nonself antigens if transplanted into another individual. An organ or a piece of tissue transplanted from one person to another is recognized as nonself by the host body and soon provokes an immune response; the tissue is then killed, or “rejected,” by the host’s cellular immune system. But if the transplant is performed immediately after birth, or if it comes from a genetically identical person (an identical twin), the material is recognized as self and is not rejected.

The rejection problem can be overcome by treating a patient with a drug, such as cyclosporin, that suppresses the immune system. **Cyclosporin blocks the activation of a transcription factor that is essential for T cell development.** However, this approach compromises the ability of transplant recipients to defend themselves against pathogens. This problem must be managed by the use of antibiotics and other drugs to combat infections that develop.

RECAP 42.5

Specific receptors on T cells bind to antigen–MHC complexes displayed on cell surfaces. During development, T cells are selected that recognize MHC proteins. T-helper cells bind antigens on MHC II proteins and contribute to the humoral immune response. Cytotoxic T cells bind antigens on MHC I proteins and contribute to the cellular immune response. The cellular immune response acts against virus-infected or mutated body cells. Tregs suppress immune responses to self antigens.

- What are the roles of a T cell receptor in cellular immunity? **See p. 871 and Figure 42.14**
- What parts do MHC proteins play in the cellular immune response? **See p. 872 and Figure 42.15**
- What occurs during the cellular immune response to a virus-infected cell? **See pp. 873–874 and Figure 42.16**

Given the numerous and complex cellular interactions that activate the immune system and generate antibody diversity, you may have perceived many points at which the immune system could fail. We will now turn to several situations in which one or more components of this complex system malfunction.

42.6 What Happens When the Immune System Malfunctions?

Sometimes the immune system fails us in one way or another. It may overreact, as in an allergic reaction; it may attack self

antigens, as in an autoimmune disease; or it may function weakly or not at all, as in an immune deficiency disease.

Allergic reactions result from hypersensitivity

An **allergic reaction** arises when the human immune system overreacts to (is hypersensitive to) a dose of antigen. Although the antigen itself may present no danger to the host, the inappropriate immune response may produce inflammation and other symptoms, which can cause serious illness or even death. Allergic reactions are the most familiar examples of this phenomenon. Allergic reactions may involve immediate hypersensitivity or delayed hypersensitivity.

IMMEDIATE HYPERSENSITIVITY **Immediate hypersensitivity** arises when an allergic individual is exposed to an antigen (in this case referred to as an allergen) from the environment, such as a food, pollen, or the venom of an insect. In response to the allergen, the individual makes large amounts of IgE. When this happens, mast cells in tissues and basophils in the blood bind the constant end of the IgE. If that individual is exposed to the same allergen again, binding of the allergen to the IgE causes the mast cells and basophils to rapidly release a large amount of histamine (**Figure 42.18**). This results in symptoms such as dilation of blood vessels, inflammation, and difficulty breathing. If not treated with antihistamines, a severe allergic reaction can lead to death. It is not known why some people produce excessive amounts of IgE in response to allergens. There is some evidence for genetic factors predisposing people to allergic responses.

42.18 An Allergic Reaction An allergen is an antigen that stimulates B cells to make large amounts of IgE antibodies, which bind to mast cells and basophils. When the body encounters the allergen again, these cells produce large amounts of histamine, which has harmful physiological effects.

Allergy to pollen can be treated using a process called desensitization. The process involves injecting small amounts of the allergen (typically just an extract of the offending plant tissue) into the skin—enough to stimulate IgG production but not enough to stimulate IgE production. The next time the person is exposed to the allergen, IgG binds to it, tying it up before IgE can bind it and exert its harmful effects.

Desensitization does not work for food allergens because the IgE response to those substances is so strong that even a small amount of antigen provokes it. The best approach for those with food allergies—there are an estimated 3 million people in the U.S.—is to avoid foods containing the allergens. This can be difficult, but food labels listing all the ingredients are helpful. Molecular biologists are beginning to identify the antigens that act as allergens, with the hope of developing vaccines or genetically modified foods that lack the allergenic epitopes.

DELAYED HYPERSENSITIVITY **Delayed hypersensitivity** is an allergic reaction that does not begin until hours after exposure to an antigen. In this case the antigen is taken up by antigen-presenting cells and a T cell response is initiated. A T_H cell produces a clone of cells that secrete various cytokines, which cause such reactions as inflammation and rash. These events take time (hence the term “delayed”). An example is the rash that develops after exposure to poison ivy.

Autoimmune diseases are caused by reactions against self antigens

Errors in the selection of T cells in the thymus can result in T cells that bind to antigen–MHC complexes that carry self antigens. Although the precise origin of **autoimmunity** is not known, there are several hypotheses:

- *Failure of negative selection.* A clone of lymphocytes making antibodies against self antigens that should have been destroyed by clonal deletion is not destroyed.
- *Molecular mimicry.* T cells that recognize a nonself antigen, such as a virus, also recognize something on a self antigen that has a similar structure.

Autoimmunity does not always result in disease, but several autoimmune diseases are common:

- People with *systemic lupus erythematosus* (SLE) have antibodies to many cellular components, including DNA and nuclear proteins released from dying cells. These antinuclear antibodies can cause serious damage when they bind to normal tissue antigens and form large circulating antigen–antibody complexes, which become stuck in tissues and provoke inflammation.
- People with *rheumatoid arthritis* have difficulty in shutting down a T cell response to self antigens. These patients may have low activity of CTLA4, an inhibitory protein that blocks T cells from reacting to self antigens. This results in inflammation of the joints and other tissue damage.

- *Hashimoto’s thyroiditis* is the most common autoimmune disease in women over 50. Immune cells attack thyroid tissue, resulting in fatigue, depression, weight gain, and other symptoms.
- *Insulin-dependent diabetes mellitus*, or type I diabetes, occurs most often in children. It is caused by an immune reaction against several proteins in the cells of the pancreas that manufacture the protein hormone insulin. This reaction kills the insulin-producing cells, so people with type I diabetes must take insulin daily in order to survive.

AIDS is an immune deficiency disorder

There are several inherited and acquired immune deficiency disorders. In some individuals, T or B cells never form; in others, B cells lose the ability to give rise to plasma cells. In either case, the affected individual is unable to mount an adaptive immune response and thus lacks a major line of defense against pathogens. The T_H cell is perhaps the most central component of the immune system because of its essential roles in both the humoral and cellular immune responses (see Figure 42.7). This cell is the target of **human immunodeficiency virus (HIV)**, the retrovirus that results in **acquired immune deficiency syndrome (AIDS)**.

HIV can be transmitted from person to person in body fluids containing the virus (such as blood, semen, vaginal fluid, or breast milk). The recipient tissue is either blood (by transfusion) or a mucous membrane lining an organ (the mucus contains a high concentration of lymphocytes). HIV initially infects macrophages, T_H cells, and antigen-presenting dendritic cells in the blood and tissues. At first there is an immune response to the viral infection, and T_H cells are activated. But because HIV infects the T_H cells, they are killed both by HIV itself and by T_C cells that lyse infected T_H cells. Consequently T_H cell numbers decline after the first month or so of infection. Meanwhile, the extensive production of HIV by infected cells activates the humoral immune system. Antibodies bind to HIV, and the complexes are removed by phagocytes. The HIV level in blood goes down. There is still a low level of infection, however, because of the depletion of T_H cells (**Figure 42.19**). This process reaches a low, steady-state level called the “set point.” This point varies among individuals and is a strong predictor of the rate of progression of the disease. For most people it takes 8 to 10 years without treatment for the more severe manifestations of AIDS to develop. In some it can take as little as a year; in others, 20 years.

During this dormant period, people carrying HIV generally feel fine, and their T_H cell levels are adequate for them to mount immune responses. Eventually, however, the virus destroys the T_H cells, and their numbers fall to the point where the infected person is susceptible to infections that the T_H cells would normally eliminate. These infections result in conditions such as Kaposi’s sarcoma, a skin tumor caused by a herpes virus; pneumonia caused by the fungus *Pneumocystis jirovecii*; and lymphoma tumors caused by the Epstein–Barr virus. These conditions result from opportunistic infections because

42.19 The Course of an HIV Infection An HIV infection may be carried, unsuspected, for many years before the onset of symptoms.

the pathogens take advantage of the crippled immune system of the host. They lead to death within a year or two.

The molecular biology of HIV and its life cycle have been intensively studied (see Figure 16.16). This has resulted in the development of drugs targeted to HIV proteins, such as the reverse transcriptase that makes cDNA from the viral RNA, and the viral protease that cuts the large precursor viral protein into its final active proteins. Treatment with combinations of

such drugs has had spectacular success. Getting AIDS before the 1990s was a death sentence, with few sufferers surviving beyond a year or two. Today the survival of a treated, infected person is not much different from that of an uninfected person. Unfortunately, like many medical treatments, HIV drugs are not available to all who need them—particularly in poor regions of the world where AIDS is prevalent. As a result, there are about 1.7 million deaths per year worldwide from AIDS.

RECAP 42.6

Failures of the immune system include allergic reactions (caused by hypersensitivity to antigens), autoimmune diseases (caused by reactions against self antigens), and immune deficiency disorders.

- How does immediate hypersensitivity develop? **See p. 875 and Figure 42.18**
- What is an autoimmune disease? Give an example. **See p. 876**
- Describe the course of events in the human immune system during HIV infection. **See pp. 876–877 and Figure 42.19**

Why do many people resist vaccination?

ANSWER

There seem to be three main reasons why a person might refuse a vaccine. The first is complacency. Measles, which used to kill thousands of children every year in the U.S. and still does in poor countries, is no longer a highly visible threat to public health. Second, some people believe that vaccines, although exhaustively tested for safety, are actually unsafe and cause disease. The internet is full of such assertions. Third, people are wary of experts because of past false alarms. The discovery of the H1N1 flu virus (swine flu) in Mexico in 2009 led to a high alert and a mass vaccination program that turned out not to be necessary. Vaccination is a scientific success in terms of bolstering immunity and eradicating disease. But like any technology, its acceptance is a political issue.

42.1 What Are the Major Defense Systems of Animals?

- Animal defenses against **pathogens** are based on the body's ability to distinguish between self and nonself.
- **Innate** (nonspecific) **defenses** are inherited mechanisms that protect the body from many kinds of pathogens. They typically act rapidly.
- **Adaptive** (specific) **defenses** respond to specific pathogens. They develop more slowly than innate defenses but are long-lasting.
- Many defenses are implemented by cells and proteins carried in the blood plasma and **lymph**. **Review Figure 42.1, ACTIVITY 42.1**
- **White blood cells** fall into two broad groups. **Phagocytes** engulf pathogens by phagocytosis. **Lymphocytes**, which include B cells and T cells, participate in adaptive responses. **Review Figure 42.2, ANIMATED TUTORIAL 42.1**

42.2 What Are the Characteristics of the Innate Defenses?

- An animal's innate defenses include physical barriers such as the skin, and competing resident microorganisms known as normal flora. **Review Figure 42.3**
- The **complement system** consists of more than 20 different antimicrobial proteins that act to alter membrane permeability and kill targeted cells.
- Circulating defensive cells, such as phagocytes and **natural killer cells**, eliminate invaders.
- A cell signaling pathway involving the **toll-like receptor** stimulates the body's defenses. **Review Figure 42.4**
- **Inflammation** involves activation of several types of cells and proteins that act against invading pathogens. **Mast cells** release **histamines**, which cause blood vessels to dilate and become "leaky." **Review Figure 42.5, ACTIVITY 42.2**

42.3 How Does Adaptive Immunity Develop?

- The adaptive immune response recognizes specific **antigens**, responds to an enormous diversity of **antigenic determinants**, distinguishes self from nonself, and remembers the antigens it has encountered. **Review ANIMATED TUTORIAL 42.2**
- Each antibody and each T cell is specific for a single antigenic determinant. **T cell receptors** bind to antigens on the surfaces of virus-infected cells and abnormal cells.
- The **humoral immune response** is directed against pathogens in the blood, lymph, and tissue fluids. The **cellular immune response** is directed against an antigen established within a host cell. Both responses are mediated by antigenic fragments being presented on a cell surface along with the proteins of the **major histocompatibility complex (MHC)**. **Review Figure 42.7**
- **Clonal selection** accounts for the specificity and diversity of the immune response and for **immunological memory**. **Review Figure 42.8**
- An activated B or T lymphocyte produces **effector cells** that attack the antigen, and **memory cells** that are long-lived and rarely divide. Effector B cells are called **plasma cells** and secrete specific **antibodies**.
- **Vaccination** is inoculation with modified pathogens or antigens that provoke an immune response but are not pathogenic. **Review Figure 42.9**

42.4 What Is the Humoral Immune Response? See ANIMATED TUTORIAL 42.3

- B cells are the basis of the humoral immune response. Naive B cells are activated by binding of antigen and by stimulation by T_H cells with the same specificity, and then form plasma cells. These cells synthesize and secrete specific antibodies.
- An antibody is an **immunoglobulin**, a tetramer of four polypeptides: two identical light chains and two identical heavy chains, each consisting of a **constant region** and a **variable region**. **Review Figure 42.10, ACTIVITY 42.3**
- The variable regions determine the specificity of an immunoglobulin, and the constant regions of the heavy chain determine its class. There are five classes of immunoglobulins with different body locations and functions. **Review Table 42.2**
- B cell genomes undergo random recombination of genes coding for regions of the immunoglobulin polypeptide chains so that each cell can produce a specific antibody protein. The immunoglobulin chains derive from "supergenes" that are constructed from different combinations of V, D, J, and C genes. This DNA rearrangement and rejoining yields millions of different immunoglobulin chains. **Review Figures 42.11, 42.12, ANIMATED TUTORIAL 42.4**
- Once a B cell becomes a plasma cell, it may undergo **class switching**, in which a deletion of one or more constant region genes results in the production of an immunoglobulin with a different constant region and a different function. **Review Figure 42.13**
- A **monoclonal antibody** can be used in diagnosis and therapy.

42.5 What Is the Cellular Immune Response? See ANIMATED TUTORIAL 42.5

- T cells are the effectors of the cellular immune response. T cell receptors are somewhat similar in structure to the immunoglobulins, having variable and constant regions. **Review Figure 42.14**
- There are three types of T cells. **Cytotoxic T cells (T_C cells)** recognize and kill virus-infected cells or mutated cells. **T-helper cells (T_H cells)** direct both the cellular and humoral immune responses. **Regulatory T cells (Tregs)** inhibit the other T cells from mounting an immune response to self antigens.
- The genes of the major histocompatibility complex (MHC) encode membrane proteins that bind antigenic fragments and present them to T cells. **Review Figures 42.15, 42.16**
- Organ transplants are rejected when the host's immune system recognizes MHC proteins on transplanted tissue as nonself and initiates an immune defense attacking the foreign tissue.

42.6 What Happens When the Immune System Malfunctions?

- An **allergic reaction** is an inappropriate immune response caused by **immediate hypersensitivity** or **delayed hypersensitivity** to certain antigens. **Review Figure 42.18**
- Autoimmune diseases result when the immune system produces B and T cells that attack self antigens.
- Immune deficiency disorders result from failure of one or another part of the immune system. **Acquired immune deficiency syndrome (AIDS)** is a disorder that arises from depletion of the T_H cells as a result of infection with **human immunodeficiency virus (HIV)**. **Review Figure 42.19**

CHAPTER REVIEW

REMEMBERING

- Phagocytes kill harmful bacteria by
 - endocytosis.
 - producing antibodies.
 - complement proteins.
 - T cell stimulation.
 - inflammation.
- Which statement about an antigenic determinant is *not* true?
 - It is a specific chemical grouping.
 - It may be part of many different molecules.
 - It is the part of an antigen to which an antibody binds.
 - It may be part of a cell.
 - A single protein has only one on its surface.
- T cell receptors
 - are the primary receptors for the humoral immune system.
 - are carbohydrates.
 - cannot function unless the animal has previously encountered the antigen.
 - are produced by plasma cells.
 - are important in combating viral infections.
- According to the clonal selection theory,
 - an antibody changes its shape to match the antigen it meets.
 - an individual animal contains only one type of B cell.
 - an individual animal contains many types of B cells, each producing one kind of antibody.
 - each B cell produces many types of antibodies.
 - many clones of antiself lymphocytes appear in the bloodstream.
- The extraordinary diversity of antibodies results in part from
 - the action of monoclonal antibodies.
 - the splicing of protein molecules.
 - the action of cytotoxic T cells.
 - the rearrangement of genes.
 - their remarkable nonspecificity.
- The major histocompatibility complex
 - codes for specific proteins found on the surfaces of cells.
 - plays no role in T cell immunity.
 - plays no role in antibody responses.
 - plays no role in skin graft rejection.
 - is encoded by a single locus with multiple alleles.

UNDERSTANDING & APPLYING

- Describe the part of an antibody molecule that interacts with an antigen. How is it similar to the active site of an enzyme? How does it differ from the active site of an enzyme?
- Contrast immunoglobulins and T cell receptors with respect to their structures and functions.
- The gene family (genes A, B, and D) determining MHC on the cell surface in humans is on a single chromosome. A father's MHC genotype is A1, A3, B5, B7, D9, D11. A mother's genotype is A2, A4, B6, B7, D11, D12. Their child's is A1, A4, B6, B7, D11, D12. What are the parents' haplotypes—that is, which alleles are linked on each of the two chromosomes of each parent? Assuming there is no recombination among the genes determining the MHC type, can these same two parents have a child who has the genotype A1, A2, B7, B8, D9, D11?

ANALYZING & EVALUATING

- Discuss the diversity of antibody specificities in an individual in relation to the diversity of enzymes. Does every cell in an animal contain genetic information for all the organism's enzymes? Does every cell contain genetic information for all the organism's immunoglobulins?
- Development of an effective HIV vaccine requires that the person being vaccinated develop both cellular and humoral immunity against HIV. What experiments would you do to test whether both types of immunity developed in people given a potential new vaccine?

Animal Reproduction

CHAPTER OUTLINE

- 43.1** How Do Animals Reproduce without Sex?
- 43.2** How Do Animals Reproduce Sexually?
- 43.3** How Do the Human Male and Female Reproductive Systems Work?
- 43.4** How Can Fertility Be Controlled?

A Unique Reproductive Strategy Among honey bees and other hymenopteran insects, the only reproductive female is the queen, seen in the center. The female workers attending her are sterile.

THE HONEY BEE *Apis mellifera* has been studied throughout recorded history. Sex and reproduction in these social insects are intriguing. A honey bee hive contains a single reproductive female, the queen, and thousands of infertile female worker bees. There are few if any male bees in a hive. The queen lays eggs continuously while the worker bees build the honeycomb, forage, clean and defend the hive, and feed and care for the young. In honey bees, fertilized eggs develop into females and unfertilized eggs develop into males. The queen controls which of her eggs are fertilized. She carries sperm from males she has mated with and occasionally produces males by *not* releasing sperm onto her eggs. It is not in her best interest to produce many males because they don't contribute to raising young or maintaining the hive; they just hang around until they have a very rare chance to mate.

Eventually a hive needs a new queen. The old queen might die, or she and a retinue of workers might leave an overcrowded hive to start a new hive (a phenomenon known as swarming). Whether the queen dies or swarms, the remaining worker bees enlarge a few cells in the honeycomb that contain fertilized eggs laid by the old queen. The larvae from those eggs are fed special food that stimulates their growth and development into prospective queens.

The first queen to pupate and emerge from her royal chamber kills the other developing queens. She then leaves the hive for her mating flight. Males from all around sense a chemical message (a pheromone) that a virgin queen is available and congregate around her. While in flight, she mates with 15 to 20 males, and each coupling is an event. After a male manages to insert his penis into the queen's vagina, he literally explodes, leaving behind not only his sperm but also his sex organs (the latter will drop out later). The males die and the queen returns to the hive with a lifetime supply of sperm. The queen lives for about 2 years and lays as many as 3,000 eggs each day. Most of those eggs develop into female worker bees that devote their lives to feeding her and raising their sisters.

Natural selection has resulted in some amazing adaptations, none more so than those involved in reproduction. Sexual or asexual, bizarre or otherwise, the anatomy, physiology, biochemistry, and behavior surrounding the urge to propagate are fascinating.

How can a queen be so different from her worker sisters when they all share the same genome?

See answer on p. 899.

43.1 How Do Animals Reproduce without Sex?

Sexual reproduction is a nearly universal trait in animals, although many species can also reproduce asexually and some reproduce only asexually. Offspring produced asexually are genetically identical to one another and to their parents. Asexual reproduction is efficient because no time or energy is wasted on mating and every member of the population can convert resources into offspring. However, asexual reproduction does not generate genetic diversity in a population as sexual reproduction does, and this diversity is the raw material that enables natural selection to shape adaptations in response to environmental change. When environmental changes occur, lack of genetic diversity can be disadvantageous to a population.

A variety of animals, mostly invertebrates, reproduce asexually. They tend to be species that are attached to their substrates and cannot search for mates, or species that live in sparse populations and rarely encounter potential mates. Asexually reproducing species are likely to be found in relatively constant environments where genetic diversity is less important for species success. In fact, asexual reproduction is a good way to preserve a successful genotype in a particular environment—as long as that environment does not change.

Three common modes of asexual reproduction are budding, regeneration, and parthenogenesis.

Budding and regeneration produce new individuals by mitosis

Many simple multicellular animals produce offspring by **budding**. New individuals form as outgrowths or buds from the bodies of older animals. A bud grows by mitotic cell division, and the cells differentiate before the bud breaks away from the parent (**Figure 43.1A**). The bud is genetically identical to the parent, and it may grow as large as the parent before it becomes independent.

Regeneration is usually thought of as the replacement of damaged tissues or lost limbs, but in some cases pieces of an

organism can regenerate complete individuals. Echinoderms, for example, have remarkable abilities to regenerate. If sea stars (starfish) are cut into pieces, each piece that includes an arm and a portion of the central disc can grow into a new animal (**Figure 43.1B**). In the early 1900s oyster fishermen in Narragansett Bay tried to eliminate the sea stars that were preying on their oysters. Whenever they encountered sea stars, they chopped them up with their knives and threw them back into the water. As a result, the sea star population increased explosively.

Regeneration can occur when an animal is broken by an outside force such as wave action in the intertidal zone. In some cases, breakage occurs in the absence of external forces. Some species of segmented marine worms develop segments with rudimentary heads bearing sensory organs. The segments then break apart and each one forms a new worm.

Parthenogenesis is the development of unfertilized eggs

Not all eggs must be fertilized to develop. A common mode of asexual reproduction in arthropods is the development of offspring from unfertilized eggs. This phenomenon, called **parthenogenesis**, also occurs in some species of fishes, amphibians, and reptiles. Most species that reproduce parthenogenetically also engage in sexual reproduction or at least sexual behavior at other times. In some species, parthenogenesis is part of the mechanism that determines sex. As we saw at the beginning of this chapter, in honey bees (as well as in most ants and wasps), males develop from unfertilized eggs and are haploid. Females develop from fertilized eggs and are diploid.

Parthenogenetic reproduction in some species requires sexual behavior even though sperm are not delivered to the female reproductive tract and eggs are not fertilized. David Crews and his students at the University of Texas extensively investigated one such case, that of parthenogenetic reproduction in a species of whiptail lizard. There are no males of this species. Females can act as males, engaging in all aspects of courtship display and mating, although no sperm are produced or transferred

(A) *Hydra* sp.

43.1 Two Forms of Asexual Reproduction (A) Budding: A new individual forms as an outgrowth from an adult hydra. (The hydra in this photo was stained with a blue dye to make it easier to see.)

(B) *Fromia* sp.

(B) Regeneration: A single severed arm and a piece of the central disc of a mature sea star can regenerate into an entire animal.

(A)

(B)

43.2 Asexual Reproduction May Require Sexual Behavior

(A) Parthenogenetic whiptail lizards are all females, but they take turns acting the male role in reproductive behavior. The stimulation from sexual behavior is necessary for ovulation to occur. (B) The ovarian cycle determines the role an individual whiptail plays.

(Figure 43.2). Whether a specific female acts as a female or as a male depends on cyclical hormonal states. When estrogen levels are high, she acts as a female. When her progesterone levels peak, she acts as a male. The stimulation resulting from the sexual activity triggers the release of eggs from the ovaries of the acting female.

RECAP 43.1

Most animals reproduce sexually, but many can also or can only reproduce asexually, through budding, regeneration, or parthenogenesis.

- Explain why asexual reproduction might be disadvantageous for an animal living in a changing environment. [See p. 881](#)
- How is parthenogenesis related to sex determination in honey bees? [See p. 881](#)

Asexual reproduction is an efficient way to use resources. Since most animals reproduce sexually, however, the genetic diversity produced by sexual reproduction must confer a tremendous advantage.

43.2

How Do Animals Reproduce Sexually?

Given the efficiency of asexual reproduction in perpetuating an organism's genome, the prevalence of sexual reproduction is somewhat surprising. Because one gender (i.e., males) cannot produce offspring, it is a much less efficient strategy. And mating behaviors involve costs and risks. Costs include time and energy spent finding, attracting, and competing for a mate, as well as the "opportunity costs" of detracting from other activities such as feeding and caring for existing offspring. Risks include increased exposure to predation and the potential for physical damage. Despite these disadvantages, most eukaryotic organisms reproduce sexually. Thus it would seem that the production of genetic diversity is an evolutionary advantage that overwhelms the cost of sex (see Sections 21.2 and 21.4).

Sexual reproduction requires the joining of two haploid sex cells to form a diploid individual. These haploid cells, or **gametes**, are produced through gametogenesis, a process that involves meiotic cell divisions. Two events in meiosis contribute to genetic diversity: crossing over between homologous chromosomes and the independent assortment of chromosomes (see Sections 11.5 and 12.1). Sexual reproduction itself also contributes to genetic diversity. The genetic variation among the gametes of a single individual and the genetic variation between any two parents produce an enormous potential for genetic variation between any two offspring of a sexually reproducing pair of individuals.

Sexual reproduction in animals consists of three fundamental steps:

- **Gametogenesis:** making gametes
- **Spawning or mating:** bringing gametes together
- **Fertilization:** fusing gametes

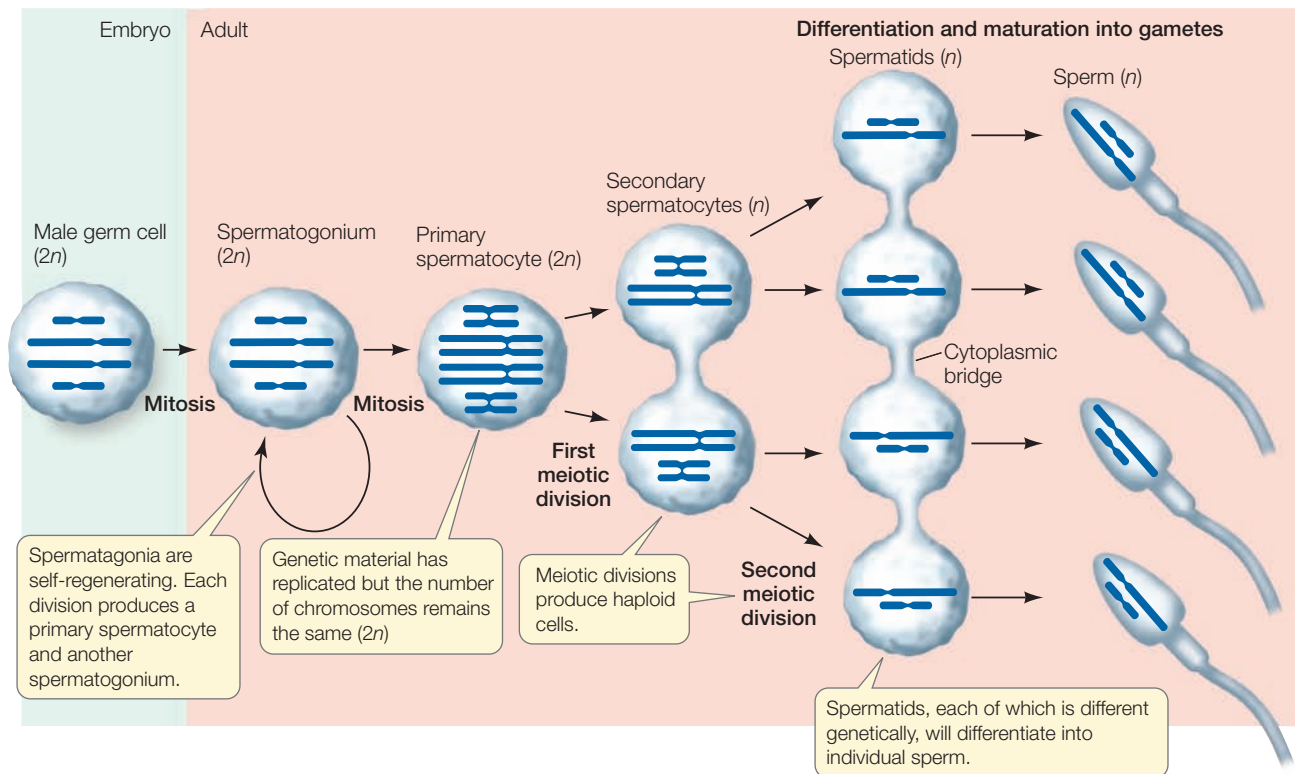

The process of gametogenesis is similar across sexually reproducing animal species. Processes of fertilization are also quite similar in widely different species. Therefore, while our discussion of gametogenesis will focus generally on mammals, and our discussion of fertilization will feature sea urchins, the facts would not be dramatically different were we to consider many other animal groups. Adaptations for spawning and mating, in contrast, show incredible anatomical, physiological, and behavioral diversity across species.

Gametogenesis produces eggs and sperm

Gametogenesis occurs in the gonads: **testes** (singular *testis*) in males and **ovaries** (singular *ovary*) in females. The tiny gametes of males, the **sperm**, move by beating their flagella. The larger gametes of females—the eggs or **ova** (singular *ovum*)—are nonmotile.

Gametes are produced from **germ cells**, which have their origin in the earliest cell divisions of the embryo and remain distinct from all the other cells of the body (the somatic cells). Germ cells are sequestered in the body of the embryo until its gonads begin to form. The germ cells then migrate to the developing gonads, where they take up residence and proliferate by

(A) Spermatogenesis

(B) Oogenesis

43.3 Gametogenesis Male and female germ cells proliferate by mitosis and produce diploid spermatogonia and oogonia that mature into primary spermatocytes and oocytes before entering meiosis. (A) Spermatogonia continue to divide by mitosis in adults, producing a steady supply of spermatocytes that divide meiotically to produce haploid spermatids, which differentiate into sperm. In many species,

the progeny of spermatocytes remain in contact through cytoplasmic bridges until the sperm mature. (B) In mammals, oogonia cease division in the embryo, and primary oocytes remain arrested in prophase I of meiosis until they are ovulated and fertilized. Each oocyte will produce one haploid ootid, which matures into an ovum.

mitosis, producing **spermatogonia** (singular *spermatogonium*) in males and **oogonia** (singular *oogonium*) in females (**Figure 43.3**). Spermatogonia and oogonia are diploid, multiply by mitosis, and are stem cells. They are self-regenerating, and they also produce progeny—spermatocytes and oocytes—that will enter the next stage of gametogenesis.

In this next stage of gametogenesis, meiotic cell division reduces the chromosomes to the haploid number (see Section 11.5). The progeny of the spermatogonia and oogonia that enter meiosis are **primary spermatocytes** and **primary oocytes**. The

steps of meiosis are similar in males and females, but there are important sex differences in gametogenesis.

SPERMATOGENESIS The initial proliferation of male germ cells into spermatogonia proceeds by mitosis in the embryo. But throughout the male life span, spermatogonia continue to divide by mitosis, with one daughter cell retaining the self-regenerating capacity of a spermatogonium while the other daughter cell becomes a primary spermatocyte. As illustrated in Figure 43.3A, primary spermatocytes then undergo the first meiotic

division—the reduction division—to form two haploid **secondary spermatocytes**. The second meiotic division produces four haploid **spermatids** for each primary spermatocyte that enters meiosis. In mammals, the progeny of primary spermatocytes remain connected by cytoplasmic bridges after each division.

One reason that mammalian spermatocytes remain in cytoplasmic contact throughout their development is the asymmetry of sex chromosomes in males. Half the secondary spermatocytes receive an X chromosome, the other half a Y chromosome. The Y chromosome contains fewer genes than the X chromosome, and some of the products of genes found only on the X chromosome are essential for spermatocyte development. By remaining in cytoplasmic contact, all four spermatocytes can share the gene products of the X chromosomes, although only half of them have an X chromosome.

A spermatid bears little resemblance to a mature sperm. Through further differentiation (spermiogenesis), the spermatid becomes compact, streamlined, and grows a flagellum to become motile. We will look at the production of human sperm in Section 43.3.

OOGENESIS Oogonia, like spermatogonia, proliferate through mitosis (see Figure 43.3B). The resulting primary oocytes immediately enter prophase of the first meiotic division. In many species, including humans, the oocyte experiences developmental arrest at this point and may remain in that state for days, months, or years. In the human female, this period of arrest is at least 10 years (i.e., until puberty), and some primary oocytes remain in prophase I for up to 50 years (i.e., until menopause). In contrast, spermatogenesis continues, uninterrupted, to completion once the primary spermatocyte has differentiated.

During this prolonged prophase I, or shortly before it ends, the primary oocyte grows larger through increased production of ribosomes, RNA, cytoplasmic organelles, and energy stores. At this point the primary oocyte acquires all the energy, raw materials, and RNA that the ovum will need to survive its first cell divisions after fertilization. In fact, the nutrients in the egg must maintain the embryo until it is either nourished by the maternal circulatory system or can feed on its own.

When a primary oocyte resumes meiosis, its nucleus completes the first meiotic division near the surface of the cell. The daughter cells of this division receive grossly unequal shares of cytoplasm. This asymmetry represents another major difference from spermatogenesis, in which cytoplasm is apportioned equally. The daughter cell that receives almost all the cytoplasm becomes the **secondary oocyte**, and the one that receives almost none forms the **first polar body** (see Figure 43.3B).

The second meiotic division—that of the large, secondary oocyte—is also accompanied by an asymmetrical division of the cytoplasm. One daughter cell forms the large, haploid **ootid**, which eventually differentiates into a mature egg, and the other forms the **second polar body**. Polar bodies degenerate, so the end result of oogenesis is only one mature egg for each primary oocyte that entered meiosis. However, that egg is a large, well-provisioned cell.

A second period of arrested development occurs after the first meiotic division forms the secondary oocyte. The egg may be expelled from the ovary in this condition. In many species, including humans, the second meiotic division is not completed until the egg is fertilized by a sperm.

Fertilization is the union of sperm and egg

The union of the haploid sperm and the haploid egg in fertilization creates a single diploid cell, called a **zygote**, which will develop into an embryo. Fertilization does more than just restore the full genetic complement of the animal. The processes associated with fertilization help the egg and sperm get together, prevent the union of the sperm and egg of different species, and guarantee that only one sperm will enter and activate the egg metabolically. Fertilization involves a complex series of events:

1. The sperm and the egg chemically recognize each other.
2. The sperm is activated, enabling it to gain access to the plasma membrane of the egg.
3. The plasma membrane of the egg fuses with the plasma membrane of a single sperm.
4. The egg blocks entry of additional sperm.
5. The egg is metabolically activated and stimulated to start development.
6. The egg and sperm nuclei fuse to create the diploid nucleus of the zygote.

SPECIFICITY IN SPERM-EGG INTERACTIONS Specific recognition molecules mediate interactions between sperm and eggs. These molecules ensure that the activities of sperm are directed toward eggs and not other cells, and they help prevent eggs from being fertilized by sperm from the wrong species. The latter function is particularly important in aquatic species that release eggs and sperm into the surrounding water, because the eggs of such animals may readily be exposed to sperm of other species. The sea urchin is a good example of such a species, and its mechanisms of fertilization have been well studied.

Sea urchin eggs release chemical attractants that increase the motility of sperm and cause them to swim toward the egg. These chemical attractants are species-specific. For example, eggs of one species of sea urchin release a specific peptide consisting of 14 amino acids. This peptide binds to receptors present on sperm of the same species. The sperm respond by increasing their mitochondrial respiration and motility. Before exposure to the peptide, the sperm swim in tight little circles, but after binding to the peptide, they swim energetically up the concentration gradient of the peptide until they reach the egg that is releasing it.

When sperm reach an egg, they must get through two protective layers before they can fuse with the egg plasma membrane. The eggs of sea urchins are covered with a jelly coat, which surrounds a proteinaceous **vitelline envelope** (Figure 43.4A). The success of a sperm's assault on these protective layers depends on a membrane-enclosed structure at the front of the sperm head called an **acrosome**.

43.4 Fertilization of the Sea Urchin Egg (A) Sea urchin eggs are protected by a jelly layer and a proteinaceous vitelline envelope. Sperm must penetrate both to reach the egg plasma membrane. Many sperm attach to the vitelline envelope, but only one penetrates the egg cell membrane and achieves fertilization. Circled numbers match structures with the events shown in panel B. (B) The acrosomal reaction allows a sea urchin sperm to recognize an egg of the same species and pass through its protective layers. Enzymes from the egg's cortical granules trigger the slow block to polyspermy.

Go to Animated Tutorial 43.1
Fertilization in a Sea Urchin
Life10e.com/at43.1

The acrosome contains enzymes and other proteins. When the sperm makes contact with an egg of its own species, substances in the jelly coat trigger an acrosomal reaction, which begins with the breakdown of the plasma membrane covering the sperm head and the underlying acrosomal membrane (**Figure 43.4B**). The acrosomal enzymes are released and digest a hole through the jelly coat.

As a result of the polymerization of actin triggered by the acrosomal reaction, an acrosomal process extends out of the head of the sperm. The acrosomal process is coated with species-specific recognition molecules called bindin, and there are bindin receptors on the vitelline envelope of the egg. The interaction of bindin and bindin receptors enables the sperm to contact the egg plasma membrane. That contact results in fusion of the sperm and egg plasma membranes and the formation of a fertilization cone that engulfs the sperm head, bringing it into the egg cytoplasm. The sperm mitochondria, which largely constitute the midpiece of the sperm, are also drawn into the egg cytoplasm, but they degrade and disappear; this means that the mitochondria and mitochondrial genes of the new urchin are derived only from the egg.

In animals that practice internal fertilization, mating behaviors help guarantee species specificity, but egg–sperm recognition mechanisms still exist. The mammalian egg is surrounded by a thick layer called the **cumulus**, which consists of a loose assemblage of maternal cells in a gelatinous matrix (**Figure 43.5**). Beneath the cumulus is a glycoprotein envelope called the **zona pellucida**, which is functionally similar to the vitelline envelope of sea urchin eggs. When mammalian sperm are deposited in the female reproductive tract, they are metabolically activated and made capable of an acrosomal reaction should they encounter an egg. An activated sperm can penetrate the cumulus and interact with the zona pellucida.

Unlike the jelly coat of sea urchin eggs, the cumulus of mammalian eggs does not trigger the acrosomal reaction. When sperm make contact with the zona pellucida, a species-specific glycoprotein binds to recognition molecules on the head of the sperm. This binding triggers the acrosomal reaction, releasing acrosomal enzymes that digest a path through the zona pellucida. When the sperm head reaches the egg plasma membrane, other proteins facilitate its adhesion to and fusion with the egg plasma membrane.

The importance of the zona pellucida and its sperm-binding molecules as a species-specific recognition mechanism was revealed in experiments on mammalian eggs and sperm in culture dishes. When the zona pellucida was stripped from human eggs and the eggs were exposed to hamster sperm, fertilization took place, resulting in a hamster–human hybrid zygote. The hybrid zygote did not survive its first cell division, but the experiment demonstrated that a recognition mechanism in mammalian species resides in the zona pellucida.

BLOCKS TO POLYSPERMY The fusion of the sperm and egg plasma membranes and the entry of the sperm into the egg initiate a programmed sequence of events. The first responses to sperm entry are **blocks to polyspermy**. These blocks are mechanisms that prevent more than one sperm from entering

43.5 Barriers to Sperm This human egg, like other mammalian eggs, is surrounded by the cumulus and zona pellucida. Sperm must penetrate both to fertilize the egg. Only one sperm will penetrate the zona pellucida and fuse with the plasma membrane.

the egg. If more than one sperm enters the egg, the embryo is unlikely to survive.

Blocks to polyspermy have been studied extensively in sea urchin eggs, which can be fertilized in a dish of seawater. Within seconds after the sperm membrane contacts the egg membrane, an influx of sodium ions changes the electric charge difference across the egg's plasma membrane. This fast block to polyspermy prevents the fusion of any other sperm with the egg plasma membrane, but it is transient. The change in membrane electric charge lasts only about a minute, but that is enough time to allow a slower block to sperm entry to develop.

The slow block to polyspermy involves converting the vitelline envelope to a physical barrier that sperm cannot penetrate. Before fertilization, the vitelline envelope is bonded to the egg plasma membrane. Just under the plasma membrane are vesicles called cortical granules (see Figure 43.4), which contain enzymes and other proteins.

The sea urchin egg, like all animal cells, sequesters calcium in its endoplasmic reticulum. Sperm entry into the egg stimulates the release of calcium ions from the endoplasmic reticulum and into the egg cytoplasm. This increase in cytosolic calcium causes the egg's cortical granules to fuse with the plasma membrane and release their contents. Cortical granule enzymes break the bonds between the vitelline envelope and the plasma membrane, and other proteins released from the cortical granules attract water into the space between them. As a result, the vitelline envelope rises to form a fertilization envelope. Cortical granule enzymes also degrade sperm-binding molecules on the surface of the fertilization envelope and cause it to harden, thus preventing additional sperm from contacting the egg's plasma membrane.

In mammalian eggs, sperm entry does not cause a rapid change in membrane potential, but it does trigger a release of

calcium from the endoplasmic reticulum. As in the sea urchin egg, increased calcium causes the cortical granules to fuse egg with the egg plasma membrane. A fertilization envelope does not form around the mammalian egg, but the cortical granule enzymes destroy the sperm-binding molecules in the zona pellucida. The rise in cytosolic calcium also signals the egg to complete meiosis. The stage is set for the first cell division.

Getting eggs and sperm together

As we have just seen, sexual reproduction requires the production of haploid gametes (gametogenesis) and the joining together of those gametes to form a diploid zygote (fertilization). Spawning and mating behaviors get eggs and sperm close enough together that fertilization can occur. Fertilization can occur externally or internally.

EXTERNAL FERTILIZATION In an aquatic environment, animals can bring their gametes together by simply releasing them into the water. This practice, called **spawning**, results in **external fertilization**. Many aquatic animals are not very mobile, but they produce huge numbers of gametes that can travel far from the point of release. A female oyster, for example, will release millions of eggs when she spawns, and the number of sperm produced by a male oyster is astronomical.

Numbers alone, however, do not guarantee that gametes will meet. The reproductive activities of the males and females of a population must be synchronized, since released gametes have a limited life span. Seasonal breeders may use day length, changes in temperature, or changes in weather to time the production and release of their gametes. Mutual stimulation is also important. Release of gametes into the water by one individual can stimulate others to spawn.

Behavior can play an important role in bringing gametes together even when fertilization is external. Many species travel great distances to congregate with potential mates and release their gametes at the same time in a suitable environment. Salmon are an extreme example. They hatch and develop in freshwater streams and then migrate to the ocean, where they remain for years. When they are mature, they travel hundreds of miles back in the stream where they hatched to spawn. Males and females expend great amounts of energy to swim up the streams to the spawning grounds, where they pair up, prepare a depression in the streambed gravel, and together release their sperm and eggs. As the gametes drift down into the gravel, fertilization occurs.

INTERNAL FERTILIZATION Terrestrial animals cannot simply release their gametes into the environment. Sperm can move only through liquid, and delicate gametes released into air would dry out and die. Terrestrial animals avoid these problems by **internal fertilization**, the release of sperm into the female reproductive tract. Some aquatic animals also practice internal fertilization, but it is ubiquitous in terrestrial animals.

Animals have evolved an astonishing diversity of behavioral and anatomical adaptations for internal fertilization. As we saw above, gametogenesis occurs in the gonads, which are the **primary sex organs**. All additional anatomical components

of an animal's reproductive system are called **accessory sex organs**. An obvious accessory sex organ in males of many species is the **penis**, which enables the male to deposit sperm in the female's **vagina**, the entry to her reproductive tract. Accessory sex organs include a variety of glands, tubules, ducts, and other structures.

Copulation is the physical joining of male and female accessory sex organs. Most male insects copulate and transfer sperm to the female's vagina through a penis. The **genitalia**—external sex organs—of insects often have species-specific shapes that ensure that the male and female genitalia match in a lock-and-key fashion. This mechanism ensures a tight, secure fit between the mating pair during the prolonged period of sperm transfer. In some insect species in which females mate with more than one male, the males have elaborate structures on their penises that can scoop sperm deposited by other males out of a female's reproductive tract, replacing it with their own.

Transfer of sperm in internal fertilization can also be indirect. Males of many invertebrate species (e.g., mites and scorpions) and a few vertebrates (e.g., salamanders) deposit spermatophores—packets of sperm protected from desiccation—in the environment. When a female mite encounters a spermatophore from a potential mate, she straddles it and opens a pair of plates in her abdomen so that the tip of the spermatophore enters her reproductive tract and allows the sperm to enter.

Male squids and spiders play a more active role in spermatophore transfer. The male spider secretes a drop containing sperm onto a bit of web, then uses a special structure on his foreleg to pick up the sperm-containing web and insert it through the female's genital opening. Male squids use one specialized tentacle to pick up a spermatophore and insert it into the female's genital opening.

Some individuals can function as both male and female

In most species, gametes are produced by individuals that are either male or female. Species that have separate male and female members are referred to as **dioecious** (Greek, “two houses”). In some species, however, a single individual may produce both sperm and eggs. Such species are **monoecious** (“one house”) or **hermaphroditic**.

Almost all invertebrate groups contain some hermaphroditic species. An earthworm is an example of a *simultaneous* hermaphrodite, meaning an individual is both male and female at the same time. When two earthworms mate, they exchange sperm, and as a result, the eggs of each are fertilized (see Figure 32.12C). Some vertebrates are *sequential* hermaphrodites, meaning that an individual may function as a male or a female at different times in its life. An example is the anemone fish, or clown fish, a species that lives in small groups within large sea anemones (Figure 43.6). All anemone fish are born male. The largest fish in a group becomes a functional female. If that fish is removed from the group, the next-largest male becomes a female. The second-largest fish in the group is the only male in breeding condition.

What is the evolutionary advantage of hermaphroditism? Some simultaneous hermaphrodites, such as parasitic

Amphiprion sp.

43.6 When Size Determines Sex Anemone fish (also known as clown fish) live in groups of about a dozen centered on a single sea anemone. All anemone fish are born male; the largest fish in the group becomes a functional female. Thus a fish may function as a male and as a female at different times in its life.

tapeworms, have a low probability of meeting a potential mate—an individual tapeworm may be the only one in its host. Tapeworms can fertilize their own eggs, but most simultaneous hermaphrodites must mate with another individual. Because every simultaneous hermaphrodite is both male and female, however, the probability of encountering a possible mate doubles. In some sequential hermaphrodites, siblings are all male or all female at the same time, thus reducing the incidence of inbreeding.

The evolution of vertebrate reproductive systems parallels the move to land

The earliest vertebrates evolved in aquatic environments. The closest living relatives of those earliest vertebrates are

modern-day fishes. They remain exclusively aquatic, and most practice external fertilization. The most primitive of the fishes, the lampreys and hagfishes, simply release their gametes into the environment. In most fishes, however, mating behaviors bring females and males into close proximity at the time of gamete release. In sharks and rays, fins have evolved into claspers that hold the male and female together and enable sperm to be transferred directly into the female reproductive tract.

Amphibians were the first vertebrates to live in terrestrial environments. They dealt with the challenge of a dry environment by returning to water to reproduce, as most amphibians still do today.

Reptiles were the first vertebrate group to solve the problem of reproduction in the terrestrial environment (**Figure 43.7**). Their solution was the amniote egg (see Figure 33.19A). A hard or leathery shell protects the embryo and impedes water loss while allowing the diffusion of oxygen into the egg and carbon dioxide out of the egg. The eggshell creates an obvious problem for fertilization. Sperm cannot penetrate the shell, so they must reach the egg before the shell forms. Hence internal fertilization and the evolution of accessory sex organs were necessary for the evolution of the amniote egg.

Male snakes and lizards have paired hemipenes, which can be filled with blood and thereby extruded from the male's body. Only one hemipenis is inserted into the female's reproductive tract at a time. It is usually rough or spiny at the end to achieve a secure hold while sperm are transferred down a groove on its surface. Retractor muscles pull the hemipenis back into the male's body when mating is completed. Some evolutionarily ancient bird species have erectile penises that channel sperm along a groove into the female's reproductive tract. Birds with more recent evolutionary origins, however, do not have erectile penises; instead, the male and female simply bring their genital openings close together to transfer sperm.

(A) *Chelonia mydas*

(B) *Merops apiaster*

43.7 The Shelled Egg The shelled egg was a major evolutionary step that allows reptiles and birds to reproduce in the terrestrial environment. (A) A female green sea turtle has deposited her eggs in the sand. (B) The shelled egg requires that sperm meet egg before the shell forms. Terrestrial animals thus must practice internal fertilization, as these European bee-eaters are doing.

Usually this involves the male standing on the female's back (see Figure 43.7B).

All mammals practice internal fertilization. With the exception of the prototherian mammals, the developing embryo is retained for some time in the female reproductive tract. Prototherian mammals (the monotremes; see Figure 33.24) lay eggs. The other mammals (the therians) vary enormously as to the developmental stage of their offspring at the time of birth.

Animals with internal fertilization are distinguished by where the embryo develops

Two patterns of care and nurture of the embryo have evolved in animals: oviparity (egg laying) and viviparity (live bearing).

Oviparous animals lay eggs in the environment, and their embryos develop outside the mother's body. Oviparous terrestrial animals such as insects, reptiles, and birds protect their eggs from desiccation with waterproof membranes or shells. Oviparity is possible because eggs are stocked with abundant nutrients to supply the needs of the embryo. Some oviparous animals engage in various forms of parental behavior to protect their eggs, but until the eggs hatch, the embryos depend entirely on the nutrients stored in the egg.

Viviparous animals retain the embryo within the mother's body during its early developmental stages. Although examples of viviparity exist in all vertebrate groups except the crocodiles, turtles, and birds (even some sharks retain fertilized eggs in their bodies and give birth to free-living offspring), there is a big difference between viviparity in mammals and in other species.

All mammals except the prototherians are viviparous and have a specialized portion of the female reproductive tract, the **uterus**, or womb, that holds the embryo and interacts with it to produce a **placenta**, which enables the exchange of nutrients and wastes between the blood of the mother and that of the embryo. Very few non-mammalian species have evolved such a connection between the embryo and the mother.

In most non-mammalian viviparous animals, such as garter snakes and the well-known aquarium fish the guppy, fertilized eggs are retained in the mother's body until they hatch. These embryos still receive nutrition from stores in the egg, so this reproductive adaptation is called **ovoviviparity**.

RECAP 43.2

Sexual reproduction involves gametogenesis, mating, and fertilization. Fertilization can be external or internal and involves mechanisms for ensuring that only one sperm from the right species enters the egg.

- Describe the steps by which a sea urchin sperm penetrates the egg. **See Figure 43.4**
- Explain how polyspermy is prevented and why it is crucial to do so. **See pp. 886–887 and Figure 43.4**
- What reproductive adaptations made life on land possible? **See p. 888**

Now that we have covered some of the general aspects of gametogenesis and fertilization and have briefly discussed the great diversity of mating systems, we will next consider the human reproductive systems in detail.

43.3 How Do the Human Male and Female Reproductive Systems Work?

In this section we describe the structures and functions of male and female reproductive systems in mammals, and we will use humans as our prime example. We will also discuss the hormonal regulation of both male and female systems. Our discussion covers:

- *The primary sex organs* (testes in males and ovaries in females) that produce gametes and serve endocrine functions.
- *The accessory sex organs*, which include the ducts through which the gametes pass, the various glands that empty into those ducts, and the external genitalia.
- *Secondary sexual characteristics*, which are not directly involved in reproduction but are responsible for the major differences in external appearance of men and women and are important in mating and in rearing offspring.

Male sex organs produce and deliver semen

Semen is the product of the male reproductive system. Semen contains sperm and a complex mixture of fluids and molecules that support the sperm and facilitate fertilization. Sperm make up less than 5 percent of the volume of the semen.

The male reproductive organs are diagrammed in **Figure 43.8**. Sperm are produced in the testes, the paired male gonads. The testes of most mammals are located outside the body cavity in a pouch of skin called the **scrotum**.

Why should the testes be located outside the body cavity? The optimal temperature for spermatogenesis in most mammals is slightly lower than the normal body temperature. The scrotum keeps the testes at this optimal temperature. Muscles in the scrotum contract in a cold environment, bringing the testes closer to the warmth of the body; in a hot environment they relax, cooling the testes by suspending them farther from the body.

Spermatogenesis takes place within the **seminiferous tubules** tightly coiled in each testis (**Figure 43.9A**). Between the seminiferous tubules are clusters of **Leydig cells** that produce testosterone (**Figure 43.9B**). Spermatogonia reside in the outer regions of the seminiferous tubules, just under the basement membrane. Moving inward toward the lumen of the tubule are germ cells in successive stages of spermatogenesis (**Figure 43.9C**). The germ cells are intimately associated with **Sertoli cells** that provide nutrients for the developing sperm.

When the second meiotic division is complete, each primary spermatocyte has produced four spermatids (see Figure 43.3A). The spermatids develop into spermatozoa as they migrate toward the lumen of the seminiferous tubule. The nucleus becomes compact, and the surrounding cytoplasm is lost. A flagellum—the sperm tail—develops. The mitochondria that provide the energy for sperm motility become condensed into a midpiece between the head and tail. An acrosome forms over the nucleus in the head of the sperm. Immature sperm are shed into the lumen of the seminiferous tubule.

43.8 Reproductive Tract of the Human Male The male reproductive organs are shown (A) from the rear and (B) from the side.

Go to Activity 43.1 The Human Male Reproductive Tract
Life10e.com/ac43.1

From the seminiferous tubules, sperm move into the **epididymis** (see Figure 43.8), where they mature, become motile, and are stored. The epididymis connects to the **urethra** via the **vas deferens** (plural *vasa deferentia*) and the **ejaculatory duct**.

The urethra originates in the bladder, runs through the penis, and opens to the outside of the body at the tip of the penis. It serves as the common final duct for the urinary and reproductive systems.

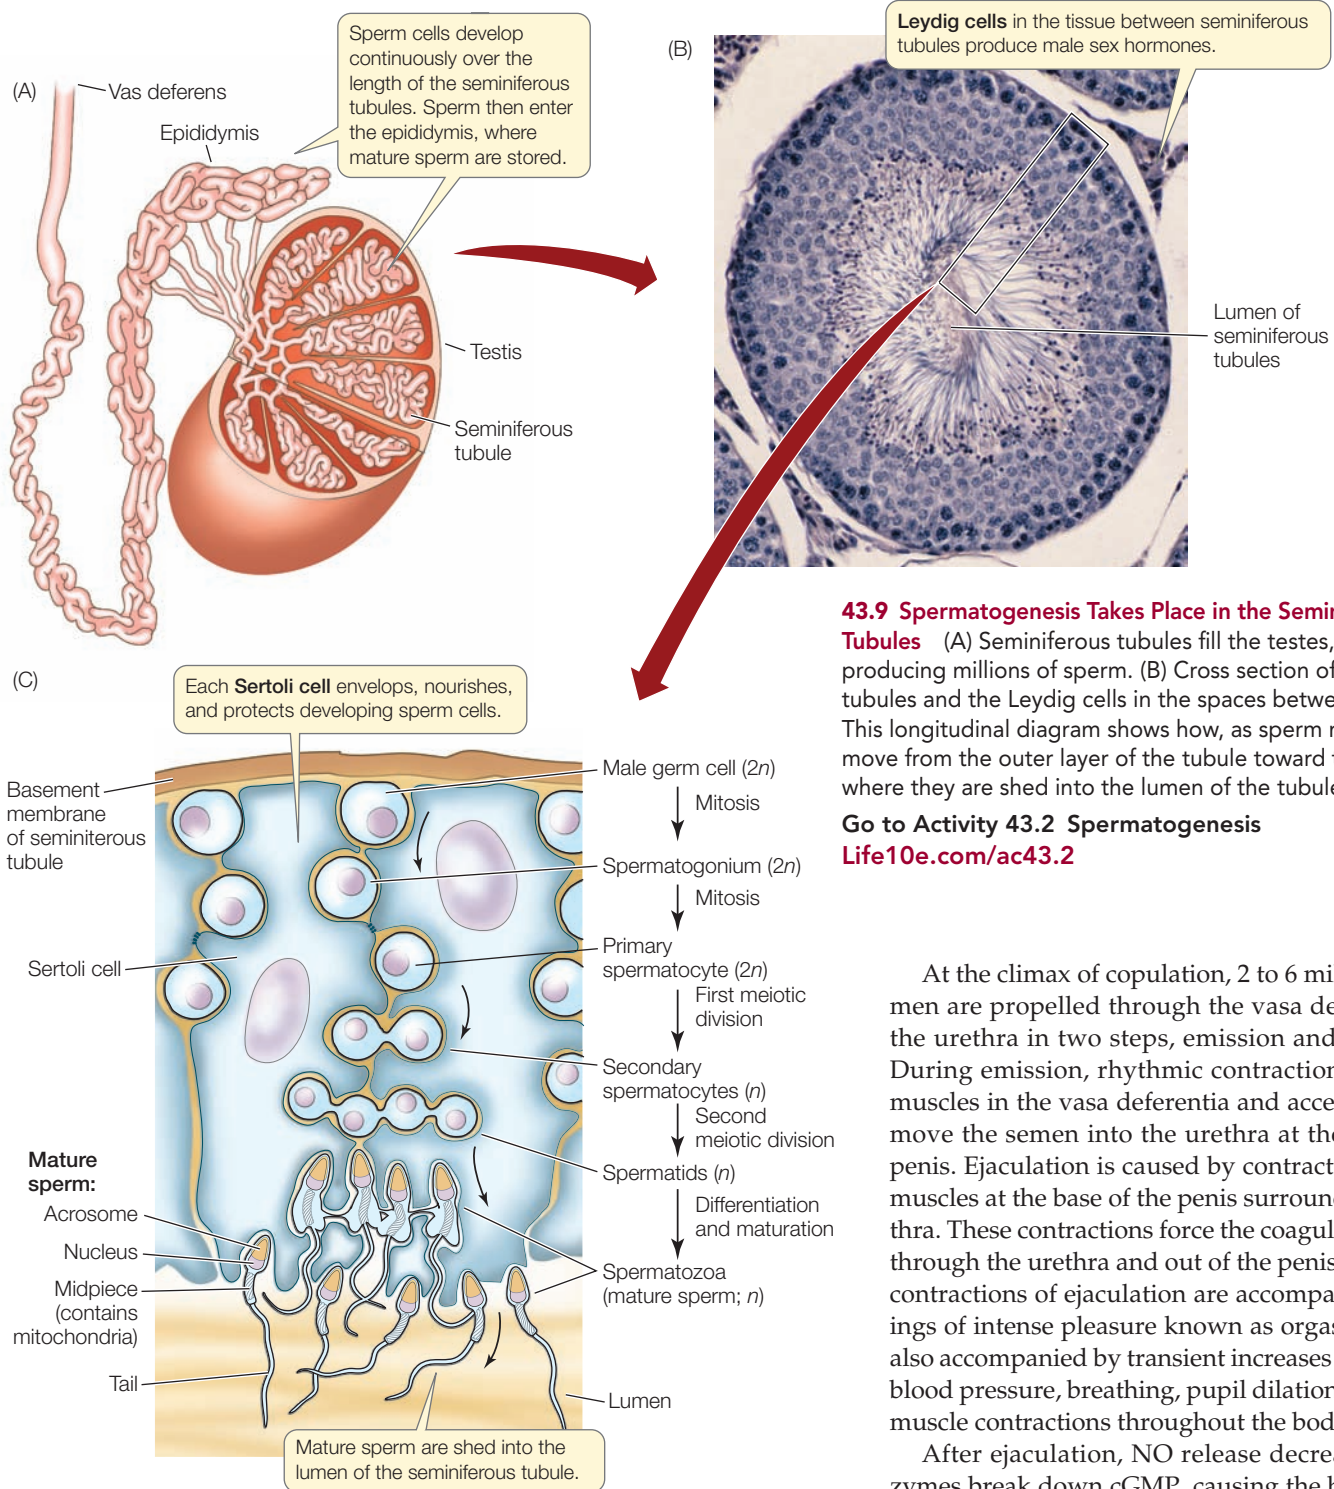

The components of the semen other than sperm come from several accessory glands. About 60 percent of the volume of semen is secreted by the paired **seminal vesicles**, which empty into the vas deferens just before it joins the urethra. Seminal fluid is thick because it contains mucus and fibrinogen, a protein also found in the blood, where it can polymerize to form blood clots. Seminal fluid also contains the monosaccharide fructose, an energy source for the sperm.

The **prostate gland** contributes about 30 percent of the volume of the semen. Prostate fluid is alkaline, so it neutralizes the acidity in the male and female reproductive tracts and makes these environments more hospitable to sperm. The prostate also secretes a clotting enzyme that causes fibrinogen from the seminal vesicles to convert the semen into a clotted, gelatinous mass, facilitating the semen's propulsion into the upper regions of the female reproductive tract. Another prostate enzyme, fibrinolysin, then dissolves the clotted semen and liberates the sperm. Prostaglandins—hormones produced by the prostate—stimulate contractions of the female reproductive tract.

The **bulbourethral glands** produce a small volume of an alkaline, mucoid secretion that helps neutralize acidity in the urethra and lubricate it to facilitate the passage of semen immediately preceding the climax of sexual intercourse. These secretions can carry with them residual sperm from prior sexual activity. It is therefore possible for pregnancy to occur even if the penis is withdrawn just before climax (an ancient but ineffective birth control practice known as *coitus interruptus*).

The penis and the scrotum are the male genitalia. The shaft of the penis is covered with normal skin, but the highly sensitive tip, the **glans penis**, is covered with thinner, more sensitive skin that is especially responsive to sexual stimulation. A fold of skin called the foreskin covers the glans of the human penis. The procedure known as circumcision removes a portion of the foreskin.

Sexual stimulation triggers responses in the nervous system that result in penile **erection**. Nerve endings release a neurotransmitter that causes the endothelial cells lining the penile blood vessels to release a gaseous neurotransmitter, nitric oxide (NO). NO diffuses into the muscle cells that control the diameter of the penile arteries and stimulates them to produce the second messenger cGMP (see Figure 7.15). Increased cGMP in these muscle cells causes them to relax; the arteries dilate and carry more blood into the penis. Increased blood flow swells

43.9 Spermatogenesis Takes Place in the Seminiferous Tubules

(A) Seminiferous tubules fill the testes, continuously producing millions of sperm. (B) Cross section of seminiferous tubules and the Leydig cells in the spaces between them. (C) This longitudinal diagram shows how, as sperm mature, they move from the outer layer of the tubule toward the center, where they are shed into the lumen of the tubule.

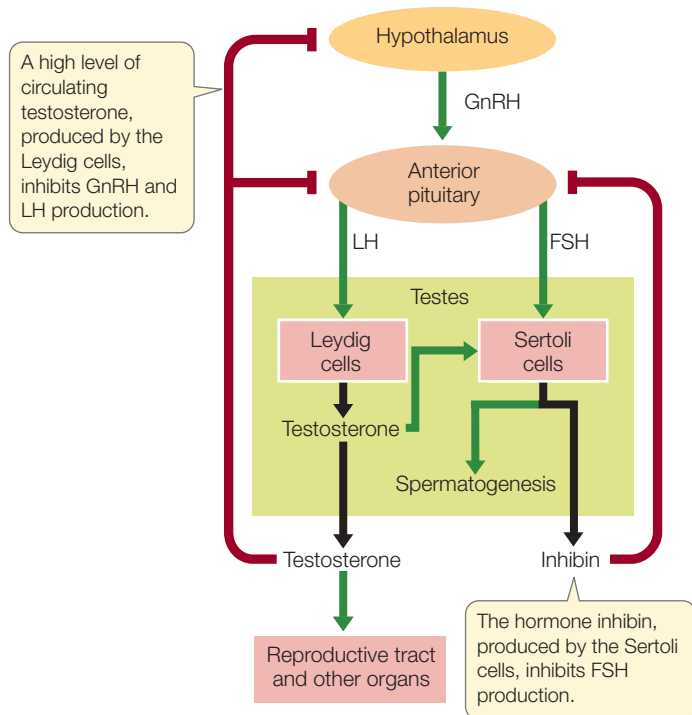

Go to Activity 43.2 Spermatogenesis
Life10e.com/ac43.2

At the climax of copulation, 2 to 6 milliliters of semen are propelled through the vasa deferentia and the urethra in two steps, emission and ejaculation. During emission, rhythmic contractions of smooth muscles in the vasa deferentia and accessory glands move the semen into the urethra at the base of the penis. Ejaculation is caused by contractions of other muscles at the base of the penis surrounding the urethra. These contractions force the coagulum of semen through the urethra and out of the penis. The muscle contractions of ejaculation are accompanied by feelings of intense pleasure known as orgasm. They are also accompanied by transient increases in heart rate, blood pressure, breathing, pupil dilation and skeletal muscle contractions throughout the body.

After ejaculation, NO release decreases and enzymes break down cGMP, causing the blood vessels flowing into the penis to constrict. The blood pressure in the erectile tissue decreases, relieving the compression of the blood vessels leaving the penis, and the erection declines.

Erectile dysfunction (ED), or impotence, is the inability to achieve or sustain an erection. ED may have different causes, including cardiovascular disease. Drugs used to treat ED act by inhibiting the breakdown of cGMP, thus enhancing the effect of NO released in the penis, which improves the ability to achieve and maintain an erection.

the shafts of spongy erectile tissue located along the length of the penis. The enlargement of these blood-filled cavities compresses the vessels that carry blood out of the penis, and the erectile tissue becomes engorged with blood. The penis becomes hard and erect, facilitating its insertion into the vagina. Many species of mammals (though not humans) have a bone in the penis, but these species still depend on erectile tissue for copulation.

43.10 Male Reproductive Hormones The male reproductive system is under hormonal control by the hypothalamus and the anterior pituitary. Red lines indicate inhibition; green lines indicate stimulation.

Male sexual function is controlled by hormones

Spermatogenesis and maintenance of male secondary sexual characteristics such as facial hair and a deep voice depend on testosterone produced by the Leydig cells of the testes. As described in Section 41.3, increased production of testosterone at puberty results from an increased release of gonadotropin-releasing hormone (GnRH) by the hypothalamus. GnRH stimulates anterior pituitary cells to secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (**Figure 43.10**). Higher levels of LH stimulate the Leydig cells to increase their production and release of testosterone. Testosterone exerts negative feedback on the anterior pituitary and the hypothalamus. At the time of puberty, the sensitivity of the hypothalamus to negative feedback from testosterone declines; as a result, the level of circulating testosterone increases.

Increased testosterone in pubertal boys causes the development of pubic and facial hair, a deeper voice, enlarged genitals, and an increased growth rate. Testosterone also promotes increased muscle mass and maturation of the testes. Continued production of testosterone after puberty is essential for the maintenance of secondary sexual characteristics and the production of sperm.

Spermatogenesis is controlled by the influence of FSH and testosterone on the Sertoli cells in the seminiferous tubules. The Sertoli cells also produce a hormone called inhibin that exerts negative feedback on the anterior pituitary cells producing and secreting FSH.

Female sex organs produce eggs, receive sperm, and nurture the embryo

The human female reproductive system is shown in **Figure 43.11**. Eggs are produced in and released from the ovaries located on either side of the lower abdominal cavity. When an egg leaves the ovary (**ovulation**), it enters the abdominal cavity, but it does not go far. The ovaries are close to the openings of the **oviducts** (also known as the Fallopian tubes). The openings are surrounded by undulating, fringed tissues called fimbria that sweep the egg into the oviduct. Cilia lining the oviduct propel the egg toward the **uterus**, a muscular, thick-walled cavity shaped in humans like an upside-down pear. The uterus is where the embryo will develop if the egg is fertilized. At its bottom, the uterus narrows into a region called the **cervix**, which opens into the vagina.

Externally, the vagina is enclosed by two sets of skin folds. The inner, more delicate folds are the labia minora; the outer, thicker folds are the labia majora. At the anterior tip of the labia minora is the clitoris, a small bulb of highly sensitive erectile tissue that has the same developmental origins as the male glans penis. The labia minora and the clitoris become engorged with blood in response to sexual stimulation. Between the vagina and the clitoris is the opening of the urethra through which urine flows.

The external opening of an infant's vagina is usually, but not always, partly covered by a thin membrane, the hymen. Eventually the hymen can be torn by vigorous physical activity or by first sexual intercourse; it can sometimes make first intercourse difficult or painful for the woman.

To fertilize an egg, sperm deposited in the vagina swim and are propelled by contractions of the female reproductive tract through the cervical opening, across the uterus, and most of the way up an oviduct. Before meeting a sperm, the egg is still a secondary oocyte, and fertilization stimulates it to complete its second meiotic division. Following that division, the haploid nuclei of the sperm and the egg can fuse to produce a diploid zygote nucleus.

While still in the oviduct, the zygote undergoes its first few cell divisions to become a **blastocyst**. The blastocyst moves down the oviduct to the uterus, where it attaches itself to the epithelial lining of the uterus—the **endometrium**. Once attached, the blastocyst implants in the endometrium and interacts with it to form the placenta, as we will see in Chapter 44. The mother's body nurtures the embryo through the placenta, which also produces hormones that help sustain pregnancy.

Just as the maturation of eggs and ovulation in the ovaries is a cyclical process, so are critical events in the uterus. In anticipation of receiving a blastocyst, the endometrium thickens and develops lots of blood vessels. If a blastocyst does not arrive within a certain window of time, the endometrium regresses. Thus female reproductive functions consist of two linked cycles: an **ovarian cycle** that produces eggs and hormones; and a **uterine, or menstrual, cycle** that prepares the endometrium for the arrival of a blastocyst. The two cycles must be synchronized so that a blastocyst arrives in the uterus at the optimal time to embed in the endometrium and continue its development.

The ovarian cycle produces a mature egg

A newborn baby girl has about a million primary oocytes in each ovary. By the time she reaches puberty, she has only about 200,000; the rest have degenerated. During a woman's fertile years, her ovaries go through about 450 ovarian cycles (**Figure 43.12A**). During each cycle, 10 to 20 primary oocytes begin to

mature, but usually only one matures completely and is ovulated; the others degenerate. At around the age of 50, a woman reaches **menopause**—the end of fertility—and may have few if any oocytes left in each ovary.

A primary oocyte surrounded by a layer of ovarian cells is the functional unit of the ovary—the **follicle** (**Figure 43.12B**). The follicle cells surrounding the oocyte supply it with nutrients and growth factors. The follicle cells are also the main site of production of the female hormones estrogen and progesterone. Usually only one follicle matures completely and reaches the stage of ovulation, releasing its egg at midcycle.

The second half of the ovarian cycle is called the luteal phase because the follicle cells left in the ovary after the egg is ovulated develop into an endocrine gland—the **corpus luteum** (yellow body)—secreting estrogen and progesterone. If the egg is not fertilized and does not embed into the endometrium, the corpus luteum becomes inactive and degenerates in 12 to 14 days.

The uterine cycle prepares an environment for a fertilized egg

The uterine cycle parallels the ovarian cycle and consists of a buildup and then a breakdown of the endometrium (**Figure 43.13**). About 5 days into the ovarian cycle, the endometrium starts to thicken in preparation for receiving a blastocyst. The uterus attains its maximal state of preparedness about 5 days after ovulation and remains in that state for another 9 days. If a blastocyst has not arrived by that time, the endometrium breaks down and the sloughed-off tissue, including blood, flows from the body through the vagina—the process of **menstruation** (Latin *menses*, “months”).

The uterine cycles of most mammals other than humans do not include menstruation; instead, the uterine lining typically is resorbed. In these species, the most obvious correlate of the ovarian cycle is a state of sexual receptivity called **estrus** (“heat”) around the time of ovulation. You may be aware of the bloody discharge that occurs in dogs at the time of estrus. This discharge is not the same as menstruation—in fact it is exactly the opposite. Bleeding in dogs occurs

during the *proliferation* of the uterine lining, which occurs just before ovulation. When the female mammal comes into estrus, she actively solicits male attention and may be aggressive to other females. Humans are unusual among mammals in that females are potentially sexually receptive throughout their ovarian cycles and at all seasons of the year.

43.12 The Ovarian Cycle (A) The ovarian cycle progresses from the development of a follicle to ovulation and finally to growth and degeneration of the corpus luteum. (B) This micrograph shows a mature mammalian follicle; the oocyte is in the center.

Hormones control and coordinate the ovarian and uterine cycles

The ovarian and uterine cycles are coordinated and timed by the same hormones that initiate sexual maturation. Gonadotropins (FSH and LH) secreted by the anterior pituitary are the central elements of this control. Before puberty (that is, before about 11 years of age), the secretion of FSH and LH is low and the ovaries are inactive. At puberty the hypothalamus increases its release of GnRH, stimulating the anterior pituitary to secrete FSH and LH. In response to FSH and LH, ovarian tissue grows and produces estrogen. The rise in estrogen causes the maturation of the accessory sex organs and the development of female secondary sexual characteristics. Between puberty and menopause, interactions of GnRH, gonadotropins, and sex steroids control the ovarian and uterine cycles.

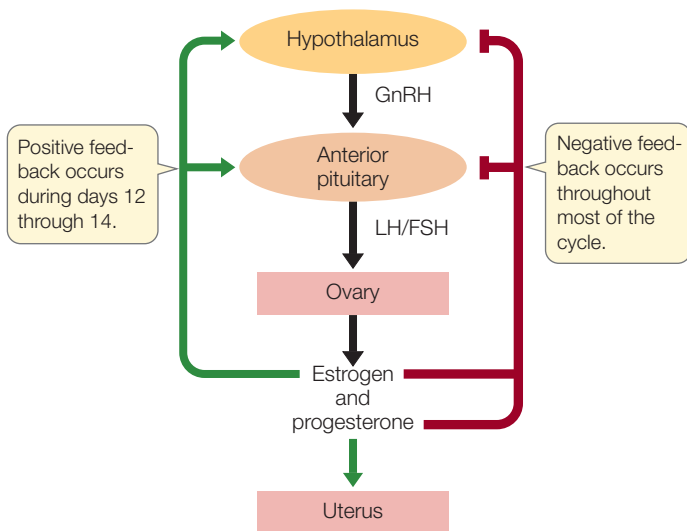

Menstruation marks the beginning of each uterine and ovarian cycle. A few days before menstruation begins, the anterior pituitary begins to increase its secretion of FSH and LH. In response, several follicles begin to mature in the ovaries, and these follicles steadily increase

43.13 The Ovarian and Uterine Cycles During a woman's ovarian and uterine cycles, coordinated changes occur in (A) gonadotropin release by the anterior pituitary, (B) the ovary, (C) the release of female sex steroids, and (D) the uterus. The cycles begin with the onset of menstruation; ovulation is at midcycle (yellow bar).

The Ovarian and Uterine Cycles
Life10e.com/at43.2

43.14 Hormones Control the Ovarian and Uterine Cycles The ovarian and uterine cycles are under a complex series of positive and negative feedback controls involving several hormones.

their production of estrogen. After about a week, all but one of the follicles wither away.

Estrogen exerts negative feedback control on gonadotropin release by the anterior pituitary during the first 12 days of the ovarian cycle. Then, on about day 12, estrogen exerts positive rather than negative feedback control on the pituitary (**Figure**

43.14). As a result, a surge of LH and a lesser surge of FSH occur (see Figure 43.13A). The LH surge triggers the mature follicle to rupture and release its egg, and it stimulates the cells of the ruptured follicle to develop into a corpus luteum.

Estrogen and progesterone secreted by the corpus luteum following ovulation are crucial to growth and maintenance of the endometrium. These sex steroids also exert negative feedback control on the pituitary, inhibiting gonadotropin release and thus preventing new follicles from maturing.

If the egg is not fertilized, the corpus luteum degenerates on about day 26 of the cycle. Without production of progesterone by the corpus luteum, the endometrium sloughs off and menstruation occurs. The decrease in circulating steroids also releases the hypothalamus and pituitary from negative feedback control, so GnRH, FSH, and LH all begin to increase. The increase in these hormones induces the next round of follicle development, and the ovarian cycle begins again.

FSH receptors determine which follicle ovulates

Early in the ovarian cycle several follicles begin to develop, but only one reaches full maturity. What determines which one will survive? There are two types of follicle cells, arranged in two layers. The inner layer immediately surrounding the ovum is made up of granulosa cells, and the outer layer contains thecal cells. Thecal cells are stimulated by LH to produce testosterone

WORKING WITH DATA:

Circadian Timing, Hormone Release, and Labor

Original Paper

Olcese, J., S. Lozier, and C. Paradise. 2012. Melatonin and the circadian timing of human parturition. *Reproductive Sciences*, epub before print, May 3, 2012.

Analyze the Data

Pregnant women are more likely to go into labor during the night than in the daytime. Frequently, however, when women in labor are taken to a well-lit hospital, their contractions decrease. James Olcese and his colleagues thought that the timing of labor contractions might be controlled by a signal from the brain's circadian timing system—specifically, the release of the hormone melatonin from the pineal gland. Melatonin is always released at night, and its release is inhibited by light (see Section 41.5).

The researchers hypothesized that rising levels of melatonin potentiate contractility of the uterine muscles. To test this hypothesis, they collected two types of data from pregnant women close to term. They collected saliva samples from 5 women at 30-minute intervals overnight and measured the melatonin levels in the samples. They also recorded the frequency of contractions of two women who were having regular but premature contractions at night. In both situations the women were exposed to bright light between 11 P.M. and midnight. The results are shown in the table.

QUESTION 1

Plot the data in the tables. How would you interpret these data? Do they support the authors' hypothesis?

QUESTION 2

It is known that the posterior pituitary hormone oxytocin stimulates the uterine contractions leading to expulsion of the fetus from the uterus. If you cultured some uterine muscle tissue, how would you investigate the possible interaction of oxytocin and melatonin? What would your hypothesis be?

Time	Data Set 1	Data Set 2	
	Salivary melatonin (percent of maximum; mean for 5 subjects)	Contractions per hour (2 subjects)	
		Subject A	Subject B
7 P.M.	5		
8 P.M.	5	2	3
9 P.M.	12	4	5
10 P.M.	30	5	5
11 P.M.	55	6	2

5 A.M.	85	5	15
6 A.M.	70	4	12
7 A.M.	60	2	4

(similar to Leydig cells in the male). Testosterone diffuses into the granulosa cells, where the enzyme aromatase converts the testosterone to estrogen. Estrogen, along with FSH, stimulates the growth and maturation of the granulosa cells (similar to the Sertoli cells in the male). The estrogen plays two important roles in the selection of the follicle that will ovulate: (1) estrogen stimulates the granulosa cells to express more FSH and LH receptors, and (2) estrogen entering the circulation feeds back on the pituitary to decrease the production of FSH. The granulosa cells also produce inhibin (similar to Sertoli cells in the male), and inhibin also decreases the production of FSH. As FSH and LH levels fall, the follicle with the most FSH and LH receptors survives and matures while the others regress.

In pregnancy, hormones from the extraembryonic membranes take over

If the egg is fertilized and a blastocyst arrives in the uterus and implants in the endometrium, a new hormone comes into play. A layer of cells covering the blastocyst begins to secrete **human chorionic gonadotropin**, or **hCG** (Figure 43.15A). This gonadotropin, a molecule similar to LH, stimulates the corpus luteum to continue to produce estrogen and progesterone to support the growth and maintenance of the endometrium and thereby prevent menstruation. Because it is present only in the blood of pregnant women, the presence of hCG is the basis for pregnancy testing. Pregnancy tests use an antibody to detect hCG in urine; they take only minutes and can be done at home.

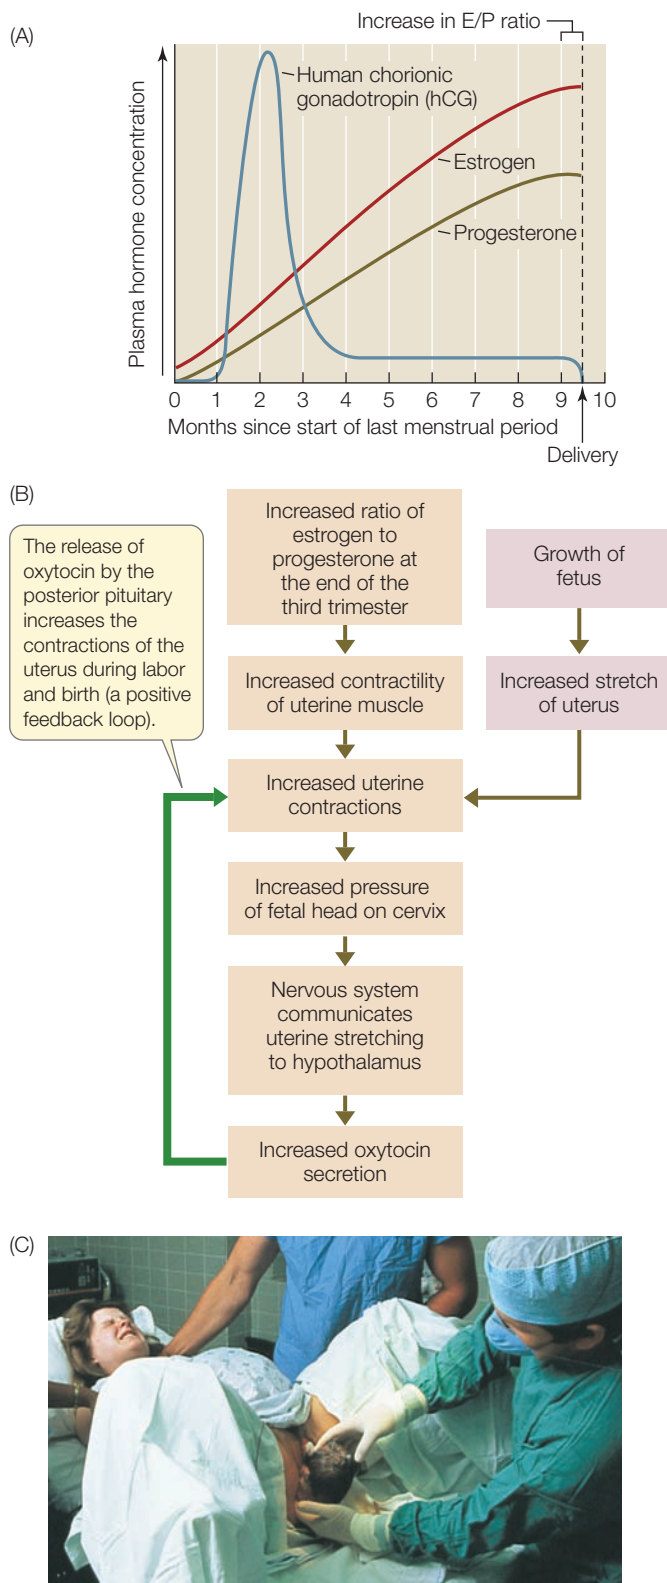

Blastocyst and endometrial tissues form the placenta, which nourishes the embryo. The placenta also replaces the corpus luteum as the major producer of estrogen and progesterone. Continued high levels of estrogen and progesterone prevent the pituitary from secreting gonadotropins; thus the ovarian cycle ceases for the duration of pregnancy. This mechanism underlies the action of birth control pills, which contain synthetic hormones resembling estrogen and progesterone that exert negative feedback control on the hypothalamus and pituitary.

Childbirth is triggered by hormonal and mechanical stimuli

Throughout pregnancy, the muscles of the uterine wall periodically undergo slow, weak, rhythmic contractions called Braxton Hicks contractions. These contractions become stronger during the third trimester of pregnancy and are sometimes called false labor. The contractions of true labor mark the beginning of childbirth. Both hormonal and mechanical stimuli contribute to the onset of labor.

Progesterone inhibits and estrogen stimulates contractions of uterine muscle. Toward the end of the third trimester, the estrogen–progesterone ratio shifts in favor of estrogen. The onset of labor is marked by increased secretion of the hormone oxytocin by the posterior pituitaries of both mother and fetus. Oxytocin is a powerful stimulant of uterine muscle contraction. Manufactured oxytocin is used to induce labor when that is necessary.

Mechanical stimuli come from the stretching of the uterus by the fully grown fetus and the pressure of the fetal head on the cervix. These mechanical stimuli increase the release of oxytocin by the mother's posterior pituitary, which in turn

43.15 Pregnancy and Childbirth (A) When a fertilized ovum implants in the uterus, cells surrounding it produce human chorionic gonadotropin, which acts like LH and keeps the corpus luteum functioning as an endocrine gland. The ovarian and uterine cycles are put on hold for the duration of pregnancy. (B) Both mechanical and hormonal signals are involved in stimulating the uterine contractions of labor and delivery. (C) A new person comes into the world head first.

increases the activity of uterine muscle, causing even more pressure on the cervix. This positive feedback loop converts the weak, slow, rhythmic Braxton Hicks contractions into stronger labor contractions (**Figure 43.15B**).

In the early stage of labor, hormonal changes and pressure created by the contractions cause the cervix to dilate (expand) until it is large enough to allow the baby to pass through. Gradually the contractions become more frequent and more intense. This stage of labor lasts an average of 12 to 15 hours in a first pregnancy, but is usually 8 hours or less in subsequent ones.

The second stage of labor begins when the cervix is fully dilated to a diameter of about 10 cm (**Figure 43.15C**). The baby's head can now move into the vagina. Passage of the fetus through the vagina is assisted by the mother's bearing down ("pushing") with her abdominal and other muscles. Once the head and shoulders of the baby clear the cervix, the rest of its body eases out rapidly, but it is still connected to the placenta by the umbilical cord. Once the baby clears the birth canal, it starts breathing and is independent of its mother's circulation. The umbilical cord may then be clamped and cut. The segment still attached to the baby dries up and sloughs off in a few days, leaving behind its distinctive signature, the belly button—more properly called the umbilicus. The third stage of labor, the detachment and expulsion of the placenta and fetal membranes, takes from a few minutes to an hour, and may be accompanied by uterine contractions. A baby's suckling at the breast immediately following birth stimulates additional secretion of oxytocin, which augments uterine contractions, reduces the size of the uterus, and helps stop bleeding.

RECAP 43.3

The reproductive systems of men and women produce gametes and hormones, and these functions are controlled by hypothalamic and anterior pituitary hormones. In women, the hormonal control of reproductive functions produces linked ovarian and uterine cycles.

- Describe the path the human sperm and ovum take in moving from their respective gonads to the point at which fertilization occurs. **See Figures 43.8 and 43.11**
- In males, increased production of GnRH at puberty stimulates the release of what two hormones of the anterior pituitary? What effect do these hormones have? **See p. 892**
- Explain the events in the ovarian cycle that result in release of a single ovum each month. What events prepare the uterus to receive the egg? **See Figures 43.12 and 43.13**

Understanding the physiology of human reproduction has led to numerous methods and technologies for controlling it, either to prevent unwanted pregnancies or to overcome infertility.

43.4 How Can Fertility Be Controlled?

Sexual issues and sexual behavior are dominant aspects of our society, and reproductive technologies have had huge impacts on our sexual and reproductive lives.

Humans use a variety of methods to control fertility

According to a recent study, almost half of the more than 6 million pregnancies that occur in the United States each year are unintended. For women of college age, a single act of unprotected intercourse in the two days prior to ovulation carries a chance of conception as high as 50 percent.

The only failure-proof methods of preventing pregnancy are either complete abstinence from sexual activity or surgical removal of the gonads. Those options are not acceptable to most people, and they turn to other methods to prevent pregnancy. Many of these methods prevent fertilization or implantation (conception) and are therefore referred to as **contraception**. **Table 43.1** lists some of the most commonly used contraceptive methods and their relative failure rates; note that these methods vary enormously in their effectiveness. Most methods are used by the woman, although some are used by the man.

Once a fertilized egg is successfully implanted in the uterus, any termination of the pregnancy is called an **abortion**. A spontaneous abortion is the medical term for what is commonly called a miscarriage. Spontaneous abortions frequently occur early in pregnancy and are usually the result of either a chromosomal abnormality in the fetus or a breakdown in the process of implantation. Many spontaneous abortions occur before the woman even realizes she is pregnant.

Abortions that result from medical intervention may be performed either for therapeutic purposes or for fertility control. A therapeutic abortion may be necessary to protect the health of the mother, or it may be performed because prenatal testing reveals that the fetus has a severe defect. In a medical abortion, the cervix is dilated and some of the endometrium, along with the implanted fetus, is removed. When performed in the first trimester of a pregnancy, a medical abortion carries less risk of death to the mother than a full-term pregnancy. The risk rises after the first 12 weeks of pregnancy but remains less than that of a full-term pregnancy through the second trimester.

Reproductive technologies help solve problems of infertility

About 15 percent of couples in the United States are infertile—that is, they can't have children. The reasons for infertility are many, and are about equally distributed between men and women. Several technologies have been developed to overcome barriers to both conceiving and bearing a child. The simplest of these is **artificial insemination**, in which the physician places sperm in the female's reproductive tract. This technique is useful if the male's sperm count is low, if his sperm lack motility, or if problems in the female's reproductive tract prevent the normal movement of sperm up to and through the oviducts. Artificial insemination is also widely used in the production of domesticated animals such as cattle.

Assisted reproductive technologies, or **ARTs**, involve procedures that remove unfertilized eggs from the ovary, combine them with sperm outside the body, and then place fertilized eggs or egg-sperm mixtures in the appropriate location in the female's reproductive tract for development to take place. The

TABLE 43.1
Methods of Contraception

Method	Mode of Action	Failure Rate ^a	Comments
Unprotected	No form of birth control.	85	High risk of pregnancy, especially for women 15–30.
Nontechnological methods			
Rhythm method	The couple abstains from intercourse between days 10 and 20 of the ovarian cycle (peak fertility).	15–35	High failure rate due to miscalculation and/or variation of individual cycles.
Coitus interruptus	The man withdraws his penis prior to ejaculation with the intention of not depositing sperm into the vagina.	20–40	Requires self-control, especially by the man. Very high failure rate.
Barrier methods^b			
Condom	A sheath of impermeable material (often latex) is fitted over the erect penis. Semen is trapped in the condom, so no sperm are deposited in the vagina.	15	If fitted correctly, an intact condom can prevent pregnancy and provide protection against sexually transmitted diseases (STDs), including HIV (AIDS).
Spermicidal jellies	Applied inside the vagina, these chemical compounds kill or immobilize sperm.	25	Used alone, spermicidal compounds have a fairly high failure rate.
Diaphragms, cervical caps	Inserted by the woman prior to intercourse, these devices work by blocking the cervix so that sperm cannot pass into the uterus.	10–15	Approximately the same failure rate as condom use by men, but do not protect against STDs. Can be used in conjunction with spermicidal jelly for extra protection.
Hormone-based contraceptives			
Oral hormones ("the pill")	A daily pill for women containing a combination of synthetic estrogens and progesterone. These hormones mimic pregnancy to the extent that the ovarian cycle and ovulation are suspended. The uterine cycle is allowed to continue by including a week of non-hormone administration every 21–28 days.	0–3	Requires medical consultation and prescription. Taken correctly, oral contraceptives are extremely effective. In the U.S., more than 12 million women use them each year; they are sometimes prescribed to treat menstrual disorders.
Non-orally administered hormones	Making use of same hormonal actions as the pill, these methods include long-acting injections, patches that release hormones transdermally (through the skin), and a hormone-containing vaginal ring.	<1	Same as oral hormones. A slightly lower failure rate because the woman does not have to remember to take a daily pill.
Progestin-only pill (Plan B®)	An oral contraceptive meant to be taken within 72 hours after unprotected sex. A high dose of progestin in two pills prevents ovulation in the same manner birth control pills do.	5–40	Not an "abortion pill," this drug will not terminate an existing pregnancy. Currently available to women over 17 without a prescription. Failure rate varies widely depending on when taken.
Implantation blockers			
Intrauterine device (IUD)	A medical professional inserts a small plastic or metal device into the uterus. The resulting inflammation reaction (see Chapter 42) releases prostaglandins, which prevent implantation of the fertilized egg.	0.5–5	A highly effective contraceptive, it is the most widely used birth control device in China (and hence the world). With medical monitoring, can remain in place for several years.
Mifepristone (RU-486)	This drug blocks progesterone receptors necessary to maintain the endometrium during implantation and pregnancy.	0.5–6	Prevents implantation when taken up to several days after unprotected intercourse. Can terminate a pregnancy up to the time of the first missed menstrual period. In the U.S., available from specialized providers.
Sterilization			
Vasectomy	The vasa deferentia (see Figure 43.8) are cut and tied off so that sperm can no longer pass into the urethra. Sperm continue to be produced but are reabsorbed by the man's body. Male hormone levels and sexual responses are not affected.	0–0.15	A simple surgical procedure performed under local anesthetic in a doctor's office. Although theoretically it can be reversed, vasectomy should be considered permanent.
Tubal ligation	The oviducts (see Figure 43.11A) are tied off so that eggs cannot reach the uterus and sperm cannot reach the egg. As with vasectomy, hormone levels and sexual responses are not affected.	0–0.05	This surgical procedure is somewhat more complex than vasectomy. It is often performed in conjunction with childbirth when a woman has decided that her family is complete.

^aFailure rate refers to the number of pregnancies per 100 women per year^bAll of these barrier methods are routinely available without medical prescription.

43.16 Intracytoplasmic Sperm Injection In this procedure, a sperm is injected directly into a mature egg cell. The fertilized egg is then placed in the female reproductive tract, where it can implant and develop into a fetus.

first successful ART was in vitro fertilization (IVF). In IVF the female is treated with hormones that stimulate many follicles in her ovaries to mature. Eggs are collected from these follicles, and sperm are collected from the male. Eggs and sperm are combined in a culture medium outside the body, where fertilization takes place. The resulting embryos can be injected into the mother's uterus in the blastocyst stage or kept frozen for implantation later. The first "test-tube baby" resulting from IVF was born in England in 1978. Since then, millions of babies have resulted from this ART.

A major cause of IVF failure is failure of sperm to gain access to the egg plasma membrane (see Figure 43.4). To solve this problem, methods have been developed to inject a sperm cell directly into the cytoplasm of an egg. In intracytoplasmic sperm injection (ICSI), an egg is held in place by suction applied to a polished glass pipette. A slender, sharp pipette is then used to penetrate the egg and inject a sperm (**Figure 43.16**). This ART was used successfully for the first time in 1992 by researchers in Belgium; now thousands of these procedures are performed in U.S. clinics each year, with a success rate of about 25 percent.

IVF, coupled with techniques of genetic analysis, can eliminate the risk that adults who are carriers of genetic diseases will produce affected children. It is now possible to take a cell from a human embryo at the 4- or 8-cell stage (see Figure

44.4) without damaging its developmental potential. The sampled cell can be subjected to molecular analysis to determine whether it carries the harmful gene. This procedure, called preimplantation genetic diagnosis (PGD), makes it possible to determine whether an embryo produced by IVF carries the genetic defect of concern.

RECAP 43.4

Controlling fertility is an important aspect of modern human life. Decreasing the probability of pregnancy is achieved through methods that prevent sperm and egg from meeting and from preventing implantation. Pregnancies can be facilitated through medical technology.

- Which method of contraception is the only one to offer protection against sexually transmitted diseases (STDs)? **See Table 43.1**
- Explain what a couple who are both carriers of a genetic disease could do to ensure that their offspring would not have the disease. **See p. 899**

The fertilized egg of a sexually reproducing organism is a single cell containing all the genetic information needed to create a new organism. Chapters 19 and 20 introduced some of the molecular aspects of the process of development in multicellular animals. Chapter 44 will describe the physiological and anatomical events of animal development.

How can a queen be so different from her worker sisters when they all share the same genome?

ANSWER

When a hive loses its queen, the workers create new queens from a few eggs that the old queen laid by feeding a substance called "royal jelly" to the larvae that hatch from the chosen eggs. This special food stimulates growth and has recently been discovered to have powerful epigenetic effects on honey bee development. As described in Chapter 16, the expression of a gene can be more or less permanently altered by the chemical modification of histones—proteins that are closely associated with the DNA—or by methylation or demethylation of the DNA itself (see Section 16.4). Because these changes do not alter the gene's nucleotide sequence, they are referred to as epigenetic ("outside the gene"). One component of royal jelly is phenyl butyrate, an inhibitor of histone deacetylation. Furthermore, the queen bee has well over 500 genes that are methylated differently than those same genes in workers. It is therefore likely that the royal jelly fed to a future queen dramatically alters the expression of her genome.

43.1 How Do Animals Reproduce without Sex?

- Asexual reproduction produces offspring that are genetically identical to their parent and to one another; it produces no genetic diversity.
- Means of asexual reproduction include **budding**, **regeneration**, and **parthenogenesis**. **Review Figures 43.1, 43.2**

43.2 How Do Animals Reproduce Sexually?

- Sexual reproduction involves three basic steps: **gametogenesis**, **spawning** or **mating**, and **fertilization**.
- **Gametogenesis** and fertilization are similar in all animals, but spawning and mating include a great variety of anatomical, physiological, and behavioral adaptations.
- Gametogenesis occurs in **testes** and **ovaries**. In spermatogenesis (the production of **sperm**) and oogenesis (the production of eggs), the **germ cells** proliferate mitotically, undergo meiosis, and mature into gametes.
- Each **primary spermatocyte** can produce four haploid sperm through the two divisions of meiosis. **Review Figure 43.3A**
- **Primary oocytes** immediately enter prophase of the first meiotic division, and in many species, including humans, their development is arrested at this point. Each **oogonium** produces only one egg. **Review Figure 43.3B**
- Fertilization involves sperm activation, species-specific binding of sperm to egg, the acrosomal reaction, digestion of a path through the protective coverings of the egg, and fusion of sperm and egg plasma membranes. Fusion of these two membranes triggers **blocks to polyspermy**, which prevent additional sperm from entering the egg and, in mammals, signal the egg to complete meiosis and begin development. **Review Figure 43.4, ANIMATED TUTORIAL 43.1**
- **External fertilization** is common in aquatic species. **Internal fertilization** is necessary in terrestrial species and usually involves **copulation**.
- **Hermaphroditic**, or **monoecious**, species have both male and female reproductive systems in the same individual, either sequentially or simultaneously. **Dioecious** species have separate male and female individuals.
- Animals can be classified as **oviparous** or **viviparous**, depending on whether the early stages of development occur outside or inside the mother's body.

43.3 How Do the Human Male and Female Reproductive Systems Work?

- Men produce **semen** consisting of sperm suspended in seminal fluid (which nourishes the sperm and facilitates fertilization).
- Sperm are generated in the **seminiferous tubules** of the testes, mature in the **epididymis**, and are delivered to the **urethra** through the **vasa deferentia**. Other components of semen are produced in the **seminal vesicles**, **prostate gland**, and **bulbo-urethral gland**. **Review Figures 43.8, 43.9, ACTIVITIES 43.1, 43.2**
- All components of the semen join in the urethra at the base of the **penis** and are ejaculated through the erect penis by muscle contractions at the culmination of copulation.
- Spermatogenesis depends on testosterone secreted by the **Leydig cells** of the testes, which are under the control of hormones produced in the anterior pituitary and the hypothalamus. The production of these hormones is controlled by negative feedback from testosterone and from inhibin, a hormone produced by the **Sertoli cells** of the testes. **Review Figure 43.10**
- Eggs mature in the woman's ovaries and are released into the **oviducts**. Sperm deposited in the **vagina** during **copulation** move up through the **cervix** and **uterus** into the oviducts. Fertilization occurs in the upper regions of the oviducts. **Review Figure 43.11, ACTIVITY 43.3**
- The maturation and release of eggs constitute an **ovarian cycle**. The **uterine cycle** prepares the uterus for receipt of a blastocyst. If no blastocyst is implanted, the lining of the uterus sloughs off in the process of **menstruation**. **Review Figure 43.13, ANIMATED TUTORIAL 43.2**
- Both the ovarian and the uterine cycles are under the control of hypothalamic and pituitary hormones, which in turn are under the feedback control of estrogen and progesterone. **Review Figure 43.14**
- Childbirth is initiated by hormonal and mechanical stimuli that increase the contraction of uterine muscle. **Review Figure 43.15**

43.4 How Can Fertility Be Controlled?

- Methods of **contraception** include abstention from copulation and the use of technologies that decrease the probability of fertilization. **Review Table 43.1**
- **Assisted reproductive technologies (ARTs)** have been developed to increase fertility.

CHAPTER REVIEW

REMEMBERING

- Which statement about human oocytes is true?
 - By birth, a human female infant has produced her lifetime supply of oocytes.
 - At the onset of puberty, ovarian follicles produce new oocytes in response to hormonal stimulation.
 - A woman stops producing oocytes at the onset of menopause.
 - A woman produces oocytes throughout adolescence.
 - Oocytes are stored in the oviducts.
- Spermatogenesis and oogenesis differ in that
 - spermatogenesis produces gametes with greater stores of raw materials than those produced by oogenesis.
 - spermatocytes remain in prophase of the first meiotic division longer than oocytes.
 - oogenesis produces four equally functional haploid cells per meiotic event, and spermatogenesis does not.
 - spermatogenesis produces many gametes with meager energy reserves, whereas oogenesis produces relatively few, well-provisioned gametes.
 - spermatogenesis begins before birth in humans, whereas oogenesis does not start until the onset of puberty.
- Semen contains all of the following except
 - fructose.
 - mucus.
 - clotting enzymes.
 - testosterone.
 - an active clot-dissolving enzyme.
- Which of the following statements about the ovarian and uterine cycles is *not* true?
 - Falling estrogen and progesterone levels induce menstruation.
 - A sudden rise in LH induces ovulation.
 - Estrogen levels reach highest levels in the follicular phase and progesterone reaches highest levels in the luteal phase of the ovarian cycle.
 - If fertilization occurs, the corpus luteum secretes hCG.
 - Estrogen is produced by follicle cells.
- Contractions of muscles in the uterine wall are stimulated by
 - progesterone.
 - estrogen.
 - prolactin.
 - oxytocin.
 - human chorionic gonadotropin.
- Which of the following methods of contraception is *most likely* to fail?
 - Rhythm method
 - Birth control pills
 - Diaphragm
 - Vasectomy
 - Condom

UNDERSTANDING & APPLYING

- In terms of characteristics and functions, explain how you would pair Leydig cells, Sertoli cells, thecal cells, and granulosa cells, and why.
- A drug called RU-486 blocks the actions of progesterone. It is called a contragestational drug because it can terminate a pregnancy after fertilization has occurred. How does RU-486 do this?

ANALYZING & EVALUATING

- Females of the marine worm *Bonellia viridis* release fertilized eggs into the water. The eggs hatch into larvae that swim and then settle on a substrate. If the larvae land on sand, they burrow in and develop into females with large bodies and a proboscis that extends into the water above to collect food. If a larva lands on a female proboscis, it burrows into the female body and becomes a tiny male whose only function is to produce sperm to fertilize the female's eggs. What selection pressures could contribute to this extreme sexual dimorphism?

- If a man carries a genetic mutation that prevents the maintenance of cytoplasmic bridges between his secondary spermatocytes and his spermatids, would you expect that he would father only sons or only daughters? Why?

CHAPTER OUTLINE

- 44.1** How Does Fertilization Activate Development?
- 44.2** How Does Mitosis Divide Up the Early Embryo?
- 44.3** How Does Gastrulation Generate Multiple Tissue Layers?
- 44.4** How Do Organs and Organ Systems Develop?
- 44.5** How Is the Growing Embryo Sustained?
- 44.6** What Are the Stages of Human Development?

Go with the Flow The internal organs of humans are not all symmetrical, and some individuals are born with the mirror-image pattern of what is seen in most people—a condition called *situs inversus*. The left-right asymmetry of the internal organs is initiated by asymmetrical stimulation of primary cilia at a very early stage in development.

PLACE YOUR HAND over your heart. Next point to your appendix. Surely you first put your hand on the left side of your chest and then pointed to the right side of your lower abdomen. Like other vertebrates, humans are bilaterally symmetrical—but our symmetry is not absolute. Some of our internal organs are oriented differently with respect to the left and right sides of the body. In about 1 out of every 7,000 people, the arrangement of the internal organs is reversed, a condition known as *situs inversus* (“location inverted”). The difference arises from events very early in the development of the embryo, and most people with *situs inversus* lead normal lives.

As you will learn in this chapter, to get from an embryo with a single layer of cells to the next stage with two layers of cells, a midline slit forms as cells in one area of the embryo migrate inward. The place where the inward movement of cells starts is called the node. Cells at the node have motile cilia that beat in a clockwise motion and move extracellular fluid across the surface of the node. That fluid movement is always leftward—that is, from right to left. Why?

Imagine the movement of the cilia describes a clock face oriented so that 12 o’clock and 6 o’clock lie along the embryo’s midline slit, with 12 o’clock closest to the future head. The cilia protrude from the cell surfaces at an angle. Thus when the cilia are rotating through the 6 o’clock position, they are closer to the cell surface and experience greater shear forces (resistance) than when they are rotating through the 12 o’clock position. In the bilaterally symmetrical early embryo, the circular beating of cilia at this critical spot—the node—creates left-right information.

How do we know the information generated by beating nodal cilia is critical for the left-right asymmetrical patterns of gene expression and developmental processes that follow? In mutant strains of mice that have no cilia or nonmotile cilia in the node, about half of the mice have reversed organ symmetry. Similarly, a spectrum of rare genetic disorders in humans, collectively called Kartagener’s syndrome, are characterized by nonmotile cilia, and about 50 percent of these individuals also have *situs inversus*.

How does the directional flow of extracellular fluid across the node stimulate a left-right asymmetry in gene expression and development?

See answer on p. 921.

44.1

How Does Fertilization Activate Development?

Fertilization is the joining of sperm and egg to produce a diploid zygote. You might therefore think of it as the event that begins development. Keep two things in mind, however. First, in animals that reproduce asexually, development proceeds without fertilization. And second, in animals where fertilization does occur, it is preceded by critical events in the maturing egg that will influence subsequent development but are suspended in developmental arrest. Thus in studying fertilization we are asking how it activates or restarts multicellular development in sexually reproducing animals.

Fertilization does more than restore a full diploid complement of maternal and paternal genes. The fusion of sperm and egg plasma membranes accomplishes several things:

- It stimulates ion fluxes across the egg membrane.
- It sets up blocks to the entry of additional sperm into the egg.
- It changes the pH of the egg cytoplasm.
- It increases egg metabolism and stimulates protein synthesis.
- It initiates the rapid series of cell divisions that produce a multicellular embryo.

The mechanisms of fertilization were described in Section 43.2. Here we will take a closer look at the cellular and molecular interactions of sperm and egg that initiate the first steps of development.

The sperm and the egg make different contributions to the zygote

In most species, eggs are much larger than sperm. Egg cytoplasm is well stocked with organelles, nutrients, and a variety of molecules, including cytoplasmic determinants such as transcription factors and mRNAs (see Section 19.2). Nearly everything the embryo needs during its early stages of development comes from the mother, including its mitochondria (and therefore all of its mitochondrial DNA). In addition to its haploid nucleus, the sperm makes one other crucial contribution to the zygote in most species—the centriole. The centriole contributes to the zygote's centrosome, which organizes the mitotic spindles for subsequent cell divisions (see Figure 11.10). Centrioles are also the origin of the microtubules of the primary cilia, which are important in cell signaling, as we saw in the opening story about *situs inversus*.

Cytoplasmic determinants in the egg play important roles in setting up the signaling cascades that orchestrate the major events of development: determination, differentiation, morphogenesis, and growth.

Rearrangements of egg cytoplasm set the stage for determination

The unique attributes of amphibian eggs make them ideal models for illustrating how rearrangements of egg cytoplasm

44.1 The Gray Crescent In amphibian eggs, cortical rotation and rearrangement of the cytoplasm after fertilization create the gray crescent opposite the point of sperm entry. These events are important for specifying the body axes and other important events in later development.

set the stage for determination. The molecules in the cytoplasm of the amphibian egg are not homogeneously distributed. The entry of the sperm into the egg stimulates rearrangements of the egg cytoplasm that introduce additional organization to the egg. Sperm entry establishes the polarity of the zygote, and informational molecules in the egg cytoplasm are organized with respect to that polarity. Therefore, when cell divisions begin, these informational molecules—which guide subsequent development—are not divided equally among daughter cells.

Rearrangement of egg cytoplasm following fertilization is easily observed in some frog species because of pigments in the cytoplasm. The nutrients in an unfertilized frog egg are dense yolk granules that are concentrated by gravity in the lower half of the egg, called the **vegetal hemisphere**. The haploid nucleus of the egg is located at the opposite end, in the **animal hemisphere**. The outermost (cortical) cytoplasm of the animal hemisphere is heavily pigmented, and the underlying cytoplasm has more diffuse pigmentation. The vegetal hemisphere is not pigmented. Because of these differences, it is easy to observe how the cytoplasm rearranges when the egg is fertilized.

The frog egg is radially symmetrical. You can turn it on its vegetal–animal pole axis, and all sides are the same. Sperm-binding sites are localized on the surface of the animal hemisphere. When a sperm binds to and enters the egg, the egg's radial symmetry is converted to bilateral symmetry and an anterior–posterior axis is created. Cortical cytoplasm rotates toward the site of sperm entry (Figure 44.1). This rotation brings the animal and vegetal regions of cytoplasm into contact with each other, producing a band of pigmented cytoplasm on the side opposite the site of sperm entry. This band, called the **gray crescent**, marks the location of important developmental events in some species of amphibians.

The centriole that was the sperm's contribution to the egg initiates the cytoplasmic reorganization that coincides with the appearance of the gray crescent. The centriole organizes the microtubules in the vegetal hemisphere cytoplasm into a parallel array that guides the movement of the cortical cytoplasm. These

44.2 Cytoplasmic Factors Set Up Signaling Cascades Cytoplasmic movement changes the distributions of critical developmental signals. In the frog zygote, the interaction of the protein kinase GSK-3, its inhibitor, and the protein β -catenin are crucial in specifying the dorsal-ventral axis of the embryo.

microtubules also appear to be directly responsible for movement of specific organelles and proteins, because these organelles and proteins move from the vegetal hemisphere to the gray crescent region even faster than the cortical cytoplasm rotates.

The movement of cytoplasm, proteins, and organelles changes the distribution of critical signals. A key transcription factor in early development is β -catenin, which is produced from maternal mRNA (mRNA produced and stored in the egg while it was maturing in the ovary). β -Catenin is found throughout the egg cytoplasm (Figure 44.2). Also present throughout the egg cytoplasm is a protein kinase, glycogen synthase kinase-3 (GSK-3), that phosphorylates β -catenin and thereby targets it for degradation. An inhibitor of GSK-3 is localized in the vegetal cortex of the egg. After sperm entry, this inhibitor moves along microtubules to the gray crescent, where it prevents the degradation of β -catenin. As a result, the concentration of β -catenin is higher on the dorsal than on the ventral side of the developing embryo.

RECAP 44.1

The egg is stocked with nutrients and informational molecules that power and direct the early stages of development. Fertilization activates the egg and stimulates rearrangement of the cytoplasm, setting up the body axes and organizing positional information that will control determination and differentiation.

- What are the contributions of the sperm and of the egg to the zygote? [See p. 903](#)
- Explain how β -catenin becomes more concentrated on the dorsal side of the embryo. [See p. 904 and Figure 44.2](#)

The uneven distribution of informational molecules in the cytoplasm of the fertilized egg is essential to later events in development. In the next section we will see how these informational molecules end up in different cells of the developing embryo.

44.2 How Does Mitosis Divide Up the Early Embryo?

β -Catenin plays a major role in the cell-cell signaling cascade that begins the process of cell determination and the formation of the embryo. But cell-cell signaling requires more than one cell. The single-celled zygote must become a multicellular embryo.

Cleavage repackages the cytoplasm

Cleavage is the sequence of early cell divisions that transforms the diploid zygote into a mass of undifferentiated cells that will develop as the embryo. Because the cytoplasm of the zygote is not homogeneous, these first cell divisions result in the differential distribution of nutrients and cytoplasmic determinants in the early embryo.

In most animals, cleavage proceeds with rapid DNA replication and mitosis but with no cell growth and little gene expression. The embryo becomes a solid ball of smaller and smaller cells. Eventually this ball forms a central fluid-filled cavity called a **blastocoel**, at which point the embryo is called a **blastula**. Its individual cells are called **blastomeres**. The pattern of cleavage in different species influences the form of their blastulas.

(A) Complete cleavage (frog)

The planes of the second cleavage are displaced only slightly by yolk in the cytoplasm.

Animal pole

Vegetal cells have incorporated yolk and are thus larger than the animal cells in the 16-cell embryo.

The embryo forms as a blastodisc that sits on top of the yolk mass.

(B) Incomplete cleavage (zebrafish)

In birds and fishes, cleavage furrows do not penetrate the large yolk mass.

(C) Superficial cleavage (fruit fly)

1 Mitosis (nuclear division) occurs without cell division.

3 The nuclei migrate to the edge of the plasma membrane.

Nucleus

2 A syncytium—a single cell with many nuclei—is produced.

4 Cellularization occurs, creating a blastoderm.

44.3 Some Patterns of Cleavage Differences in patterns of early embryonic development reflect differences in the way the egg cytoplasm is organized. (A) The frog is a model organism representing complete cleavage in these scanning electron micrographs. (B) SEMs of zebrafish embryos illustrate incomplete cleavage, in which the large yolk mass limits the planes of cleavage. (C) Nuclear staining reveals the syncytial nuclei characteristic of the early embryo of a fruit fly. These nuclei migrate to the periphery. Cleavage furrows then move inward to separate the nuclei into individual cells, forming the blastoderm.

- **Complete cleavage** occurs in most eggs that have little yolk. Early cleavage furrows divide the egg completely. The frog egg undergoes complete cleavage, but because its vegetal pole contains more yolk, the division of the cytoplasm is unequal and the blastomeres in the animal hemisphere are smaller than those in the vegetal hemisphere (**Figure 44.3A**).
- **Incomplete cleavage** occurs in species in which the egg contains a lot of yolk and the cleavage furrows do not penetrate it all. **Discoidal cleavage** is a type of incomplete cleavage common in fishes and in birds and other reptiles, in which the embryo forms as a disc of cells, or **blastodisc**, that sits on top of the dense yolk mass (**Figure 44.3B**).
- **Superficial cleavage** is a variation of incomplete cleavage that occurs in insects such as the fruit fly (*Drosophila*). Early in development, cycles of mitosis occur without cell division, producing a **syncytium**—a single cell with many nuclei (**Figure 44.3C**). The nuclei eventually migrate to the periphery of the egg, after which the plasma membrane of the egg grows inward, creating a **blastoderm** by partitioning the nuclei into individual cells surrounding a core of yolk.

The positions of the mitotic spindles during cleavage are not random but are defined by cytoplasmic determinants produced from the maternal genome and stored in the egg (see Section 19.2). The orientation of the mitotic spindles can determine the planes of cleavage and the arrangement of the blastomeres.

In complete cleavage, if the mitotic spindles of successive cell divisions form parallel or perpendicular to the animal–vegetal axis of the zygote, a pattern of **radial cleavage** occurs. The first two cell divisions are parallel to the animal–vegetal axis, and the third is perpendicular to it (see **Figure 44.4A**). **Spiral cleavage** results when the mitotic spindles are at oblique angles to the animal–vegetal axis. In spiral cleavage, each new cell layer is shifted to the left or right, depending on the orientation of the mitotic spindles. Most mollusks have spiral cleavage, reflected in some species by a coiling shell pattern (as seen in snails).

Early cell divisions in mammals are unique

Several features of early cell divisions in placental mammals (eutherians) are very different from those seen in other animal groups. First, this process in mammals is very slow. Cell divisions are 12 to 24 hours apart, compared with tens of minutes to a few hours in non-mammalian species. Also, the cell

44.4 Becoming a Blastocyst (A) Mammals have rotational cleavage, in which the plane of the first cleavage is parallel to the animal–vegetal (A–V) axis, but the second cell division involves two planes (beige) at right angles to each other. (B) Scanning electron micrographs (color added) of early cleavage (leading to the formation of the blastocyst) in a human embryo. The cells' outer surfaces are covered with cilia (bright yellow). The small spheres, or "blebs," of cytoplasmic material, prominent at the 8-cell stage, disintegrate as cleavage progresses. (C) Seen in cross section under a light microscope, a mammalian blastocyst consists of an inner cell mass adjacent to a fluid-filled blastocoel and surrounded by trophoblast cells.

divisions of mammalian blastomeres are not in synchrony with each other. Because the blastomeres do not undergo mitosis at the same time, the number of cells in the embryo does not increase in the regular progression (2, 4, 8, 16, 32, etc.) typical of other species. This slow mammalian cleavage means that genes expressed during cleavage play roles in cleavage. In animals such as sea urchins and frogs, very little if any gene transcription occurs in the blastomeres, with cleavage being directed by molecules that were present in the egg before fertilization.

The pattern of mammalian cleavage is unique and is called rotational cleavage. The first cell division is parallel to the animal–vegetal axis as in radial cleavage, but in the second cell division, the two blastomeres divide at right angles to one another. One blastomere divides parallel to the animal–vegetal axis, while the other divides perpendicular to this axis (Figure 44.4A). As in other animals that have complete cleavage, the early cell divisions in a mammalian zygote produce a loosely associated ball of cells. After the 8-cell stage, however, the behavior of the mammalian blastomeres changes. They change shape to maximize their surface contact with one another, form tight junctions (see Figure 6.7), and become a compact mass of cells (Figure 44.4B).

Soon after the transition to the 32-cell stage, the cells separate into two groups. The **inner cell mass** will develop as the embryo, while the surrounding outer cells become an encompassing sac called the **trophoblast**. Trophoblast cells secrete fluid, creating a cavity—the **blastocoel**—with the inner cell mass at one end. At this stage the mammalian embryo is called a **blastocyst**, distinguishing it from the blastulas of other animal groups (Figure 44.4C). The pluripotent cells of the inner cell mass are known as **embryonic stem cells** and are the subject of much research because of their therapeutic potential (see Section 19.5).

Why is mammalian cleavage so different? A key factor is that mammalian eggs contain little or no yolk and must derive

all nutrients from the mother. To support the developing embryo, a connection develops between the circulatory systems of the embryo and the mother. As we will see later in this chapter, the structures that provide this connection are the placenta and the umbilical cord. Thus the blastocyst of placental mammals must produce both the embryo (from the inner cell mass) and its support structures (from the trophoblast).

Fertilization in mammals occurs in the upper reaches of the oviduct, and cleavage occurs as the zygote travels down the oviduct to the uterus (Figure 44.5). When the blastocyst arrives in the uterus, the trophoblast adheres to the lining of the uterus (the **endometrium**), beginning the process of **implantation**. In humans, implantation begins about 6 days after fertilization and is aided by adhesion molecules and enzymes secreted by the trophoblast.

As the blastocyst moves down the oviduct to the uterus, it must not embed itself in the oviduct (Fallopian tube) wall, or the result will be an ectopic, or tubal, pregnancy—a very dangerous condition. Early implantation is prevented by the zona pellucida, which surrounded the egg (see Figure 43.5) and remains around the cleaving ball of cells. At about the time the blastocyst reaches the uterus, it hatches from the zona pellucida, and implantation can occur.

Specific blastomeres generate specific tissues and organs

Cleavage results in a repackaging of the egg cytoplasm into a large number of small cells surrounding the fluid-filled blastocoel. Except in mammals, there is little gene expression during cleavage. Nevertheless, cells in different regions of the blastula possess different complements of the nutrients and cytoplasmic determinants that were present in the egg. For example, Figure 44.2 illustrated the processes by which β -catenin becomes localized in the region of the zygote that will become the dorsal side of the embryo.

44.5 A Human Blastocyst at Implantation Adhesion molecules and proteolytic enzymes secreted by trophoblast cells allow the blastocyst to burrow into the endometrium. Once the blastocyst is implanted in the wall of the uterus, the trophoblast cells send out numerous projections—the chorionic villi—which increase the embryo's area of contact with the mother's bloodstream.

The blastocoel prevents cells from different regions of the blastula from coming into contact and interacting, but that will soon change. During the next stage of development, the cells of the blastula will move around and come into new associations with one another, communicate instructions to one another, and begin to differentiate. In many animals, these movements of the blastomeres are so regular and well orchestrated that it is possible to label each specific blastomere with a dye, thus producing **fate maps** that identify the tissues and organs formed from each blastomere's progeny (Figure 44.6).

Blastomeres become **determined**—committed to specific fates—at different times in different species. In some species, such as roundworms, the fates of blastomeres are restricted as early as the two-cell stage. If one of these blastomeres is experimentally removed, a particular portion of the embryo will not form. This type of development has been called **mosaic**

development because each blastomere seems to contribute a specific set of “tiles” to the final “mosaic” that is the adult animal.

In contrast to mosaic development, the loss of some cells during cleavage in **regulative development** does not affect the developing embryo, because the remaining cells compensate for the loss. Regulative development is typical of many vertebrate species. Because development is regulative in humans, a single blastomere can be removed from early embryos without harming the remaining blastomeres or disrupting normal development. Cells removed from embryos produced by in vitro fertilization can be used for preimplantation genetic diagnosis to ensure that healthy embryos are selected for implantation in the mother.

If some blastomeres can change their fate to compensate for the loss of other cells during cleavage and blastula formation, can those cells form an entire embryo? To a certain extent, yes. During cleavage or early blastula formation in mammals, for example, if the blastomeres are physically separated into two groups, both groups can produce complete embryos. Since the two embryos come from the same zygote, they will be monozygotic twins—genetically identical.

Non-identical twins occur when two separate eggs are fertilized by two separate sperm. Thus, although identical twins are always of the same sex, non-identical twins have a 50 percent chance of being the same sex (that is, the same as two non-twin siblings). In about 1 out of 50,000 human pregnancies, genetic or environmental factors cause the inner cell mass to split partially. The result is twins who are conjoined at some point on their bodies and usually share some of their organs and limbs.

44.6 Fate Map of a Frog Blastula Colors indicate the portions of the blastula that will form the three germ layers and subsequently the frog's tissues and organs. This cutaway view shows the inside of the blastula. The cells fated to become mesoderm are in the deeper layer of cells, whereas the superficial layers of cells will mostly form ectoderm and endoderm.

Germ cells are a unique lineage even in species with regulative development

Molecules present in the egg cytoplasm determine which lineage of cells will eventually populate the gonads and become the reproductive stem cells—oogonia and spermatogonia. In fruit flies, at the ninth nuclear division (recall that the egg is a multinucleate syncytium at this stage), a group of nuclei migrate to the posterior pole of the egg where they become surrounded by **pole plasm**—cytoplasm containing a complex mixture of fibrils, mitochondria, and specific proteins and mRNAs. As the cellularization of the blastoderm proceeds, the nuclei within the pole plasm give rise to the lineage of cells that will eventually migrate to the gonads (when they form) and produce germ cells (eggs and sperm).

As in fruit flies, the germ cell lineage in frogs starts with a special type of cytoplasm—the germ cell plasm—localized to one part of the egg. As a result of cleavage, the germ cell plasm becomes enclosed within some of the cells in the vegetal hemisphere; descendants of these cells will eventually migrate to the gonads once those structures form. The components of germ cell plasm have not been fully characterized, but one hypothesis is that they include inhibitors of transcription and translation that prevent these cells from differentiating into anything other than germ cells.

RECAP 44.2

Cleavage divides up the cytoplasm of the zygote such that different blastomeres contain different combinations of informational molecules. The amount of nutrients stored in the egg influences the pattern of cell cleavage that produces the blastula. Blastulation in mammals is different than in other vertebrates. The cells that will give rise to germ cell lineages are set aside very early in development.

- In general terms, describe the difference between complete and incomplete cleavage. [See p. 905 and Figure 44.3](#)
- What does a fate map tell us? How are fate maps constructed? [See p. 907 and Figure 44.6](#)
- Explain the statement that “the germ cell lineage exists outside of the processes of determination and differentiation.” [See p. 908](#)

Of the next stage of development—gastrulation—the developmental biologist Lewis Wolpert once said, “It is not birth, marriage, or death, but gastrulation which is the most important time in your life.” During gastrulation, cell movements create new cell-to-cell contacts, which in turn sets up signaling cascades that initiate the differentiation of cells and tissues and set the stage for the emergence of the body plan.

44.3

How Does Gastrulation Generate Multiple Tissue Layers?

The blastula is typically a fluid-filled ball of cells. How does this simple ball of cells become an embryo made up of multiple

tissue layers with head and tail ends and dorsal and ventral sides? **Gastrulation** is the process whereby the blastula is transformed by massive movements of cells into an embryo with multiple tissue layers and distinct body axes. The resulting spatial relationships between tissues make possible the inductive interactions between cells that trigger differentiation and organ formation (see Figure 19.4).

In the triploblastic animals (see Section 33.1), three **germ layers** (also called cell layers or tissue layers, and not to be confused with germ cells) form during gastrulation:

- The **endoderm** is the innermost germ layer, created as some blastomeres move to the inside of the embryo. The endoderm gives rise to the lining of the digestive tract, respiratory tract, pancreas, thyroid, and liver.
- The **ectoderm** is the outer germ layer, formed from those cells remaining on the outside of the embryo. The ectoderm gives rise to the nervous system, including the eyes and ears; and to the epidermal layer of the skin and structures derived from skin, such as hair, feathers, nails or claws, sweat glands, oil glands, and even teeth and other tissues of the mouth.
- The **mesoderm** is the middle layer and is made up of cells that migrate between the endoderm and the ectoderm. The mesoderm contributes tissues to many organs, including the heart, blood vessels, muscles, and bones.

The three germ layers are illustrated for a very early embryo in the fate map shown in Figure 44.6.

Some of the most interesting and important challenges in animal development have dealt with two related questions: what directs the cell movements of gastrulation, and what is responsible for the resulting patterns of cell differentiation and organ formation? Scientists have made significant progress in answering both these questions at the molecular level. In the following discussion we will begin with sea urchin gastrulation because it is the simplest to conceptualize in spatial terms. We will then describe the more complex pattern of gastrulation in frogs, and then to the still more complex patterns in reptiles, birds, and mammals.

Go to Animated Tutorial 44.1

Gastrulation

Life10e.com/at44.1

Invagination of the vegetal pole characterizes gastrulation in the sea urchin

The sea urchin blastula is a hollow ball of cells only one cell layer thick. The end of blastulation is marked by slowing of the rate of mitosis, and the beginning of gastrulation is marked by a flattening of the vegetal hemisphere (**Figure 44.7**). Some cells at the vegetal pole break away from neighboring cells and migrate into the cavity. These cells become **mesenchyme**—cells of the middle germ layer, the mesoderm. Mesenchymal cells are not organized in tightly packed sheets or tubes like epithelial cells are; they act as independent units, migrating into and among the other tissue layers.

44.7 Gastrulation in Sea Urchins During gastrulation, cells move to new positions and form the three germ layers from which differentiated tissues develop.

The flattening at the vegetal pole results from changes in the shape of individual blastomeres. These cells, which are originally rather cuboidal, become wedge-shaped, with smaller outer edges and larger inner edges. As a result, the vegetal pole bulges inward, or invaginates, as if someone were poking a finger into a hollow ball (see Figure 44.7). The invaginating cells become endoderm and form the primitive gut, called the **archenteron**. At the tip of the archenteron, more cells enter the blastocoel to form mesoderm.

Changes in cell shapes cause the initial invagination of the archenteron, but eventually the archenteron is pulled inward by the mesenchyme cells. These cells, attached to the tip of the archenteron, send out extensions called filopodia that adhere to the overlying ectoderm. When the filopodia contract, they pull the archenteron toward the ectoderm at the opposite end of the embryo from where the invagination began. The mouth of the animal forms where the archenteron makes contact with this overlying ectoderm. The opening created by the invagination of the vegetal pole is called the **blastopore**, and it will become the anus of the animal.

What mechanisms control the various cell movements of sea urchin gastrulation? The immediate answer is that specific properties of particular blastomeres change. For example, some vegetal cells change shape and bulge into the blastocoel, and these cells become mesenchyme. Once they lose contact with their neighboring cells on the surface of the blastula, they send out filopodia that then move along an extracellular matrix of proteins laid down by the cells lining the blastocoel.

A deeper understanding of gastrulation requires that we discover the molecular mechanisms whereby different blastomeres develop different properties. Cleavage systematically divides up the cytoplasm of the egg. The sea urchin blastula at the 64-cell stage is radially symmetrical, but it has polarity, as described in Section 19.2. It consists of tiers of cells. As in the frog blastula, the top is the animal pole and the bottom the vegetal pole.

If different tiers of blastula cells are separated experimentally, they show different developmental potentials; only cells from the vegetal pole are capable of initiating the development of a complete larva. It has been proposed that these differences are due to uneven distribution of various transcriptional regulatory proteins in the egg cytoplasm. As cleavage progresses, these proteins end up in different groups of cells. Therefore specific sets of genes are activated in different cells, determining their different developmental capacities.

Next we will turn to gastrulation in the frog and to the key signaling molecules involved.

Gastrulation in the frog begins at the gray crescent

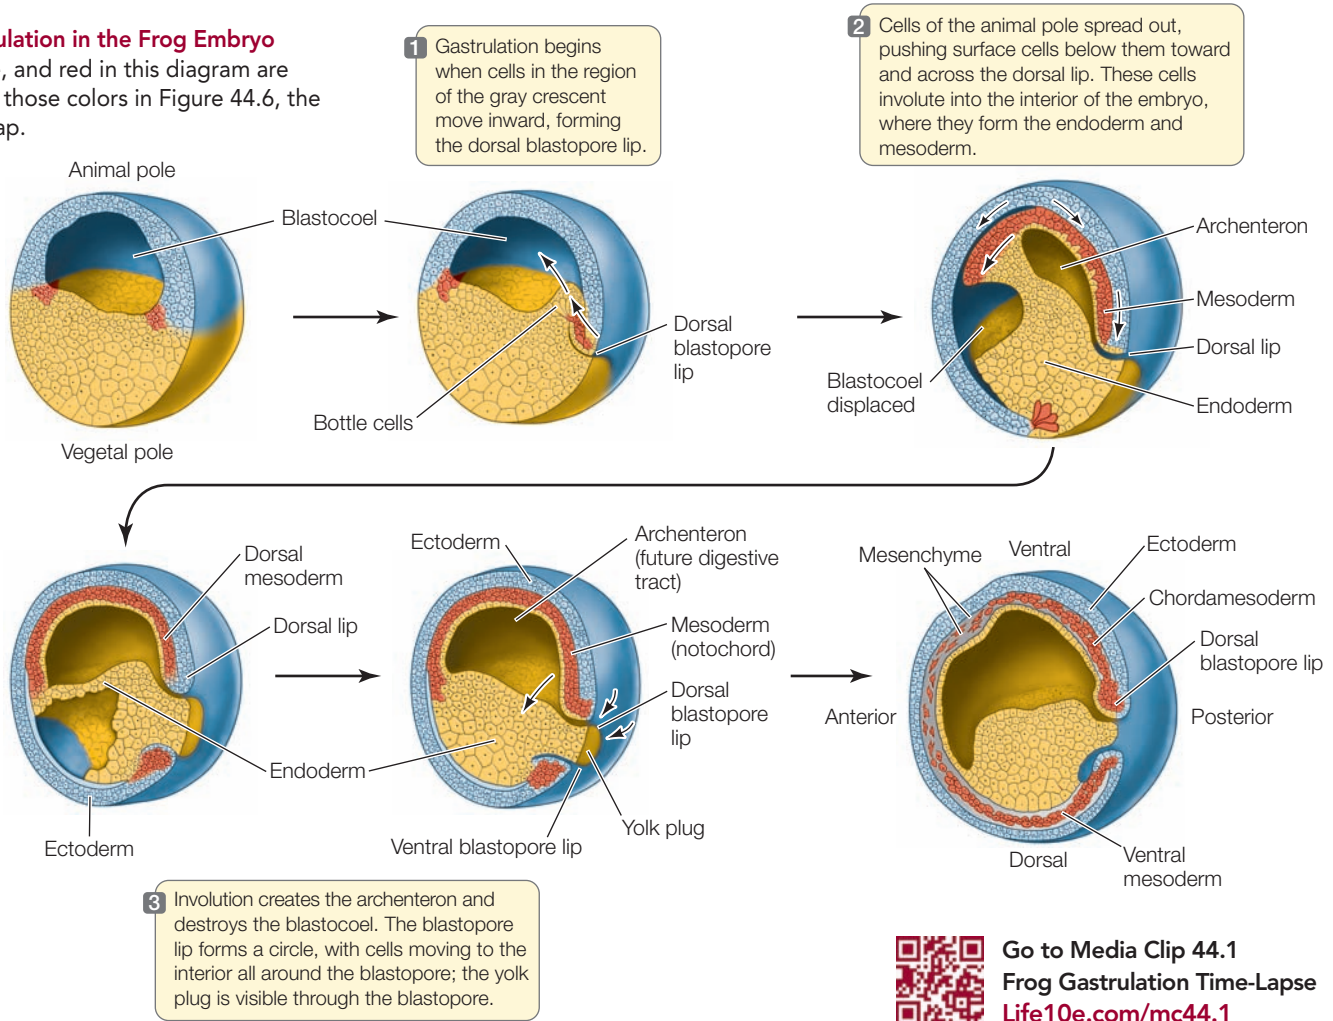

Amphibian blastulas have considerable yolk and are more than one cell layer thick; gastrulation is therefore more complex in amphibians than in sea urchins. Variation is considerable across different species of amphibians, so this brief account describes results from studies done on different species to produce a generalized picture of amphibian development.

Amphibian gastrulation begins when certain cells in the gray crescent region (see Figure 44.1) change their shapes and cell-adhesion properties. These cells bulge inward toward the blastocoel while they remain attached to the outer surface of the blastula by slender necks; because of their shape, they are called bottle cells. Bottle cells mark the spot where the **dorsal lip** of the blastopore will form (Figure 44.8).

As the bottle cells move inward, the dorsal lip is created, and a sheet of cells moves over it into the blastocoel. This process is called **involution**. One group of involuting cells is the prospective endoderm; these cells form the primitive gut, or archenteron. Another group will move between the endoderm and the outermost cells to form the mesoderm. These rearrangements are due to changes in cell properties called **convergent extension**. The cells elongate in the direction of movement, but they also intercalate (move in between each other). If they just elongated, the migrating group of cells would become much

44.8 Gastrulation in the Frog Embryo

Go to Media Clip 44.1
Frog Gastrulation Time-Lapse
Life10e.com/mc44.1

narrower; by intercalating, they maintain the width of the migrating cell group.

As gastrulation proceeds, cells from the animal hemisphere flatten and move toward the site of involution in a process called **epiboly**. The blastopore lip widens and eventually forms a complete circle surrounding a “plug” of yolk-rich cells. As cells continue to move inward through the blastopore, the archenteron grows, gradually displacing the blastocoel.

As gastrulation comes to an end, the amphibian embryo consists of three germ layers: ectoderm on the outside, endoderm on the inside, and mesoderm in between. The embryo also has a dorsal–ventral and anterior–posterior organization. Most importantly, the fates of specific regions of the endoderm, mesoderm, and ectoderm have been determined. The beautiful experiments revealing how determination takes place in the amphibian embryo are an old but exciting story.

The dorsal lip of the blastopore organizes embryo formation

In the early 1900s the German biologist Hans Spemann was studying the development of salamander eggs. He was interested in finding out whether the nuclei of blastomeres remain capable of directing the development of complete embryos or whether these nuclei lose some developmental potential. With

great patience and dexterity, he formed loops from single hairs taken from a baby (in fact, his daughter) and tied them around fertilized eggs along the plane of the first cell division, effectively dividing the eggs in half, with the nucleus restricted to one side. That side went through cell divisions and developed into a salamander; the other half simply degenerated. Up until the 16-cell stage, if one nucleus escaped to the other side of the constriction, twin salamanders could develop. Thus each of the nuclei of the blastula (at least up to the 16-cell stage) was capable of directing and supporting development of the whole organism.

As often happens in science, Spemann’s bisection experiments revealed a new phenomenon. Sometimes the half of the blastula receiving an escaped nucleus did not develop. When his loops bisected the gray crescent, both halves of the zygote developed into a complete embryo. When he tied the loops so the gray crescent was on only one side of the constriction, however, only that half of the zygote developed into a complete embryo (Figure 44.9). The half lacking gray crescent material underwent cell division, but even if it contained a nucleus, it became a clump of undifferentiated cells that Spemann called a “belly piece.” Spemann hypothesized that cytoplasmic factors unequally distributed in the fertilized egg were necessary for gastrulation and the development of a normal salamander.

44.9 Gastrulation and the Gray Crescent Spemann's research revealed that gastrulation and subsequent normal development in salamanders depend on cytoplasmic determinants localized in the gray crescent.

To further test the hypothesis that cells receiving different complements of cytoplasmic factors had different developmental fates, Spemann transplanted pieces of early gastrulas to various locations on other gastrulas. Guided by fate maps (see Figure 44.6), he was able to take a piece of ectoderm he knew would develop into the epidermis of the skin and transplant it to a region that normally becomes part of the nervous system, and vice versa.

When he performed these transplants in early gastrulas—when the blastopore was just beginning to form—the transplanted pieces always developed into tissues that were appropriate for the location where they were placed. Transplanted cells destined to become epidermis in their original location developed into nervous system tissue, and transplanted cells destined to become nervous system tissue in their original location developed into host epidermis. Thus Spemann learned that the fates of the transplanted cells had not been determined before the transplantation.

In late gastrulas, however, the same experiment yielded opposite results. Transplanted cells destined to become epidermis in their original location produced patches of skin cells in the host nervous system, and the transplanted cells from regions that would develop into nervous system tissue produced neural tissue in the skin of the recipient. At some point during gastrulation, the fates of the embryonic cells had become determined.

Spemann's next experiment, done with his student Hilde Mangold, produced momentous results: they transplanted the dorsal lip of the blastopore (Figure 44.10). When this small piece of tissue was transplanted into the presumptive belly area of another gastrula, it stimulated a second site of gastrulation—and a second complete embryo formed belly-to-belly with the original embryo. Because the dorsal lip of the blastopore was apparently capable of inducing the host tissue to form an entire embryo, Spemann and Mangold dubbed the dorsal lip tissue the **primary embryonic organizer**, or simply the **organizer**. For more than 90 years, the organizer has been an active area of research.

Transcription factors and growth factors underlie the organizer's actions

With the advent of modern molecular methods, the primary embryonic organizer has been studied intensively to discover the molecular mechanisms involved in its action. The distribution of the transcription factor β -catenin in the late blastula corresponds to the location of the organizer in the early gastrula, so β -catenin is a candidate for the initiator of organizer activity. To prove that a protein is an inductive signal, it has to be shown that it is both *necessary* and *sufficient* for the proposed effect. In other words, the effect should not occur if the candidate protein is not present (necessity), and the candidate protein should be capable of inducing the effect where it would otherwise not occur (sufficiency).

The criteria of necessity and sufficiency have been satisfied for β -catenin. If β -catenin mRNA transcripts are depleted by injections of antisense RNA into the egg (see Section 18.4), gastrulation does not occur. If β -catenin is experimentally overexpressed in another region of the blastula, it can induce a second axis of embryo formation, as the transplanted dorsal lip did in the Spemann–Mangold experiments. Thus β -catenin appears to be both necessary and sufficient for the formation of the primary embryonic organizer—but it is only one component of a complex signaling process.

How the presence of β -catenin creates the organizer, and how the organizer then induces the beginnings of the body plan, involves a complex series of interactions between transcription factors and growth factors that control gene expression. What follows is only a portion of this complex and still emerging story. What you should take from this description is not the names of the genes and gene products involved. Rather, we hope you will gain a basic appreciation for how signaling molecules interact to produce different combinations of signals that convey spatial and temporal information. This information guides cells into different paths of determination and differentiation.

Studies of early gastrulas revealed that primary embryonic organizer activity is generated by the interaction of β -catenin with signals coming from the vegetal cells. Together they activate the expression of the transcription factor Goosecoid. Expression of the *goosecoid* gene depends on two signaling pathways.

The first of these pathways involves a *goosecoid*-promoting transcription factor called Siamois. The *siamois* gene is normally

INVESTIGATINGLIFE

44.10 The Dorsal Lip Induces Embryonic Organization In a classic experiment, Hans Spemann and Hilde Mangold transplanted the dorsal blastopore lip mesoderm of an early gastrula stage salamander embryo.^a The results showed that the cells of this embryonic region, which they dubbed “the organizer,” could direct the formation of an entire embryo.

HYPOTHESIS The early dorsal blastopore lip organizes cell differentiation in amphibian embryos.

Method

1. Excise a patch of mesoderm tissue from above the dorsal blastopore lip of an early gastrula stage salamander embryo (the donor).
2. Transplant the donor tissue onto a recipient embryo at the same stage. The donor tissue is transplanted onto a region of ectoderm that should become epidermis (skin).

**Results**

CONCLUSION The cells of the dorsal blastopore lip can induce other cells to change their developmental fates.

Tissue Transplants Reveal the Process of Determination
Life10e.com/at42.2

repressed by a ubiquitous transcription factor called Tcf-3, but in cells in which β -catenin is present, an interaction between Tcf-3 and β -catenin induces *siamois* expression (Figure 44.11). But Siamois protein alone is not sufficient for *goosecoid* expression.

The second pathway involves mRNAs from the original egg cytoplasm for a family of proteins called transforming growth factor- β (TGF- β). TGF- β interacts with the Siamois protein to turn on *goosecoid* transcription. Thus you can see it is a complex combination of factors that determines which cells become the primary organizer.

The organizer changes its activity as it migrates from the dorsal lip

Organizer cells begin the process of formation of the dorsal lip of the blastopore. Specifically, these cells are at the center of the dorsal lip and involute, moving forward on the midline (i.e., the middle of the anterior–posterior axis). The first organizer cells to enter the embryo migrate anteriorly to become the head endoderm and head mesoderm. Here they induce neighboring cells to participate in making structures of the head. Organizer cells that involute into the later embryo will induce structures of the trunk, and the last of the organizer cells to move inward from the dorsal lip will induce structures of the tail. How does the nature of the organizer cells change to enable them to induce head, trunk, or tail structures?

Inductive tissue interactions can suppress as well as activate. As we learned above, the early organizer cells express the transcription factor *Goosecoid*, which activates genes encoding soluble signals. As these cells move forward in the blastocoel, they come into contact with new populations of cells that produce several different growth factors. For head structures to form, certain of these growth factors have to be suppressed. The most anterior organizer cells, under the influence of *Goosecoid*, produce and release antagonists to those growth factors.

The induction of trunk structures requires suppression of a different set of growth factors. In organizer cells that involute later than the head organizers, *Goosecoid* is no longer the dominant transcription factor, and these cells express different growth factor antagonists. The induction of tail structures requires still different activities of the organizer cells that involute last. Thus the organizer cells express appropriate sets of growth factor antagonists at the right times to achieve different patterns of differentiation on the anterior–posterior axis.

The initiation of nervous system development also involves a suppressive tissue interaction. For a long time it was thought that the involuting organizer cells actively induced the overlying ectoderm to form neural tissue rather than becoming epidermis. We now

44.11 Molecular Mechanisms of the Organizer In amphibians, the organizing potential of the gray crescent depends on the activity of the *goosecoid* gene, which in turn is activated by signaling pathways set up in the vegetal cells below the gray crescent.

know, however, that epidermis is not the default state of the dorsal ectoderm. Rather, the underlying mesoderm secretes factors called BMP proteins that induce the ectoderm to become epidermis. The role of the involuting organizer cells is to block that induction, allowing the overlying ectodermal cells to follow what is really their default pathway—differentiation into neural tissue (**Figure 44.12**).

Reptilian and avian gastrulation is an adaptation to yolky eggs

The eggs of reptiles and birds contain a mass of yolk, and the blastulas of these groups develop as a disc of cells on top of the yolk (see **Figure 44.3B**). We will use the chicken egg to show how gastrulation proceeds in a flat disc of cells rather than in a ball of cells.

Cleavage in the chick results in a flat, circular layer of cells called a blastodisc (**Figure 44.13**). Between the blastodisc and the yolk mass is a fluid-filled space. Some cells from the blastodisc break free and move into this space. These cells come together to form a continuous layer called the **hypoblast**, which will later contribute to extraembryonic membranes that will support and nourish the developing embryo. The overlying cells make up the **epiblast**, from which the embryo will form.

INVESTIGATINGLIFE

44.12 Differentiation Can Be Due to Inhibition of Growth Factors

When organizer cells involute to underlie dorsal ectoderm along the embryo midline, that overlying ectoderm becomes neural tissue rather than skin (epidermis). But do the organizer cells cause dorsal ectoderm to become neural tissue, or do they prevent this ectoderm from becoming skin?^a

HYPOTHESIS The default state of amphibian dorsal ectoderm is neural; it is induced by underlying mesoderm to become epidermis.

Method

- Excise the animal caps of late-stage frog blastulas and disperse the cells in culture medium so there is no cell-to-cell contact.

- Prepare four separate cultures of embryonic ectodermal cells. Incubate with no additions (control); with BMP4 (isolated from mesodermal cells) with BMP4 inhibitor (isolated from organizer cells) and with both molecules.

- After incubation, extract mRNAs from the ectodermal cells and analyze for the presence of mRNAs for marker proteins NCAM (neural cell adhesion molecule, a neural protein) and/or keratin (an epidermal protein).

Results

The control ectoderm (no inductive factors added) expresses the neural marker. In the presence of mesodermal BMP4, ectoderm expresses the epidermal marker. If BMP4 is inhibited, ectoderm expresses the neural marker.

This control message is from a gene expressed in all cells and verifies that each sample contains similar amounts of mRNA.

CONCLUSION The default state of amphibian dorsal ectoderm is neural. BMP4 protein from mesoderm can induce ectoderm cells to differentiate into epidermis. Thus the organizer cells must secrete an inhibitor of BMP4.

Chick embryo viewed from above

44.13 Gastrulation in Birds Because their eggs contain a large yolk mass, bird and reptile embryos have a flattened blastodisc and display a pattern of gastrulation very different from that of amphibians.

Thus the avian blastula is a flattened structure consisting of an upper epiblast and a lower hypoblast, which are joined at the margins of the blastodisc. The blastocoel is the fluid-filled space between the epiblast and hypoblast.

Gastrulation begins with a thickening in the posterior region of the epiblast, caused by the movement of cells toward the midline and then forward along the midline (see Figure 44.13). The result is a midline ridge called the **primitive streak**. A depression called the primitive groove forms along the length of the primitive streak. The primitive groove functions as the blastopore, and cells migrate through it into the blastocoel to become endoderm and mesoderm.

In the chick embryo, no archenteron forms, but the endoderm and mesoderm migrate forward to form the gut and other structures. At the anterior end of the primitive groove is a thickening called **Hensen's node**, which in reptiles, birds, and mammals is the equivalent of the dorsal lip of the amphibian blastopore. Many signaling molecules that have been identified in the frog organizer are also expressed in Hensen's node. Cells moving into the blastocoel and moving anteriorly from Hensen's node become the notochord and organize the chick embryo in a manner similar to that of the frog embryo.

The embryos of placental mammals lack yolk

Mammalian embryos (with the exception of monotremes) derive their nourishment from the maternal circulation, and therefore mammalian eggs do not have large amounts of yolk constraining their cleavage and early development.

Nevertheless, mammals evolved from reptilian ancestors, so it is not surprising that mammals, birds, and reptiles share certain patterns of early development. Earlier we described the development of the mammalian inner cell mass (the equivalent of the avian blastodisc) and the outer trophoblast.

As in avian development, in placental mammals the inner cell mass splits into an upper layer called the epiblast and a lower layer called the hypoblast. The embryo forms from the epiblast, while the hypoblast contributes to the extraembryonic membranes that will encase the developing embryo and help form the placenta (see Figure 44.5). The epiblast also contributes to the extraembryonic membranes; specifically, it splits off an upper layer of cells that will form the amnion. The amnion will grow to surround the developing embryo as a membranous sac filled with amniotic fluid. Gastrulation occurs in the mammalian epiblast just as it does in the avian epiblast. A primitive groove forms, and epiblast cells migrate through the groove to become layers of endoderm and mesoderm. At the top of the groove is the node, which, as we learned at the start of this chapter, is where the beating of nodal cell cilia creates an asymmetrical flow of extracellular fluid. The asymmetrical

WORKING WITHDATA:

Nodal Flow and Inverted Organs

Original Paper

Nonaka, S., H. Shiratori, and H. Hamata. 2002. Determination of left–right patterning of the mouse embryo by artificial nodal flow. *Nature* 418: 96–99.

Analyze the Data

The phenotype of the mutant mouse strain *inversus viscerum* (*iv/iv*) mimics human situs inversus. These mice have nonmotile primary cilia in the ventral (bellyward) node of the early embryo. Left alone, roughly half of all *iv/iv* mouse embryos will develop with normal left–right organ asymmetry while the other half show reversed asymmetry. Researchers in Japan used *iv/iv* embryos to test the hypothesis that the leftward flow of extracellular fluid created by the beating of nodal primary cilia is the stimulus for breaking bilateral symmetry in organ development.

The researchers anchored very early mouse embryos with their nodal ends pointed upward in a chamber filled with culture medium. Culture medium was then artificially pumped through the chamber either from the left (normal) or from the right (reversed) and at slow or fast flow rates. After 4 days the

embryos were assessed as to the direction of looping (normal or reversed) of their developing heart tubes. The researchers compared the effects of speed and direction culture medium flow on wild-type and mutant embryos that were at the presomite stage when they were placed in the chamber.

A second set of experiments explored the effects of fast, reversed flow on wild-type embryos that were at later stages of development (1, 2, or 3 somites) when placed in the chamber. The results are shown in the table below.

QUESTION 1

Do the data support the hypothesis that nodal flow is a stimulus that determines left–right organ asymmetry? Why or why not?

QUESTION 2

How would you explain the different results for the slow rightward flow in the presomite wild-type and *iv/iv* mice?

QUESTION 3

What do you conclude from the results on the 1-, 2-, and 3-somite wild-type embryos?

Genotype, stage	Speed and direction of culture medium flow			
	Fast left	Slow left	Slow right	Fast right
<i>iv/iv</i> , presomite	10N, 0R, 10T ^a	8N, 2R, 10T	3N, 25R, 34T	1N, 11R, 12T
Wild-type, presomite	9N, 0R, 10T	12N, 4R, 16T	13N, 3R, 16T	2N, 21R, 24T
Wild-type, 1-somite	—	—	—	9N, 0R, 12T
Wild-type, 2-somite	—	—	—	22N, 0R, 22T
Wild-type, 3-somite	—	—	—	14N, 0R, 14T

^aThe normal direction for fluid flow is left. Developmental outcomes indicated as follows: N, normal; R, reversed; T, total embryos in sample. Note that some embryos were neither normal nor reversed but were included in the total.

flow stimulates nonmotile cilia, generating signaling cascades that determine the left–right asymmetry of the internal organs.

RECAP 44.3

The cell movements of gastrulation convert the blastula into an embryo with three tissue layers. New contacts between cells set up inductive signaling interactions that determine cell fates. Dorsal lip tissue is the source of organizer cells that induce development of preliminary head, trunk, and tail structures.

- Describe and compare the cell movements that occur during gastrulation in a sea urchin, a frog, and a bird. **See Figures 44.7, 44.8, and 44.13**
- Explain the molecular basis for the inductive capabilities of the organizer. **See pp. 912–913 and Figures 44.11 and 44.12**

We have described how the fertilized egg develops into an embryo with three germ layers and how cellular signals trigger different patterns of differentiation. In the next section we will describe how organs and organ systems develop.

44.4 How Do Organs and Organ Systems Develop?

Gastrulation produces an embryo with three germ layers that are positioned to influence one another through inductive tissue interactions. During the next phase of development, called **organogenesis**, organs and organ systems develop simultaneously and in coordination with each other. In the chordates (see Section 33.1), an early process of organogenesis is **neurulation**, the initiation of the nervous system. We will examine neurulation in the amphibian embryo, but it occurs in a similar fashion in reptiles, birds, and mammals.

The stage is set by the dorsal lip of the blastopore

As we learned in the previous section, one group of cells that passes over the dorsal lip of the blastopore moves anteriorly and becomes the endodermal lining of the digestive tract. Another group of cells that involutes over the dorsal lip on the midline becomes chordamesoderm, so named because it forms a rod of mesoderm—the **notochord**—that extends down the

44.14 Neurulation in a Vertebrate (A) At the start of neurulation, the ectoderm of the neural plate (green) is flat. (B) The neural plate invaginates and folds, forming a tube. (C,D) The completely formed neural tube seen (C) in diagrammatic form and (D) in a scanning electron micrograph of a chick embryo.

center of the embryo. These cells also have important organizer functions (see Figure 44.8). The notochord gives structural support to the developing embryo and in vertebrates is replaced by the vertebral column. The organizing capacity of the chordamesoderm enables the overlying ectoderm to become neural ectoderm (see Figure 44.12). It does this by expressing signaling molecules (one appropriately called *Noggin* and another one called *Chordin*) that initiate differentiation of the different divisions of the nervous system.

Neurulation involves the formation of an internal neural tube from an external sheet of cells. The first signs of neurulation are flattening and thickening of the ectoderm overlying the notochord; this thickened area forms the neural plate (Figure 44.14A). The edges of the neural plate that run in an anterior–posterior

direction continue to thicken to form ridges or folds. Between these neural folds, a groove forms and deepens as the folds roll over it to converge on the midline. The folds fuse, forming a cylinder, the **neural tube**, and a continuous overlying layer of epidermal ectoderm (Figure 44.14B–D).

Cells from the most lateral portions of the neural plate do not become part of the neural tube, but disassociate from it and come to lie between the neural tube and the overlying epidermis. These **neural crest cells** migrate outward to lead the development of the connections between the central nervous system (brain and spinal cord) and the rest of the body.

The neural tube develops bulges at the anterior end, which become the major divisions of the brain; the rest of the tube becomes the spinal cord. In humans, failure of the neural folds to fuse in this posterior region results in *spina bifida*, a birth defect in which the spinal cord is exposed because the vertebrae do not fuse. If the folds fail to fuse at the anterior end, an infant can develop without a forebrain (a condition called *anencephaly*). Although several genetic factors can cause these defects, other factors are environmental, including maternal diet. The incidence of neural tube defects in the United States in the early 1900s was as high as 1 in 300 live births; today it is less than 1 in 1,000. A major factor in this improvement has been the inclusion of folic acid (a B vitamin, also known as folate) in the mother's diet. It is essential for pregnant women to ingest sufficient folic acid.

Body segmentation develops during neurulation

The vertebrate body plan, like that of arthropods, consists of repeating segments that are modified during development. These segments are most evident as the repeating patterns of vertebrae, ribs, nerves, and muscles along the anterior–posterior axis.

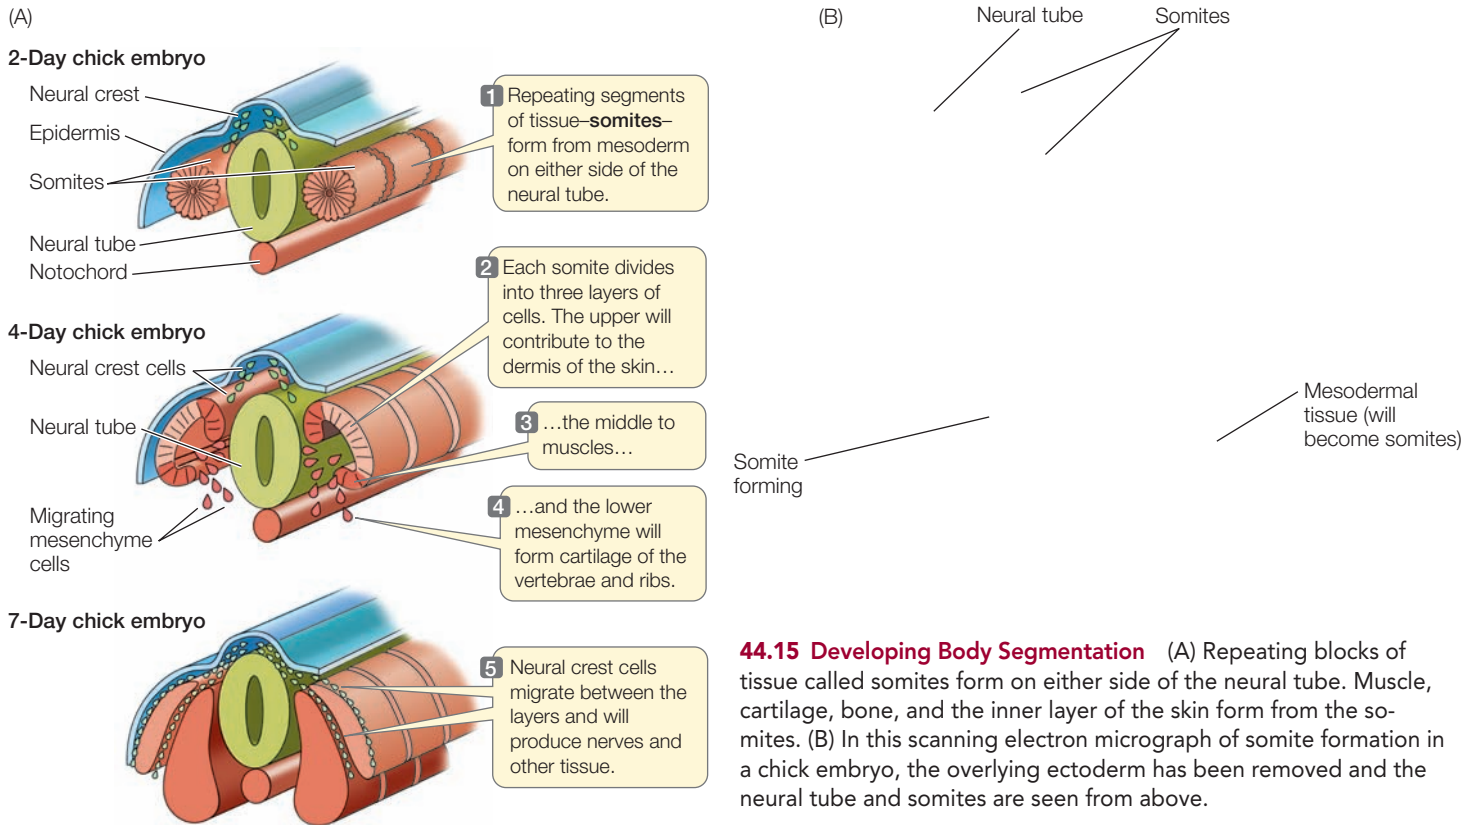

As the neural tube forms, mesodermal tissues gather along the sides of the notochord to form separate, segmented blocks of cells called **somites** (Figure 44.15). Somites produce cells that will become the vertebrae, ribs, muscles of the trunk, and limbs.

Nerves that connect the brain and spinal cord with tissues and organs throughout the body are also arranged segmentally. The somites help guide the organization of these peripheral nerves, but the nerves are not of mesodermal origin. As we saw above, when the neural tube fuses, the neural crest cells break loose and migrate inward between the epidermis and the somites and through the somites. These neural crest cells have diverse fates, including the development of peripheral nerves.

As development progresses, the different segments of the body change. Regions of the spinal cord differ, regions of the vertebral column differ in that some vertebrae grow ribs of various sizes and others do not, forelegs arise in the anterior part of the embryo, and hind legs arise in the posterior region.

Hox genes control development along the anterior–posterior axis

How is mesoderm in the anterior part of a mouse embryo programmed to produce forelegs rather than hind legs? In Section 19.4, we saw how homeotic genes control body segmentation in *Drosophila*. We also learned that all homeotic genes contain a

44.15 Developing Body Segmentation (A) Repeating blocks of tissue called somites form on either side of the neural tube. Muscle, cartilage, bone, and the inner layer of the skin form from the somites. (B) In this scanning electron micrograph of somite formation in a chick embryo, the overlying ectoderm has been removed and the neural tube and somites are seen from above.

DNA sequence called the **homeobox**. Some of the genes directing gastrulation in the frog are homeobox genes—for example, *goosecoid* and *siamois*. In vertebrates, the homeotic genes that control differentiation along the anterior–posterior body axis are called **Hox genes**.

In mammals, four Hox gene complexes reside on different chromosomes in clusters of about 10 genes each. Remarkably, the temporal and spatial expression of these genes follows the same pattern as their linear order on their chromosome. That is, the Hox genes closest to the 3' end of each gene complex are expressed first and in the anterior of the embryo. The Hox genes at the 5' end of the gene complex are expressed later and in a more posterior part of the embryo. As a result, different segments of the embryo receive different combinations of Hox gene products, which serve as transcription factors (**Figure 44.16**; see also Figure 20.2).

Whereas Hox genes give cells information about their position on the anterior–posterior body axis, other genes provide information about their dorsal–ventral position. Tissues in each segment of the body differentiate according to their dorsal–ventral location. The notochord provides many of these signals. One example of a dorsal–ventral difference is seen in the spinal cord; sensory nerve connections develop in the dorsal region, and motor nerve connections in the ventral region. The protein Sonic hedgehog (named for the video-game character), which is expressed in the mammalian notochord, induces cells in the overlying neural tube (i.e., the ventralmost cells of the tube) to become motor neurons.

44.16 Hox Genes Control Body Segmentation Hox genes are expressed along the anterior–posterior axis of the embryo in the same order as their arrangement between the 3' and 5' ends of the gene complex. As a result of gene duplication during evolution, vertebrates have four copies of the Hox gene complex shown.

After body segmentation develops, the formation of organs and organ systems progresses rapidly. The development of an organ involves extensive inductive interactions of the kind we saw in the example of the vertebrate eye (see Figure 19.4). These inductive interactions are a current focus of study for developmental biologists.

RECAP 44.4

Gastrulation sets up tissue interactions that initiate organogenesis. Neurulation is initiated by organizer mesoderm that forms the notochord.

- Describe the formation of the neural tube in vertebrates.
See p. 916 and Figure 44.14
- How do somites relate to segmentation of the body axis?
See p. 916 and Figure 44.15
- Explain what Hox genes are and how they instruct patterns of differentiation along the body axis. (You may want to refer back to Section 19.4 for more information on Hox genes.)
See pp. 916–917 and Figure 44.16

We have seen how the basic structure of the developing embryo arises, through the establishment of the anterior–posterior and dorsal–ventral axes, the formation of the neural tube, and the emergence of a segmented body plan. In the next section we will examine the developmental events that result in the formation of structures that support the developing embryo: the extraembryonic membranes and the placenta.

44.5

How Is the Growing Embryo Sustained?

There is more to a developing reptile, bird, or mammal than the embryo itself. As mentioned earlier, the embryos of these vertebrates are surrounded by several **extraembryonic membranes** that originate from the embryo but are not part of it. Extraembryonic membranes function in nutrition, gas exchange, and waste removal. In mammals they interact with tissues of the mother to form the placenta. The evolutionary relationships between the extraembryonic membranes of birds and mammals were discussed in Section 33.4.

Extraembryonic membranes form with contributions from all germ layers

The chicken provides a good example of how extraembryonic membranes form from the germ layers created during gastrulation. In the chick, four membranes form—the yolk sac, the allantoic membrane, the amnion, and the chorion. The **yolk sac** is the first to form, and it does so by extension of the hypoblast layer along with some adjacent mesoderm. The yolk sac grows to enclose the entire body of yolk in the egg (Figure 44.17). It constricts at the top to create a tube that is continuous with the gut of the embryo. However, yolk does not pass through this tube. Yolk is digested by the cells of the yolk sac, and the nutrients are transported to the embryo through blood vessels that form from mesoderm and line the outer surface of the yolk sac. The **allantoic membrane** is also an outgrowth of the

44.17 The Extraembryonic Membranes In birds and mammals, the embryo constructs four extraembryonic membranes. In birds, the yolk sac encloses the yolk, and the amnion and chorion enclose the embryo. Fluids secreted by the amnion fill the amniotic cavity, providing an aqueous environment for the embryo. The chorion, along with the allantoic membrane, mediates gas exchange between the embryo and its environment. The allantois stores the embryo's waste products. (See also Figure 33.19.)

Go to Activity 44.1 Extraembryonic Membranes
Life10e.com/ac44.1

extraembryonic endoderm plus adjacent mesoderm. It forms the **allantois**, a sac for storage of metabolic wastes.

Ectoderm and mesoderm combine and extend beyond the limits of the embryo to form the other extraembryonic membranes. Two layers of cells extend all along the inside of the eggshell, both over the embryo and below the yolk sac. Where they meet, they fuse, forming two membranes, the inner **amnion** and the outer **chorion**. The amnion surrounds the embryo, forming the amniotic cavity. The amnion secretes fluid into the cavity, providing a protective environment for the embryo. The outer membrane, the chorion, forms a continuous membrane just under the eggshell (see Figure 44.17). It limits water loss from the egg and also works with the enlarged allantoic membrane to exchange respiratory gases between the embryo and the outside world.

44.18 The Mammalian Placenta In humans and most other mammals, nutrients and wastes are exchanged between maternal and fetal blood in the placenta, which forms from the chorion and tissues of the uterine wall. The embryo is attached to the placenta by the umbilical cord. Embryonic blood vessels invade the placental tissue to form fingerlike chorionic villi. Maternal blood flows into the spaces surrounding the villi, and placental blood flows through the villi so nutrients and respiratory gases can be exchanged between the maternal and fetal blood.

Extraembryonic membranes in mammals form the placenta

In placental mammals, the first extraembryonic membrane to form is the trophoblast (see Figures 44.4C and 44.5). When the blastocyst reaches the uterus and hatches from its encapsulating zona pellucida, trophoblast cells interact directly with the endometrium. Adhesion molecules expressed on the surfaces of these cells attach them to the uterine wall. By secreting proteolytic enzymes, the trophoblast burrows into the endometrium, beginning the process of implantation. Eventually the entire trophoblast is within the wall of the uterus. The trophoblast cells send out numerous projections, or villi, to increase the surface area of contact with maternal blood.

Meanwhile, the hypoblast cells proliferate to form what in the bird would be the yolk sac. But there is virtually no yolk in eggs of placental mammals, so the yolk sac contributes mesodermal tissues that interact with trophoblast tissues to form the chorion. The chorion, along with tissues of the uterine wall, produces the **placenta**, the organ that exchanges nutrients, respiratory gases, and metabolic wastes between the mother and the embryo (Figure 44.18).

At the same time the yolk sac is forming from the hypoblast, the epiblast produces the amnion, which grows to enclose the entire embryo in a fluid-filled amniotic cavity. The rupturing of the amnion and chorion and the loss of the **amniotic fluid** (the “water breaks”) herald the onset of labor in humans.

An allantois also develops in mammals, but its importance depends on how well nitrogenous wastes can be transferred across the placenta. The human placenta deals effectively with the fetal nitrogenous wastes, so the human allantoic sac is small. In contrast, the pig placenta is not very good at clearing nitrogenous wastes from the fetus, so the pig’s allantoic sac is

large. In humans and other placental mammals, allantoic tissues contribute to the formation of the umbilical cord, by which the embryo is attached to the chorionic placenta (see Figure 33.19B). It is through the blood vessels of the umbilical cord that nutrients and oxygen from the mother reach the developing fetus, and wastes, including carbon dioxide and urea, are removed.

RECAP 44.5

The extraembryonic membranes of reptiles, birds, and mammals sustain the growing embryo. In reptiles and birds these membranes surround the embryo within the shelled egg. In mammals the extraembryonic membranes form the placenta, an organ that exchanges nutrients, respiratory gases, and metabolic wastes between the mother and the embryo.

- Describe each of the four extraembryonic membranes and their functions in the developing chick egg. See p. 918 and Figure 44.17
- Explain the role of the trophoblast in the early development of a mammalian embryo. See p. 919 and Figure 44.5

44.6 What Are the Stages of Human Development?

In humans, **gestation**, or pregnancy, lasts about 266 days, or 9 months. Gestation is shorter in smaller mammals—21 days in mice, for example—and in larger mammals it is longer—330 days in horses and 600 days in elephants. The events of human gestation can be divided into three **trimesters** of roughly 3 months each.

44.19 Stages of Human Development (A) At 4 weeks, most of the embryo's organ systems have been formed and the heart is beating. (B) The body structures of this 8-week-old embryo are forming rapidly, and it is visibly a male. The umbilical cord attaches the embryo to the placenta (upper left). (C) At 4 months, the fetus has fully formed limbs with fingers and toes and moves freely within the amniotic cavity. (D) This fetus is well along in its ninth month. Soon its lungs will be mature enough to trigger the onset of contractions and birth.

(A) 4 Weeks

Actual length ~0.4 cm (4 mm)

(B) 8 Weeks

Actual length ~3 cm

(C) 4 Months

Actual length ~10 cm

(D) 9 Months

Actual length ~40 cm

Organ development begins in the first trimester

Implantation of the human blastocyst begins about 6 days after fertilization. After implantation, gastrulation occurs, tissues differentiate, the placenta forms, and organs begin to develop. The heart begins to beat during week 4, and limbs are formed by week 8 (**Figure 44.19A,B**). By the end of the first trimester, most organs have started to form. The embryo is about 8 centimeters long and weighs about 40 grams (less than 2 ounces). At about this point in time, the human embryo is medically and legally referred to as a **fetus**. (The distinction between embryo and fetus is not made for other mammals; developing mice, for example, remain embryos until they are born.)

The first trimester is a time of rapid cell division and tissue differentiation. Signal transduction cascades and the resulting branching sequences of developmental processes are in their early stages. Therefore the first trimester is the period during which the embryo is most sensitive to damage from radiation, drugs, chemicals, and pathogens that can cause birth defects. An embryo can be damaged before the mother even realizes she is pregnant. A classic case is that of thalidomide, a drug widely prescribed in Europe in the late 1950s to treat nausea. Women who took this drug in the fourth and fifth weeks of pregnancy, when the embryo's limbs are beginning to form, gave birth to children with missing or severely malformed arms and legs.

Organ systems grow and mature during the second and third trimesters

During the second trimester the fetus grows rapidly to a weight of about 600 grams. The limbs of the fetus elongate, and the

fingers, toes, and facial features become well formed (**Figure 44.19C**). Eyebrows and fingernails grow, and the fetus's nervous system develops rapidly. Fetal movements are first felt by the mother early in the second trimester and become progressively stronger and more coordinated.

The fetus grows rapidly during the third trimester (**Figure 44.19D**). As this final stage approaches its end, the internal organs mature. The digestive system begins to function, the liver stores glycogen, the kidneys produce urine, and the brain undergoes cycles of sleep and waking. A human infant is born when the last of its critical organs—the lungs—mature.

Although the first-trimester embryo is the most susceptible to adverse effects of drugs, chemicals, and diseases, the potential for serious effects from exposure to environmental factors exists throughout pregnancy. Protein malnutrition and exposure to alcohol and cigarette smoke are examples of factors that can result in low birth weight, mental retardation, and other developmental complications.

Developmental changes continue throughout life

Development does not end with birth. Growth continues until adult size is reached, and even when growth stops, organs of the body continue to repair and renew themselves through cycles of cell replacement by the progeny of undifferentiated stem cells. In humans especially, enormous developmental changes occur in the brain in the years between birth and adolescence. Especially in the early years, there is a great deal of plasticity in the organization of the nervous system as the connections between neurons develop.

For example, a child born with misaligned eyes (a condition known as strabismus) will use mostly one eye. The connections to the brain from one eye will become strong while connections from the other eye remain weak, and the child will develop with reduced visual acuity and depth perception. If eye alignment is corrected in the first 3 years of life, the connections between the eyes and the brain can improve and the child is likely to develop normal vision. After the age of 3, corrective measures are less likely to result in improvement and visual impairments may persist. Thus plasticity in human visual system development declines during early childhood. However, recent data indicate that it is not lost entirely and may be reactivated even in adulthood.

RECAP 44.6

Human gestation lasts 9 months and is divided into three trimesters. At the end of the first trimester, the fetus is very small but most of its organs have begun to form. In the second trimester, limbs elongate and the fetus moves. By the end of the third trimester, most organs have begun to function.

- Why is a first-trimester embryo particularly sensitive to environmental risks? [See p. 920](#)

Having briefly outlined how multicellular tissues and organ systems emerge from a single cell (the fertilized egg), the remainder of this unit will discuss the physiological functioning of organ systems. The next three chapters will describe the workings of perhaps the most complicated of these, the vertebrate nervous system.

How does the directional flow of extracellular fluid across the node stimulate a left–right asymmetry in gene expression and development?

ANSWER

Surrounding the node are cells with nonmotile cilia that are believed to sense the direction of fluid flow across the node. There are two hypotheses about how these cilia function, one chemical and the other mechanical. Both sensory mechanisms are used by cilia elsewhere in the body. In the nose, cilia of the olfactory cells sense chemicals. In the ear, cilia are bent by sound waves, which opens ion channels. The leftward flow of fluid across the node certainly can create mechanical forces on the nonmotile cilia that differ on the two sides of the node. Other research, however, supports the possibility of chemical signaling. Research on the mouse node shows that the beating of the cilia causes proteins of a certain size range to form a concentration gradient across the node. More important, it was discovered that nodal cells secrete small vesicles that are swept to the left side of the node by the flow and burst when they contact the nonmotile cilia of surrounding cells. The contents of these vesicles could be the chemical signals that initiate left–right asymmetry in gene expression and development.

CHAPTER SUMMARY 44

44.1 How Does Fertilization Activate Development?

- The sperm and the egg contribute differentially to the zygote. The sperm contributes a haploid nucleus and, in most species, a centriole. The egg contributes a haploid nucleus, nutrients, ribosomes, mitochondria, mRNAs, and proteins.
- In amphibians, the cytoplasmic contents of the egg are not distributed homogeneously, and they are rearranged after fertilization to set up the major axes of the future embryo. The nutrient molecules are generally found in the **vegetal hemisphere**, whereas the nucleus is found in the **animal hemisphere**.

[Review Figures 44.1, 44.2](#)

44.2 How Does Mitosis Divide Up the Early Embryo?

- **Cleavage** is a period of rapid cell division. Except in mammals, little if any gene expression occurs during cleavage. Cleavage can be complete or incomplete, and the pattern of cell divisions depends on the orientation of the mitotic spindles. The result of cleavage is a ball or mass of cells called a **blastula**. [Review Figure 44.3](#)
- Early cell divisions in mammals are unique in being slow and allowing for gene expression early in the process. These cell divisions produce a **blastocyst** composed of an **inner cell mass** that becomes the embryo and an outer cell mass that develops as the **trophoblast**. At the time of **implantation**, the trophoblast secretes molecules that help the blastocyst implant in the uterine wall. [Review Figures 44.4, 44.5](#)

- A **fate map** can be created by labeling specific **blastomeres** and observing what tissues and organs are formed by their progeny.

[Review Figure 44.6](#)

- Some species undergo **mosaic development**, in which the fate of each cell is determined during early divisions. Other species, including vertebrates, undergo **regulative development**, in which remaining cells can compensate for cells lost in early cleavages.

44.3 How Does Gastrulation Generate Multiple Tissue Layers?

- **Gastrulation** involves massive cell movements that produce three **germ layers** and place cells from various regions of the blastula into new associations with one another. [Review Figure 44.7, ANIMATED TUTORIAL 44.1](#)
- The initial step of sea urchin and amphibian gastrulation is inward movement of certain blastomeres. The site of inward movement becomes the **blastopore**. Cells that move into the blastula become the **endoderm** and **mesoderm**; cells remaining on the outside become the **ectoderm**. Cytoplasmic factors in the vegetal pole cells are essential to initiate development. [Review Figures 44.7, 44.8](#)
- The **dorsal lip** of the amphibian blastopore is a critical site for cell determination. It has been called the **primary embryonic organizer** because it induces determination in cells that pass over it during gastrulation. [Review Figures 44.8, 44.9, 44.10, ANIMATED TUTORIAL 44.2](#)

continued

- The protein β -catenin activates a signaling cascade that induces the primary embryonic organizer and sets up the anterior–posterior body axis. **Review Figures 44.2, 44.11**
- Gastrulation in reptiles and birds differs from that in sea urchins and frogs because the large amount of yolk causes the blastula to form a flattened disc of cells. **Review Figure 44.13**
- Although their eggs have no yolk, placental mammals have a pattern of gastrulation similar to that of reptiles and birds.

44.4 How Do Organs and Organ Systems Develop?

- Gastrulation is followed by **organogenesis**, the process whereby tissues interact to form organs and organ systems.
- In the formation of the vertebrate nervous system, one group of cells that migrates over the blastopore lip is determined to become the **notochord**. The notochord organizes the overlying ectoderm to thicken, form parallel ridges, and fold in on itself to form a **neural tube** below the epidermal ectoderm. The nervous system develops from this neural tube. **Review Figure 44.14**
- The notochord and **neural crest cells** participate in the segmental organization of mesoderm into structures called **somites** along the body axis. Rudimentary organs and organ systems form during these stages. **Review Figure 44.15**
- In vertebrates, **Hox genes** determine the pattern of anterior–posterior differentiation along the body axis. Other genes, such as *Sonic hedgehog*, contribute to dorsal–ventral differentiation. **Review Figure 44.16**

44.5 How Is the Growing Embryo Sustained?

- The embryos of reptiles, birds, and mammals are protected and nurtured by four **extraembryonic membranes**. In birds and reptiles the **yolk sac** surrounds the yolk and provides nutrients to the embryo, the **chorion** lines the eggshell and participates in gas exchange, the **amnion** surrounds the embryo and encloses it in an aqueous environment, and the **allantois** stores metabolic wastes. **Review Figure 44.17, ACTIVITY 44.1**
- In mammals the chorion and the trophoblast cells interact with the maternal uterus to form a **placenta**, which provides the embryo with nutrients and gas exchange. The amnion encloses the embryo in an aqueous environment. **Review Figure 44.18**

44.6 What Are the Stages of Human Development?

- Human pregnancy, or **gestation**, can be divided into three trimesters. The embryo forms in the first trimester; during this time, it is most vulnerable to environmental factors that can lead to birth defects. During the second and third trimesters the **fetus** grows, the limbs elongate, and the organ systems mature.
- Development continues throughout childhood and throughout life.

CHAPTERREVIEW

REMEMBERING

- How does cleavage in mammals differ from cleavage in frogs?
 - Slower rate of cell division
 - Formation of tight junctions
 - Expression of the embryo's genome
 - Early separation of cells that will not contribute to the embryo
 - All of the above
- Which statement about gastrulation is *true*?
 - In frogs, gastrulation begins in the vegetal hemisphere.
 - In sea urchins, gastrulation produces the notochord.
 - In birds, cells from the surface of the blastodisc move down through the primitive groove to form the hypoblast.
 - In mammals, gastrulation occurs in the hypoblast.
 - In sea urchins, gastrulation produces only two germ layers.
- Which of the following was a conclusion from the experiments of Spemann and Mangold?
 - Cytoplasmic determinants of development are homogeneously distributed in the amphibian zygote.
 - In the late blastula, certain regions of cells are determined to form skin or nervous tissue.
 - The dorsal lip of the blastopore can be isolated and will form a complete embryo.
 - The dorsal lip of the blastopore can initiate gastrulation.
 - The dorsal lip of the blastopore gives rise to the neural tube.
- Which of the following characterizes neurulation?
 - The notochord forms a neural tube.
 - The neural tube is formed from ectoderm.
 - A neural tube forms around the notochord.
 - The neural tube forms somites.
 - In birds, the neural tube forms from the primitive groove.
- Which statement about trophoblast cells is *true*?
 - They are capable of producing monozygotic twins.
 - They are derived from the hypoblast of the blastocyst.
 - They are endodermal cells.
 - They secrete proteolytic enzymes.
 - They prevent the zona pellucida from attaching to the oviduct.

UNDERSTANDING & APPLYING

6. The glycogen synthase kinase-3 (GSK-3)-inhibiting protein in the amphibian egg is a product of the *Disheveled* gene. If you had both Disheveled protein and an inhibitor of Disheveled protein, what experiments might you do to test whether β -catenin was both necessary and sufficient to initiate gastrulation?
7. If you used a laser to kill a small number of cells on the midline of the dorsal blastopore lip of an amphibian embryo, what defects would you expect to see during subsequent development?

ANALYZING & EVALUATING

8. During gastrulation in birds, the *Sonic hedgehog* gene is expressed only on the left side of Hensen's node. What might be the cause of this expression pattern, and what is its significance? How could you test your hypotheses?
9. When oogonia or spermatogonia divide by mitosis, one daughter cell remains a germinal stem cell and one becomes a primary oocyte or spermatocyte. What mechanism could possibly account for these different cell fates?
10. There is controversy over therapeutic cloning as a way of obtaining embryonic stem cells to treat diseases. Given that human development is regulative, suggest a way to produce a source of isogenic (i.e., identically matching a person's own body) stem cells for an individual without resorting to therapeutic cloning.

Neurons, Glia, and Nervous Systems

CHAPTER OUTLINE

- 45.1** What Cells Are Unique to the Nervous System?
- 45.2** How Do Neurons Generate and Transmit Electric Signals?
- 45.3** How Do Neurons Communicate with Other Cells?
- 45.4** How Are Neurons and Glia Organized into Information-Processing Systems?

YOUR BRAIN ENABLES YOU to learn the material in this chapter. It enables you to read the words, understand the illustrations, and store that information so you can use it to answer the questions at the end of the chapter. You have to spend time studying in order to master this chapter; it may be hard work, but eventually you will have learned something about how the brain receives and processes information.

Imagine what it would be like if you could not learn any of this material—no matter how much you poured over the book, no matter how hard you tried. This is the situation faced by individuals with a learning disability that is part of the condition known as Down syndrome, which affects 1 out of every 700 children born in the United States.

Individuals with Down syndrome are born with three copies of chromosome 21. This smallest of the human somatic chromosomes contains only some 250 genes, but having an extra copy of these genes causes numerous developmental and functional problems, including a learning disability in which the brain does not properly take in and store new information. How can we understand the cause of this disability and perhaps find a way to remedy it?

One productive way of investigating the causes and possible treatments for a human disease or deficit is to develop an animal model. Through genetic engineering, researchers created a “Down syndrome mouse” that has most of the same genes triplicated as those in humans with Down syndrome. Using this mouse model, biologists found out that the learning disability

Trying and Learning To varying degrees, individuals with Down syndrome are unable to learn basic concepts and tasks despite intense effort on their own part and that of their teachers. Understanding the cellular basis of this learning disability may lead to new ways of alleviating it.

of these mice was due to overinhibition in the brain, and that when this inhibition was reduced with drugs, the ability of these mice to learn was increased. But what do we mean by “overinhibition in the brain”?

We often think of the brain as a puppet master, pulling the strings that activate the muscles and organs of the body. In fact the brain is more like an orchestra conductor, making some sections louder, some softer, speeding up, slowing down. The brain must constantly maintain a delicate balance of excitation and inhibition, acting on some signals and ignoring others. In the brains of “Down syndrome mice,” there is consistently too much inhibition. If inhibition is reduced using certain drugs, the mice appear able to learn. Research like this is a first step toward bringing potential therapies for humans into clinical trials in the hope of someday alleviating suffering.

What causes overinhibition in the nervous system, and how can it be reduced?

See answer on p. 943.

45.1 What Cells Are Unique to the Nervous System?

Nervous systems are informational systems. They encode, process, and store a wide variety of information from the external and internal environments, and they use that information to control and regulate the physiological processes and behavioral actions of the organism. Nervous systems are able to carry out these functions because of the properties of two unique types of cells: nerve cells, or **neurons**, and glial cells, or **glia**. The many different types of neurons vary enormously in structure and appearance, but all neurons are **excitable**, meaning they can generate and transmit electric signals; the electric signals generated by neurons are known as **action potentials**. Generally glia do not generate action potentials, but they interact intimately with neurons, modulating their activity and supporting them in many ways.

The structure of neurons reflects their functions

All neurons have a basic structure that includes four regions (**Figure 45.1**).

45.1 A Generalized Neuron The diagram shows the features typical of most neurons. The forms of these features, including the length of the single axon and the density and branching patterns of the dendrites, vary greatly across the many different types of neurons.

45.2 Neurons Have Many and Varied Forms The morphological differences in neurons from different parts of the mammalian nervous system are related to their specific functional adaptations. The small sample here shows two neuronal types from the human brain (a Purkinje cell and a pyramidal cell) and a sensory neuron from the retina of the human eye.

- A **cell body** contains the nucleus and most of the cell's organelles.
- Shrublike projections called **dendrites** (Greek *dendron*, "tree") may extend from the cell body. Dendrites bring information from other neurons or sensory cells to the cell body. Neurons with few dendrites are receiving information from specific and limited sources, whereas neurons with large arrays of dendrites can collect and integrate information from a wider range of sources.
- In most neurons, one projection—the **axon**—is much longer than the others. Axons carry information in the form of action potentials away from the originating cell body (the **presynaptic cell**) to the receiving target cell (the **postsynaptic cell**).
- At the postsynaptic cell, the axon divides into a spray of fine nerve endings. At the tip of each of these tiny nerve endings is a swelling called the **axon terminal**.

A wide variety of forms can be seen among the many different types of neurons (**Figure 45.2**), but all neurons share the mechanisms whereby their plasma membranes generate and conduct action potentials. Information received by dendrites

is integrated by the cell body, and the result of that integration can generate an action potential that is conducted down the axon toward its terminals at the target cell. Action potentials can travel at speeds up to 100 m/sec (360 km/hr), making it possible for an individual to sense, process, and act on information very quickly. The axon terminal comes extremely close to (apposes) the membrane of the target cell, forming a **synapse** at which the information conveyed by the action potential is communicated from the presynaptic cell to the postsynaptic cell (see Figure 45.1).

As we will discuss in Section 45.3, synapses can be either chemical or electrical. Electrical synapses allow the action potential to pass directly between two neurons. In vertebrates, however, most synapses are chemical. At chemical synapses a space about 25 nanometers wide (about 1/2000th the width of a human hair) separates the presynaptic and postsynaptic membranes. An action potential arriving at an axon terminal causes it to release chemical messenger molecules called **neurotransmitters**. The neurotransmitters diffuse across the space and bind to receptors on the plasma membrane of the postsynaptic (target) cell. This binding alters the activity of the postsynaptic neuron. Some neurotransmitter–receptor combinations inhibit activity of the postsynaptic neuron, and other neurotransmitter–receptor combinations excite it. Neurons integrate information by summing excitatory and inhibitory inputs.

Glia are the “silent partners” of neurons

The human brain has about 10 times more glial cells than neurons. A neurobiologist once said that “flashy neurons get all of the attention, but glial cells do most of the brain’s work and are the cause of many of its diseases.” It has been easier to study the functions of neurons because their action potentials can be observed. The mostly silent glia have been more difficult to study, and therefore we know much less about them. Our knowledge of glia will grow enormously in the years to come, and there are likely to be many surprises.

Like neurons, glia come in several forms and have diverse functions. In the brain and spinal cord, glia called **oligodendrocytes** wrap around the axons of neurons, covering them with concentric layers of insulating plasma membrane. Outside the brain and spinal cord, glia called **Schwann cells** wrap axons (Figure 45.3). **Myelin** is the covering produced by oligodendrocytes and Schwann cells, and it gives many parts of the nervous system a glistening white appearance. Not all axons are myelinated, but those that are can conduct action potentials more rapidly than can axons that are not myelinated, for reasons we will describe in Section 45.2.

Diseases that affect myelin can be devastating because they impair conduction of action potentials. The most common of these demyelinating diseases is multiple sclerosis—literally “multiple scars”—which occurs in about 1 in 700 people in the United States. Individuals with this autoimmune disease produce antibodies to proteins in the myelin in the brain and spinal cord. The symptoms and damage from the disease depend on where in the nervous system the antibody attacks occur. Motor impairment is common. An example of a demyelinating

45.3 Wrapping Up an Axon (A) Schwann cells produce layers of myelin, a type of plasma membrane that provides electrical insulation to the axon. At the intervals between Schwann cells—the nodes of Ranvier—the axon is exposed. Action potentials travel along the axon by “jumping” from node to node. (B) A myelinated axon, seen in cross section through an electron microscope.

disease that attacks myelin outside the brain and spinal cord is Guillain–Barre syndrome, which is usually the result of a severe infection. Environmental factors such as pesticide exposure can also damage myelin. There are no known cures for demyelinating diseases.

Glia called **astrocytes** (because they look like stars) contribute to the **blood–brain barrier**, which protects the brain from toxic chemicals in the blood. Blood vessels throughout the body are very permeable to many chemicals, including toxic ones, which would reach the brain if this barrier did not exist. Astrocytes help form the blood–brain barrier by surrounding the smallest, most permeable blood vessels in the brain. The barrier is not perfect, however. Because it consists of plasma membranes, it is permeable to fat-soluble substances such as anesthetics and alcohol (which explains why these substances have such rapid and marked effects on the nervous system).

In addition to their role in the blood–brain barrier, astrocytes have several known functions at the synapse:

- They can take up neurotransmitter that has been released into the synapse and thereby control communication between the pre- and postsynaptic cells.
- They can supply neurons with nutrients. Neurons have no energy reserves, but astrocytes store glycogen that they can break down to supply the neurons with fuel.
- They have signaling properties. Even though most astrocytes do not generate action potentials, they do release neurotransmitters that can alter the activities of neurons.

45.4 Astrocytes Communicate with Many Synapses Cell-type-specific antibodies have been used to label the astrocytes and their processes (red) and the neurons and their processes (green) in this fluorescence micrograph. The blue label visualizes the nuclei of both cell types.

- They aid in the repair and regeneration of neurons.
- They make contact with both blood vessels and neurons and can therefore signal changes in the composition of the blood.

Astrocytes play crucial yet poorly understood roles in modulating synapse activity. The projections of a single astrocyte may make contact with more than 100,000 synapses (**Figure 45.4**). The contact of the astrocyte with the neuronal components of the synapse is so intimate that it has inspired the concept of the **tripartite synapse**—the idea that a synapse includes not only the pre- and postsynaptic neurons but also connections from astrocytes.

Microglia are another type of glial cell. The blood–brain barrier typically prevents antibodies in the general circulation from entering the brain and spinal cord. Microglia that originate during development from stem cells in the bone marrow come to reside in the nervous system and act as macrophages and mediators of inflammatory responses, thus providing the nervous system with immune defenses.

RECAP 45.1

Nervous systems have two unique types of cells: neurons and glia. There are many types of neurons, but they all generate action potentials. A neuron has four regions: cell body, dendrites, axon, and axon terminals. Neurons communicate with target cells at synapses, which can be chemical or electrical. Although glia do not generate action potentials, they have a wide variety of functions that are only beginning to be elucidated.

- Describe the different parts of a neuron and their functions. **See pp. 925–926 and Figure 45.1**
- What are some types of glia, and what are their functions? **See pp. 926–927**
- What is meant by the “tripartite synapse”? **See p. 927**

The one feature common to all neurons is that they process information in the form of action potentials. In the next section we will focus on how action potentials are generated and transmitted.

45.2 How Do Neurons Generate and Transmit Electric Signals?

Sodium–potassium pumps create concentration gradients across all animal cell membranes, with Na^+ concentration higher outside the cell and K^+ concentration higher inside. Both inside and outside the cell, the positive charges of these ions are balanced by negatively charged ions. But *across the plasma membrane* there is an electric charge difference, with the inside of the cell being negative relative to the outside. This is because there are “leak channels” that allow only certain ions—usually K^+ —to passively leak across the cell membrane.

Because there is a higher concentration of K^+ inside the cell than in the extracellular fluid outside, K^+ diffuses out of the cell down its concentration gradient. But when K^+ leaks out of the cell, it leaves behind an unbalanced negative electric charge that tends to pull K^+ back into the cell. An equilibrium is reached when the tendency for K^+ to diffuse out is countered by the electric charge pulling K^+ back in. The result is a charge difference—a **membrane potential**—across the membrane, with the inside of the cell negative relative to the outside.

Membrane potentials exist in all cells. In neurons the steady state membrane potential is called the **resting potential**. An action potential is a sudden, large, transient reversal in the resting potential that is generated by sudden openings and rapid closings of ion channels. Before describing the properties of ion channels and action potentials in detail, a review of some simple concepts of electricity may be useful.

Simple electrical concepts underlie neural function

Voltage (electric potential difference) is a force that causes electrically charged particles to move between two points. Voltage is to the flow of electrically charged particles as pressure is to the flow of water. If the negative and positive poles of a battery are connected by a wire, an electric current will flow through the wire because there is a voltage difference between the two poles. This flow of electric current can be used to do work, just as a current of water can be used to do work.

In wires, electric current is carried by electrons, but in solutions and across cell membranes, electric current is carried by ions. The major ions that carry electric charges across the plasma membranes of neurons are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and chloride (Cl^-). Recall that ions with opposite charges attract one another and that those with like charges repel one another. How do these basic principles of bioelectricity establish the resting potential of the neural plasma membrane? And how is the flow of ions through membrane channels turned on and off to generate action potentials? We will address these questions next.

RESEARCHTOOLS

45.5 Measuring the Membrane Potential An electrode can be made from a glass pipette with a very sharp tip filled with a solution that conducts electric charges. If one electrode is placed

inside the plasma membrane of an axon and another is placed just outside the axon, the difference in voltage can be measured.

Membrane potentials can be measured with electrodes

We can record electrical events in a cell using electrodes. **Figure 45.5** shows how this technique is applied across an unstimulated axon to measure the resting potential, which is usually between -60 and -70 millivolts (mV). The minus sign indicates that the inside of the cell is electrically negative compared with the outside.

The resting potential provides a means for neurons to respond to a stimulus. Because of the voltage difference across the membrane, and the different ion concentrations on either side of the membrane, ions would cross the membrane if they could. For example, Na^+ ions are more abundant outside the cell than inside, and the inside of the resting cell is negatively charged. Therefore if the membrane suddenly became permeable to Na^+ , those positively charged ions would rush into the cell. Any chemical or physical stimulus that changes the permeability of the plasma membrane to ions will produce a change in the cell's membrane potential. The most extreme change in membrane potential is the action potential, a sudden and rapid reversal in the voltage across a portion of the plasma membrane. For 1 or 2 milliseconds, positively charged ions flow into the cell, making the inside of the cell *more positive* than the outside.

Ion transporters and channels generate membrane potentials

The plasma membranes of neurons, like those of all other cells, are lipid bilayers that are impermeable to ions but contain many protein molecules that serve as ion transporters and channels. Ion transporters and channels are responsible for the distribution of charges across the membrane that create resting and action potentials.

Ion transporters require energy to move ions against their concentration or electrical gradients and are therefore called ion pumps. A major ion transporter in the plasma membranes of neurons (and all other cells) is the **sodium-potassium pump**, so called because it actively expels Na^+ ions from inside the cell, exchanging them for K^+ ions from outside the cell (**Figure 45.6A**). The Na^+-K^+ pump is also known as sodium-potassium ATPase, a term emphasizing that it is an enzyme complex requiring ATP to do its work. The Na^+-K^+ pump keeps the concentration of K^+ inside the cell greater than the K^+ concentration of the extracellular fluid, and the concentration of Na^+ inside the cell less than that of the extracellular fluid. The concentration differences established by this active transporter means that K^+ would diffuse out of the cell and Na^+ would diffuse in if the ions could cross the lipid bilayer. How do these concentration gradients relate to the electrical gradients we discussed above?

Ion channels permit the diffusion of ions across membranes. These channels are water-filled pores formed by proteins that cross the lipid bilayer and are generally selective,

(A) Na^+ – K^+ pump (ATPase)(B) Na^+ – K^+ channels

45.6 Ion Transporters and Channels (A) The sodium–potassium pump is an active transporter that moves K^+ to the inside of a neuron and Na^+ to the outside. (B) Ion channels allow specific ions to diffuse down their concentration gradients; K^+ tends to leave neurons when potassium channels are open, and Na^+ tends to enter neurons when sodium channels are open. Leak channels like the K^+ channel shown are always open and create the resting membrane potential. Gated channels like the Na^+ channels shown are opened by chemical or electrical stimulation.

allowing some types of ions to pass through more easily than others (Figure 45.6B). Thus there are potassium channels, sodium channels, chloride channels, and calcium channels, and there are different kinds of channels for each ion. Ions can diffuse through these channels in either direction. The direction and magnitude of the net movement of ions through a channel depend on the concentration gradient of that ion type across the plasma membrane, as well as on the voltage difference across that membrane. These two motive forces acting on an ion are termed its **electrochemical gradient**. Although the electrochemical gradient drives the movement of ions through channels, that movement is modified by gates that open and close the channels.

Potassium channels are the most common open, or leak, channels in the plasma membranes of resting (nonstimulated) neurons. As a consequence, resting neurons are more permeable to K^+ than to any other ion. Thus open potassium channels are

largely responsible for the resting membrane potential. Because the potassium channels make the plasma membrane permeable to K^+ , and because the Na^+ – K^+ pump keeps the concentration of K^+ inside the cell much higher than that outside the cell, K^+ tends to diffuse down its electrochemical gradient, out of the cell, through the channels. As these positively charged potassium ions diffuse out of the cell, they leave behind unbalanced negative charges, generating an electric potential across the membrane that tends to pull K^+ back into the cell.

The membrane potential at which the net diffusion of K^+ out of the cell ceases (that is, the point at which K^+ diffusion out due to the concentration gradient is balanced by its movement in due to the negative electric potential) is the **potassium equilibrium potential**, or E_{K} . The value of E_{K} can be calculated from the concentrations of K^+ on the two sides of the membrane using the **Nernst equation** (Figure 45.7). This equation, developed in the late 1800s, shows that the existence of ion channels in neural membranes was hypothesized long before their specific structures and properties were described.

In the late 1940s, A. L. Hodgkin and A. F. Huxley at the University of Cambridge set out to study the electrical properties of axonal membranes. With the techniques available at that time, the necessary measurements could be made only if you had a very large axon to work with. Such an axon exists in nature, in the huge neuron that controls the escape response of squid. Hodgkin and Huxley used electrodes to measure the voltage across the plasma membrane of this large axon, as seen in Figure 45.7, and to pass electric current into it to change its membrane potential. They also changed the concentrations of Na^+ and K^+ both inside and outside the squid axon and measured the resulting changes in membrane potential. On the basis of their many careful experiments, Hodgkin and Huxley developed virtually all of our basic concepts about the electrical properties of neurons, and shared a Nobel Prize in 1963.

We now know that, in general, the resting potential is less negative than the E_{K} calculated from the Nernst equation. This means that the resting potential is not due solely to leak K^+ channels. The neuronal membrane is slightly permeable to other ions, especially Na^+ and Cl^- , and movements of these ions influence the resting potential. A different equation takes into account (1) all of the ions that can cross the membrane and (2) the relative permeability of the membrane to those ions. This equation, called the **Goldman equation**, predicts the membrane potential more accurately than does the Nernst equation (see p. 931).

Ion channels and their properties can now be studied directly

Because Hodgkin and Huxley were working long before there were laboratory techniques that could investigate ion channels, they could only hypothesize their properties. These hypotheses could not be tested until the late 1970s, when B. Sakmann and E. Neher developed a technique called **patch clamping**, for which they shared the Nobel Prize in 1991. Patch clamping, described in Figure 45.8, is widely used by neurobiologists, enabling them to record in real time the tiny electric currents caused by the openings and closings of single ion channels.

RESEARCHTOOLS

45.7 Using the Nernst Equation The Nernst equation calculates membrane potential when only one type of ion can cross a membrane that separates solutions with different concentrations of that ion.

1. Measure concentrations of ions inside and outside a neuron.

To measure the concentration of ions in a neuron, the neuron (and its axon) must be big. Squid have giant neurons that control their escape response (see Figure 45.17C). It is possible to sample the cytoplasm of these axons, which are about 1 mm in diameter.

2. Use the Nernst equation to calculate what the membrane potential would be if it were permeable to each of the ions that are differently concentrated on the two sides of the membrane: Na⁺, K⁺, Ca²⁺, and Cl[−].

The Nernst equation predicts the membrane potential resulting from membrane permeability to a single type of ion that differs in concentration on the two sides of the membrane. The equation is written

$$E_{\text{ion}} = 2.3 \frac{RT}{zF} \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$$

where *E* is the equilibrium (resting) membrane potential (the voltage across the membrane in mV), *R* is the universal gas constant, *T* is the absolute temperature, *z* is the charge on the ion (+1, +1, +2, or −1), and *F* is the Faraday constant. The subscripts *o* and *i* indicate the ion concentrations outside and inside the cell, respectively.

At this point you could just “plug and play,” but do you understand this equation?

A concentration difference of ions across a membrane creates a *chemical* force that pushes the ions across the membrane; however, the resulting unbalanced *electric charges* will pull the ions back the other way. At *equilibrium*, the work done moving ions in each direction will be the same.

The *chemical* energy pushing the ions will equal $2.3 RT \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$
The *electric* energy pulling the ions will equal zEF . So, at equilibrium:

$$zEF = 2.3 RT \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$$

Rearranging the equation to solve for *E*, we get the Nernst equation:

$$E_{\text{ion}} = 2.3 \frac{RT}{zF} \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$$

We can simplify the equation by picking a temperature—let’s use “room temperature,” or 20°C—and solving for 2.3 *RT*/*F*. At 20°C, 2.3 *RT*/*F* equals 58. Thus:

$$E_{\text{ion}} = 58/z \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$$

3. Measuring ion concentrations in squid giant axon cytoplasm and in seawater, then solving the Nernst equation for each ion, we find:

Ion	Ion concentration (mM)		Predicted membrane potential (mV)
	in squid axon	in seawater	
K ⁺	400	20	−75
Na ⁺	50	460	+56
Ca ²⁺	0.5	10	+38
Cl [−]	50	560	−60

4. Since the measured membrane potential is −66 mV, it is clear that the resting potential of the axon is due to permeability of the membrane to more than just one type of ion.

Gated ion channels alter membrane potential

The ion channels called leak channels are always open, but other ion channels in the plasma membranes of neurons behave as if they contain “gates”; they are open under some conditions and closed under other conditions. **Voltage-gated channels** open or close in response to a change in the voltage across the plasma membrane. **Chemically gated channels** open or close depending on the presence or absence of a specific molecule that binds to the

channel protein, or to a separate receptor that in turn alters the channel protein. **Mechanically gated channels** open or close in response to mechanical force applied to the plasma membrane. Gated channels play important roles in neural function.

Openings and closings of gated channels alter the membrane potential. Imagine what happens, for example, if sodium channels in the plasma membrane suddenly open. Na⁺ diffuses into the neuron down its electrochemical gradient to approach

WORKING WITH DATA:

**Equilibrium Membrane Potential:
The Goldman Equation**

Original Papers

Goldman, D. E. 1943. Potential, impedance and rectification in membranes. *Journal of General Physiology* 27: 37–60.

Hodgkin, A. L. and B. Katz. 1949. The effect of sodium ions on the electrical activity of the giant axon of the squid. *Journal of Physiology* 108: 37–77.

Analyze the Data

Figure 45.7 presented the Nernst equation by which the membrane potential for a single ion can be determined. But we also saw (at the end of Figure 45.7) that the equilibrium membrane potential is the product of more than one ion. The Goldman equation (sometimes called the Goldman, Hodgkin, Katz equation) calculates the equilibrium membrane potential by taking into account all of the ions that can diffuse across a given membrane and the relative permeabilities of the membrane to those ions. The ions involved in mammalian neurons here are K^+ , Na^+ , and Cl^- , and the Goldman equation is

$$V_m = \frac{RT}{F} \ln \left(\frac{p_K [K^+]_o + p_{Na} [Na^+]_o + p_{Cl} [Cl^-]_i}{p_K [K^+]_i + p_{Na} [Na^+]_i + p_{Cl} [Cl^-]_o} \right)$$

Relative permeabilities (p) are expressed as percentages. The membrane's permeability to potassium ions is the highest, so $p_K = 1.0$. Then $p_{Na} = 0.05$ and $p_{Cl} = 0.45$. Bracketed elements refer to the inside and outside ion concentrations, as in the Nernst equation.

QUESTION

The table gives the intra- and extracellular ion concentrations for a mammalian neuron. Use these values and the Goldman equation to calculate the membrane potential. Refer to Figure 45.7 for a comparison with calculations based on the Nernst equation. (Hint: In redrafting the equation, you can substitute “ $2.3RT/F \log$ ” for “ $RT/F \ln$.”)

	Ion concentration (mM)	
	Intracellular	Extracellular
K^+	140	5
Na^+	10	145
Cl^-	20	110

Go to **BioPortal** for all WORKING WITH DATA exercises

the equilibrium potential for Na^+ (E_{Na}). Therefore the inside of the cell becomes less negative. When the inside of a neuron becomes less negative (or more positive) in comparison to its resting condition, its plasma membrane is **depolarized** (Figure 45.9).

An opposite change in the membrane potential occurs if gated K^+ channels open. When K^+ efflux from the neuron increases over the normal leak current (the movement of K^+ through the leak channels), the membrane potential becomes even more negative, and the plasma membrane is **hyperpolarized**.

RESEARCH TOOLS

45.8 Patch Clamping The patch clamp is a glass micropipette filled with an electrically conductive solution that has the same composition as extracellular fluids. When this pipette/electrode is positioned against the membrane of a cell and slight suction is applied, a seal forms. If a single ion channel (or a few ion channels) are within the patch of membrane bounded by the seal, the openings and closings of individual channels can be recorded by the electrode. If the pipette is retracted, it can tear the patched membrane away from the cell, and the activities of the ion channels in the patch can continue to be recorded.

The openings and closings of ion channels that result in changes in the voltage across the plasma membrane are the basic mechanisms by which neurons respond to stimuli, be they electrical, chemical, or mechanical. How do such local changes in membrane potential get communicated to other parts of the cell?

A local change in membrane potential causes a flow of ions that spreads the change in membrane potential to adjacent regions of the membrane. For example, when Na^+ enters a neuron through open sodium channels at one location, those positively charged ions are attracted to adjacent areas on the inside of the membrane that are more negative, and thus there is a rapid flow of ionic electric current (movement of charged ions) away from the site of the open Na^+ channels. However,

45.9 Membranes Can Be Depolarized or Hyperpolarized The resting potential is produced by leak K^+ channels. A shift from the resting potential to a less negative membrane potential, as occurs when Na^+ enters the cell through a gated sodium channel, is called

depolarization. Hyperpolarization occurs when the membrane potential becomes more negative, as when additional K^+ leaves the cell through gated K^+ channels, which occurs extensively in your brain when you fall asleep.

this local flow of ionic electric current decays as it spreads and therefore does not spread very far. The small number of electrically charged ions that enter are rapidly diluted by the large number of oppositely charged particles, and the Na^+/K^+ ATPases are continuously pumping them out.

Graded changes in membrane potential can integrate information

Even though the flow of ionic electric current along plasma membranes can only extend over short distances, it can cause graded changes in membrane potentials locally. A **graded membrane potential** is a change from the resting potential. Such changes can be due to chemical or mechanical influences on ion channels. Graded potentials are a means of integrating inputs to a cell because the membrane can respond to those inputs with proportional amounts of depolarization or hyperpolarization.

Graded potentials can transmit signals over very short distances and play an important role at the neuromuscular junction (see Section 45.3). In the next chapter we will learn how they play important roles in sensory systems. However, axons are too long to transmit information as a continuous flow of ionic electric current. Therefore axons code information as discrete action potentials that travel along their membranes. Graded potentials, however, play an important role in the generation of action potentials.

Sudden changes in Na^+ and K^+ channels generate action potentials

Action potentials are sudden, transient, large changes in membrane potential. In unmyelinated axons (those not wrapped in myelin by oligodendrocytes or Schwann cells), they can be conducted at speeds of up to 2 meters per second, but in myelinated axons the conduction velocity can be 100 meters per second. Think of running the 100-meter dash—the world record is slightly under 10 seconds.

If we place the tips of a pair of electrodes on either side of the plasma membrane of a resting axon and measure the voltage difference, the reading might be about -60 mV, as we saw in Figure 45.5. If these electrodes are in place when an action potential travels down the axon, they register a rapid change in membrane potential, from -60 mV to about $+50$ mV. The membrane potential then rapidly returns to its resting level of -60 mV as the action potential passes (**Figure 45.10**).

The action potential is generated by the actions of voltage-gated Na^+ and K^+ channels in the plasma membrane of the axon. At the resting potential, most of these channels are closed (balloon 1 in Figure 45.10). A slight depolarization of the membrane causes them to open. For example, if a neuron is stimulated sufficiently to cause the plasma membrane of its cell body to depolarize slightly, that graded potential can spread by local current flow to the **axon hillock**, the region of the cell body at the base of the axon (see Figure 45.1). Voltage-gated

Na^+ channels are concentrated in the axon hillock. A slight depolarization of the plasma membrane in this area causes some of these voltage-gated channels to open briefly—for less than a millisecond (balloon 2 in Figure 45.10). When these channels open, Na^+ rushes into the axon and depolarizes the membrane even more, causing more Na^+ channels to open—a positive feedback effect. When the membrane is depolarized about 5 to 10 mV above the resting potential, a **threshold** is reached; a large number of sodium channels open (balloon 3 in Figure 45.10), and the membrane potential becomes positive—an action potential. The rising phase of the action potential halts abruptly in 1 to 2 milliseconds, and the membrane potential rapidly becomes negative once again.

What causes the axon to return to resting potential? There are two contributing factors: the voltage-gated Na^+ channels close, and voltage-gated K^+ channels open (balloon 4 in Figure 45.10). Voltage-gated K^+ channels open more slowly than the Na^+ channels and stay open longer, allowing K^+ to carry excess positive charges out of the axon. As a result, the membrane potential returns to a negative value and usually becomes even more negative than the resting potential until the voltage-gated K^+ channels close (balloon 5 in Figure 45.10).

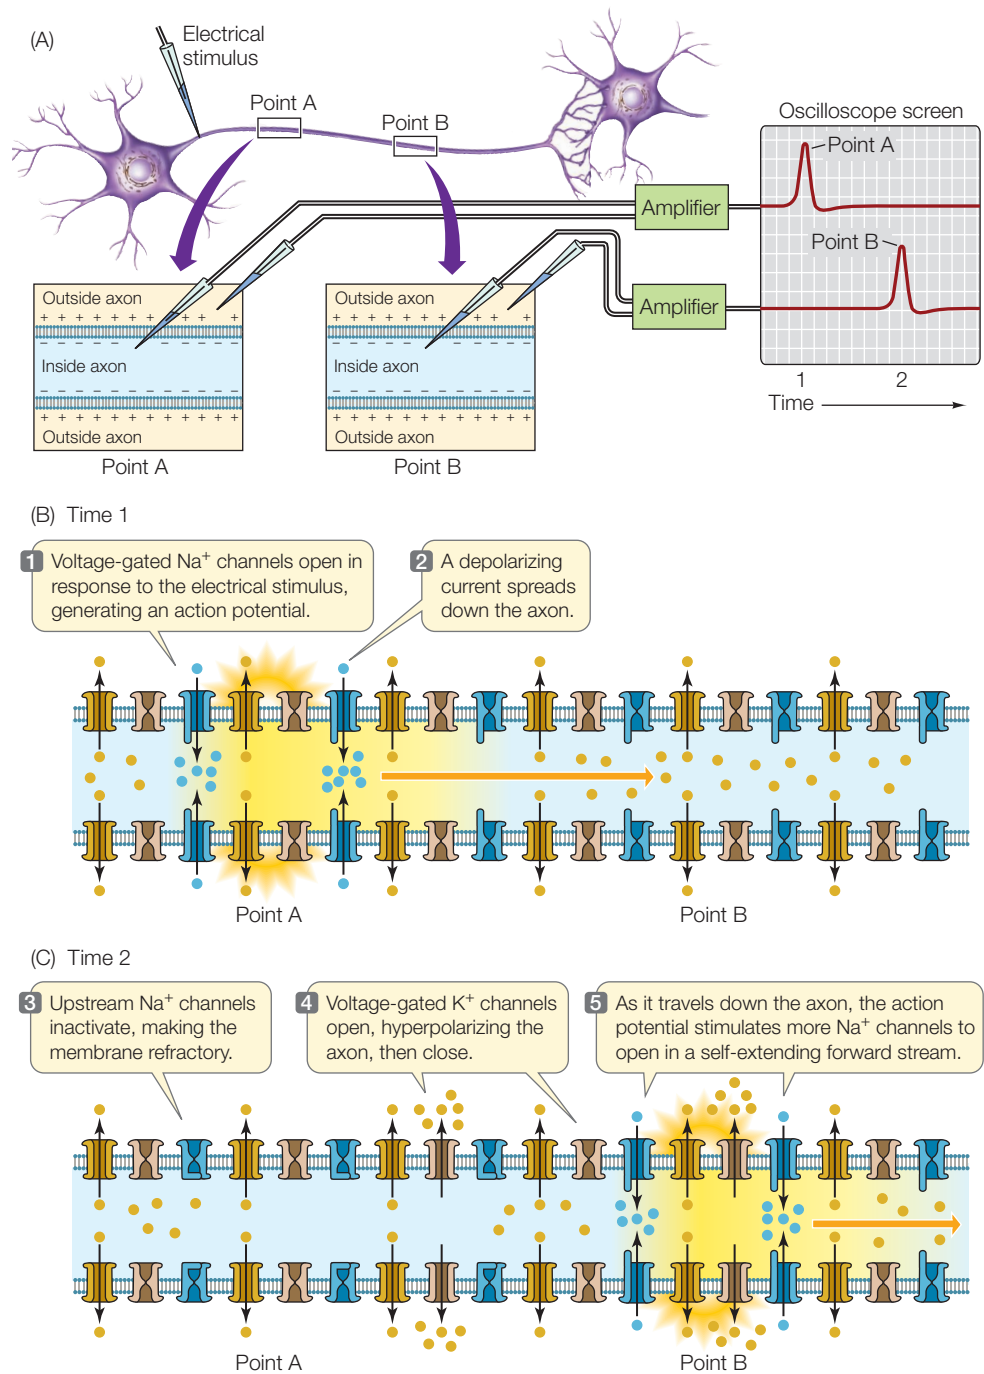

Another feature of the voltage-gated Na^+ channels is that once they open and close, they have a **refractory period** of 1 to 2 milliseconds during which they cannot open again. This property can be explained by the channels having two gates, an

activation gate and an **inactivation gate** (see Figure 45.10). Under resting conditions, the activation gate is closed and the inactivation gate is open. Depolarization of the membrane to the threshold level causes both gates to change state, but the activation gate responds faster. As a result, the channel is open for a brief time between the opening of the activation gate and the closing of the inactivation gate. Inactivation gates remain closed for 1 to 2 milliseconds before they spontaneously open again, thus explaining why the membrane has a refractory period before it can fire another action potential. By the time the inactivation gate reopens, the activation gate is closed, and the membrane is poised to generate another action potential. Another contribution to the refractory period is the duration of the opening of the voltage-gated K^+ channels, as we saw above. The dip in the membrane potential following an action potential is called the **after-hyperpolarization** or **undershoot**.

The difference in the concentration of Na^+ across the plasma membrane and the negative resting potential constitute the “battery” that drives action potentials. How rapidly does the battery run down? It might seem that a substantial number of ions would have to cross the membrane for the membrane potential to change from -60 mV to $+50$ mV and back to -60 mV again. In fact, only a vanishingly small percent of the Na^+ concentrated just outside the plasma membrane moves through the channels during the passage of an action potential. Thus the effect of a single action potential on the concentration gradients of Na^+ and K^+ is very small, and it is possible in most cases for the sodium–potassium pump to keep the “battery” charged, even when the neuron is generating many action potentials every second.

Action potentials are conducted along axons without loss of signal

Action potentials can travel over long distances with no loss of signal. If we place two pairs of electrodes at two different locations along an axon, we can record an action potential at those two locations as it travels along the axon (Figure 45.11A). The magnitude of the action potential does not change between the two recording sites. This constancy is possible because an action potential is an all-or-none, self-regenerating event.

45.11 Action Potentials Travel along Axons (A) There is no loss of signal as an action potential travels along an axon. (B) When an action potential is stimulated in one region of membrane, electric current flows to adjacent areas of membrane and depolarizes them. (C) The advancing wave of depolarization causes more Na^+ channels to open, and the action potential is generated anew in the next section of membrane. Meanwhile, in the region where the action potential has just fired, the Na^+ channels are inactivated and the voltage-gated K^+ channels are still open, rendering this section of the axon incapable of generating an action potential. Hence the action potential cannot “back up,” but moves continuously forward, regenerating itself as it goes.

- An action potential is *all-or-none* because of the interaction between the voltage-gated Na^+ channels and the membrane potential. If the membrane is depolarized slightly, some voltage-gated Na^+ channels open. Some sodium ions cross the plasma membrane and depolarize it even more, opening more voltage-gated Na^+ channels, and so on, generating an action potential. This positive feedback

mechanism ensures that action potentials always rise to their maximum value.

- An action potential is *self-regenerating* because it spreads by local current flow to adjacent regions of the plasma membrane. The resulting depolarization brings those neighboring areas of membrane to threshold. So when an action potential occurs at one location on an axon, it stimulates the adjacent region of axon to generate an action potential, and so on down the length of the axon.

We can use an electrode to stimulate an axon, causing it to depolarize and to fire an action potential that is then conducted along the axon. **Figure 45.11B** shows the changes in the ion channels in the membrane that are responsible for conducting the action potential along the axon without a reduction in amplitude. Normally an action potential is propagated in only one direction—away from the cell body. It cannot reverse itself because the voltage-gated Na^+ channels in the region of the membrane it came from are in their refractory period (**Figure 45.11C**).

Action potentials do not travel along all axons at the same speed. They travel faster in large-diameter axons than in small-diameter axons because the resistance to ionic current flow decreases as an axon's diameter gets bigger. They travel faster in myelinated than in nonmyelinated axons because they can move down the axon in short “jumps” (think of a kangaroo jumping down a path) (**Figure 45.12**). Invertebrates mostly depend on increased axon diameter for fast conduction, but vertebrates mostly depend on myelination of axons to increase conduction velocity.

Action potentials jump along myelinated axons

In vertebrate nervous systems, increasing the speed of action potentials by increasing the diameter of axons is not feasible because of the huge number of axons involved. Each of our eyes, for example, has about a million axons connecting it to the brain. These axons conduct action potentials at about the same speed as does the squid giant axon—about 20 meters per second—yet the diameter of each is 200 times smaller than the squid axon's diameter. Imagine having optic tracts 200 times bigger. A different way of increasing conduction velocity of axons has evolved in vertebrates, and that adaptation is myelination.

When glia wrap around axons, they cover the axons with concentric layers of myelin (see **Figure 45.3**). However, they leave regularly spaced gaps called **nodes of Ranvier**, where the axon is not covered (see **Figure 45.12**). The leakage of ions across the regions of the plasma membrane that are wrapped in myelin is reduced, so ionic electric current can spread farther

45.12 Saltatory Action Potentials Action potentials “jump” from node to node in myelinated axons, allowing faster transmission of information.

along the inside of a myelinated axon than it can along a nonmyelinated axon. Additionally, voltage-gated ion channels are clustered at the nodes of Ranvier. Thus an axon can fire action potentials only at nodes, and those action potentials cannot be propagated through the adjacent patch of membrane covered with myelin. The positive charges that flow into the axon at the node do, however, flow down the inside of the axon in the form of ionic electric current. When the current reaches the next node, the plasma membrane at that node is depolarized to threshold and fires another action potential. Action potentials therefore jump from node to node along the axon.

The speed of conduction is increased in these myelin-wrapped axons because ionic electric current flows much faster through the cytoplasm than ion channels can open and close. This form of rapid impulse propagation is called **saltatory conduction** (Latin *saltare*, “to jump”).

RECAP 45.2

Neurons have membrane potentials due to ionic concentration differences across their membranes and because leak channels make the membrane differentially permeable to ions. Changes in ion channel permeabilities cause graded changes in membrane potentials. Sudden openings and closings of gated ion channels in the membrane produce action potentials. Action potentials are rapid, all-or-none changes in membrane potential that are conducted along axons from the cell body to the axon terminals.

- How are membrane resting potentials generated and altered? See pp. 928–929 and Figures 45.6 and 45.9
- What does the Nernst equation calculate, and why does that calculation not equal the measured resting potential of a membrane? See p. 929 and Figure 45.7
- How are action potentials generated? See pp. 932–934 and Figure 45.10
- How are action potentials transmitted along axons? See pp. 934–936 and Figures 45.11 and 45.12

Having described how action potentials are generated and transmitted along axons, we will next address the question of what happens when an action potential reaches the axon terminal. How is its signal communicated to the next cell—which could be another neuron, a muscle cell, or a secretory cell?

45.3

How Do Neurons Communicate with Other Cells?

Neurons communicate with each other and with other cells at synapses. In **electrical synapses**, which are common among invertebrates, the action potential spreads directly from presynaptic to postsynaptic cell. The most common type of synapse in the vertebrate nervous system is the **chemical synapse**, in which neurotransmitters released from a presynaptic cell induce changes in a postsynaptic cell. We will begin this section with a discussion of the synapses between neurons and muscle cells. We will then consider the diversity in synapses and how they integrate information.

The neuromuscular junction is a model chemical synapse

Neuromuscular junctions are synapses between neurons and skeletal muscle cells. They are excellent models for how chemical synaptic transmission works. Like other neurons, a motor neuron has only one axon, but that axon can branch into numerous axon terminals that form many synapses with muscle cells. At each axon terminal an enlarged knob or buttonlike structure contains vesicles filled with neurotransmitter molecules. The neurotransmitter used by all vertebrate neuromuscular synapses is **acetylcholine (ACh)**. ACh is released by exocytosis when the membrane of a vesicle fuses with the presynaptic membrane of the axon terminal.

Where does the neurotransmitter come from? Some neurotransmitters, such as ACh, are synthesized in the axon terminal and packaged in vesicles. The enzymes required for ACh

biosynthesis, however, are produced in the cell body of the motor neuron and are transported along microtubules down the axon to the terminals. In contrast, peptide neurotransmitters are produced in the cell body and packaged into membrane-bound vesicles by the Golgi apparatus. These vesicles are transported down the axon to the terminals.

The postsynaptic membrane of the neuromuscular junction is a modified part of the muscle cell plasma membrane called a **motor end plate**. It appears as a depression in the muscle cell membrane, and the terminals of the motor neuron sit in the depression. The space between the presynaptic membrane and the postsynaptic membrane is the **synaptic cleft**, which in chemical synapses is about 20 to 40 nanometers wide. ACh released into the cleft by the presynaptic cell diffuses across to the postsynaptic membrane (**Figure 45.13**).

The arrival of an action potential causes the release of neurotransmitter

Neurotransmitter is released when an action potential arrives at the axon terminal and causes the opening of voltage-gated Ca^{2+} channels in the presynaptic membrane. Because the Ca^{2+} concentration is greater outside the cell than inside, Ca^{2+} enters the axon terminal. This increase in Ca^{2+} inside the axon terminal causes the vesicles containing neurotransmitter to fuse with the presynaptic membrane and empty their contents into the synaptic cleft.

In neuromuscular synapses, vesicle fusion and emptying is all-or-none. The vesicle membrane is incorporated into the presynaptic membrane, which actually gets larger as a result—at least until the extra membrane is recycled through endocytosis. The membrane is reprocessed by the cell into new vesicles that are refilled with neurotransmitter.

Synaptic functions involve many proteins

The description above of the release of neurotransmitter from the presynaptic membrane may seem simple, but it involves hundreds of proteins that are responsible for various aspects of the process: vesicle formation, transport of neurotransmitter into vesicles, anchoring of vesicles to cytoskeletal elements, docking of the vesicles with the presynaptic membrane, fusion of the vesicular and cell membranes, and endocytosis of the vesicle membrane for recycling.

Some of these proteins are the targets of toxins. For example, botulinum and tetanus toxins from bacteria of the genus *Clostridium* act on several of the proteins necessary for the docking of vesicles to the presynaptic membrane, resulting in diseases that are frequently fatal. Botulinum toxin impairs muscle contraction, whereas tetanus toxin causes uncontrolled muscle contraction. Poisons can become medicines, however. Botulinum toxin (in the form of Botox®) is used therapeutically to subdue muscle spasms and cosmetically to subdue wrinkles.

The postsynaptic membrane responds to neurotransmitter

When acetylcholine is released at a synapse, some of it diffuses across the synaptic cleft and binds to ACh receptors on the postsynaptic membrane (**Figure 45.14**). The postsynaptic

membrane of the motor end plate is highly folded. ACh receptors are on the crests of the folds, and voltage-gated cation channels are at the bottoms of the folds and in the surrounding muscle cell membrane (see Figure 45.13). The ACh receptors are chemically gated channels that allow both Na^+ and K^+ to flow through, but since the electrochemical gradients favor a net influx of Na^+ , the response of the motor end plate to ACh is to depolarize. That graded potential reflecting the number of receptors activated spreads to the depths of the folds of the motor end plate membrane and to surrounding muscle cell membrane, which contain voltage-gated Na^+ channels.

45.14 Acetylcholine Receptors ACh receptors are chemically gated ion channels found in the motor end plate and other types of postsynaptic membranes. When one of these receptors binds ACh, its channel pore opens and Na^+ moves into the postsynaptic cell, depolarizing its membrane. The enzyme acetylcholinesterase (AChE) breaks down ACh in the synapse, closing the channel. The breakdown products (acetate and choline) are then taken up by the presynaptic membrane and resynthesized into more ACh.

45.15 The Postsynaptic Neuron Sums Information

Individual neurons sum excitatory and inhibitory postsynaptic potentials over space (A) and time (B). When the sum of the potentials depolarizes the axon hillock to threshold, the neuron generates an action potential.

If the axon terminal of a motor neuron releases sufficient amounts of ACh to depolarize a motor end plate, that spreading depolarization activates the voltage-gated Na^+ channels and causes the firing of an action potential. This action potential is then conducted throughout the muscle cell's system of membranes, causing the cell to contract. We will discuss the contraction of muscle cells in greater detail in Section 48.1.

How much neurotransmitter is enough? Neither a single ACh molecule nor the contents of an entire vesicle (about 10,000 ACh molecules) will bring the membrane of a muscle cell to threshold. However, a single action potential in an axon terminal releases the contents of about 100 vesicles—more than enough to fire an action potential in the muscle cell and cause it to contract.

 **Go to Animated Tutorial 45.4**
Neurons and Synapses
Life10e.com/at45.4

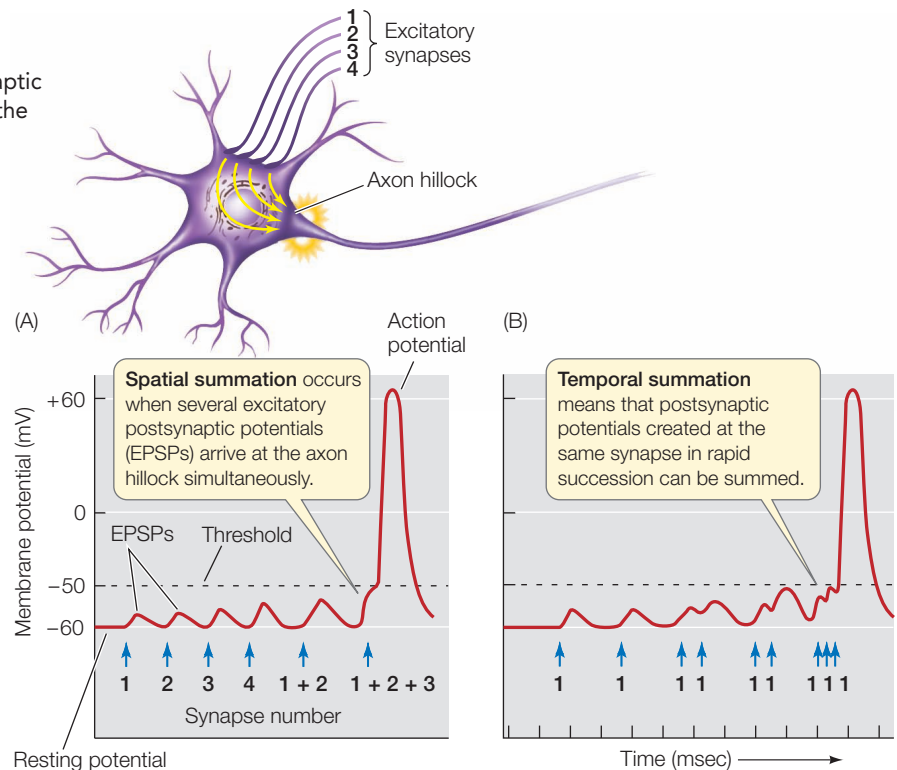

Synapses can be excitatory or inhibitory

In vertebrates, the synapses between motor neurons and muscle cells are always excitatory; that is, motor end plates always respond to ACh with a graded potential that is less negative than the resting potential (depolarization). However, synapses between neurons are frequently inhibitory; such a synapse causes hyperpolarization of the postsynaptic membrane. For example, recall that there are more chloride ions (Cl^-) outside the cell than inside it. If the receptors on the postsynaptic membrane open Cl^- channels, Cl^- ions enter the postsynaptic cell and hyperpolarize it. Hyperpolarization takes the membrane farther from the threshold potential for the voltage-gated Na^+ channels, and therefore makes it less likely that the cell will fire action potentials.

Recall that most neurons have many dendrites. Axon terminals from many other neurons can form synapses with those dendrites and with the cell body. The axon terminals of different presynaptic neurons can store and release different neurotransmitters, and the plasma membrane of the dendrites and cell body of a postsynaptic neuron can have receptors for a variety of neurotransmitters. The mix of synaptic activity impinging on a cell will cause it to have a graded membrane potential that can be either more positive or more negative than its resting potential.

The postsynaptic cell sums excitatory and inhibitory input

What determines when an individual neuron will fire an action potential? As we just learned, the sum of excitatory and inhibitory postsynaptic potentials creates a graded membrane potential in the postsynaptic cell body. This summation ability is

the major mechanism by which the nervous system integrates information. Each neuron receives 1,000 or more synaptic inputs, but it has only one output: an action potential in a single axon. At any one time, the information from all of the active inputs is translated into the rate at which that neuron generates action potentials in its axon.

For most neurons, summation takes place in the axon hillock at the base of the axon. The plasma membrane of the axon hillock is not insulated by glia and has many voltage-gated Na^+ channels. Excitatory and inhibitory postsynaptic potentials from synapses anywhere on the dendrites or the cell body spread to the axon hillock by local current flow. If the resulting graded potential depolarizes the axon hillock to threshold, it fires an action potential. Because postsynaptic potentials decrease in strength as they spread from the site of the synapse, a synapse at the tip of a dendrite has less influence than a synapse on the cell body, near the axon hillock.

Excitatory and inhibitory postsynaptic potentials are summed over space and over time. **Spatial summation** adds up the simultaneous influences of synapses at different sites on the postsynaptic cell (**Figure 45.15A**). **Temporal summation** adds up postsynaptic potentials generated at the same site in a rapid sequence (**Figure 45.15B**).

Synapses can be fast or slow

Most neurotransmitter receptors induce changes in postsynaptic cells by opening or closing ion channels. How they do so is the basis for grouping receptors into two general categories:

- **Ionotropic receptors** are themselves ion channels. Neurotransmitter binding to an ionotropic receptor causes a direct change in ion movement across the plasma membrane of the postsynaptic cell. These proteins enable fast, short-lived responses.

The ACh receptor of the motor end plate is an example of an ionotropic receptor. Each of its five subunits extends through the plasma membrane. When assembled, the subunits create a central pore that allows ions to pass through (see Figure 45.14). Of several different kinds of subunit, only one kind has the ability to bind ACh. Each functional receptor has two ACh-binding subunits and three other subunits.

- **Metabotropic receptors** are not ion channels, but they induce signaling cascades in the postsynaptic cell that secondarily lead to changes in ion channels (see Figure 7.10A). Postsynaptic cell responses mediated by metabotropic receptors are generally slower and longer-lived than those induced by ionotropic receptors.

Metabotropic receptors are also transmembrane proteins, but instead of acting as ion channels, they initiate an intracellular signaling process that results in the opening or closing of an ion channel and other changes in the postsynaptic cell.

Electrical synapses are fast but do not integrate information well

Electrical synapses are different from chemical synapses because they couple neurons electrically. Electrical synapses contain numerous gap junctions. At these synapses, the presynaptic and postsynaptic cell membranes are separated by a space of only 2 or 3 nanometers, and membrane proteins called connexins link the two neurons by forming pores that connect the cytoplasm of the two cells (see Figure 7.19A). Ions and small molecules can pass directly from cell to cell through these pores. Transmission at electrical synapses is very fast and can proceed in either direction, whereas transmission at chemical synapses is slower and unidirectional.

Electrical synapses are less common in the nervous systems of vertebrates than are chemical synapses for several reasons. First, electrical continuity between neurons does not allow temporal summation of synaptic inputs. Second, an effective electrical synapse requires a large area of contact between the presynaptic and postsynaptic cells. This condition rules out the possibility of thousands of synaptic inputs to a single neuron—which is the norm in complex nervous systems. Third, electrical synapses cannot be inhibitory. Thus electrical synapses are useful for rapid communication, but they are less useful for processes of integration and learning.

The action of a neurotransmitter depends on the receptor to which it binds

More than 100 neurotransmitters are now recognized, and more will surely be discovered. ACh, as we have seen, is an important neurotransmitter because it is how the nervous system commands muscles to contract. ACh also plays roles in certain synapses between neurons in the brain, but it accounts for only a small percent of the total neurotransmitter content of the brain.

The workhorse neurotransmitters of the brain are three simple amino acids: glutamate, which is excitatory, and glycine and γ -aminobutyric acid (GABA), which are inhibitory. The integration of information at the cellular level is a balance between excitation and inhibition, so it is understandable that

INVESTIGATINGLIFE

45.16 Reducing Neuronal Inhibition May Enhance Learning

Learning and memory in mice can be studied using the “novel object recognition task” described in the method below. Genetically engineered mice that are models for Down syndrome (i.e., the genes known to be present on human chromosome 21 have been triplicated in the mouse) cannot perform this task. Treatment of these model mice with a drug that partially blocks GABA receptors (GABA being an inhibitor of synaptic transmission) appears to increase their ability to learn.^a

HYPOTHESIS Excessive inhibition of neurons by GABA impairs learning ability in a mouse model of Down syndrome.

- Method**
1. Place the mouse in arena with two objects and allow them to explore and investigate; remove mouse.
 2. After 24 hours, change one of the two objects and return the mouse to the arena. Compare the amount of time the mouse spends with the old versus the novel object. If the mouse spends more time with the novel object, it remembers the old object (has “learned”).
 3. Repeat the experiment with normal and Down syndrome mice before and after the subject mice are treated with a drug that blocks GABA receptors (GABA_R).

Results

CONCLUSION Blocking GABA receptors improved learning capacity in the Down syndrome model mice.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

^aFernandez, F. et al. 2007. *Nature Neuroscience* 10: 411–413.

excessive inhibition such as we saw in the Down syndrome mice described at the start of this chapter could impair an animal’s ability to process and integrate new information. Indeed, when GABA’s inhibitory action in these mice was reduced by a drug that blocks the GABA receptor, the learning ability of the mice increased (**Figure 45.16**).

Another important group of neurotransmitters in the brain is the monoamines, which are derivatives of amino acids. They

include dopamine and norepinephrine (derivatives of tyrosine) and serotonin (a derivative of tryptophan). Peptides also function as neurotransmitters; for example, endorphins and enkephalins are the body's opiates and modulate the sensation of pain. Another peptide, substance P, transmits pain sensations. Even a gas, nitric oxide, is used by neurons as an intercellular messenger (see Figure 7.15).

Neurotransmission is complex in part because each neurotransmitter has multiple receptor types. ACh, for example, has two receptor types: nicotinic receptors, which are ionotropic; and muscarinic receptors, which are metabotropic. Both types of ACh receptors are found in the brain and spinal cord, where nicotinic receptors tend to be excitatory and muscarinic receptors tend to be inhibitory. ACh actions can differ outside the brain and spinal cord as well. ACh acting through nicotinic receptors causes the smooth muscle of the gut to increase its motility, but ACh acting through muscarinic receptors causes cardiac muscle to hyperpolarize and therefore to slow down. There are many more examples of neurotransmitters that have different effects in different tissues, but the important thing to remember is that the action of a neurotransmitter depends on the receptor to which it binds. In addition, keep in mind that turning neurotransmitter action off is as important as turning it on.

Go to Activity 45.1 Neurotransmitters
Life10e.com/ac45.1

To turn off responses, synapses must be cleared of neurotransmitter

If released neurotransmitter molecules simply remained in the synaptic cleft, the postsynaptic membrane would become saturated and receptors would be constantly activated. The postsynaptic cell would remain hyperpolarized or depolarized and would be unresponsive to short-term changes in the presynaptic cell. The more rapidly neurons can respond to input, the more information they can process in a given amount of time. Thus neurotransmitter must be cleared from the synaptic cleft shortly after it is released by the axon terminal.

Neurotransmitter action can be terminated in several ways. First, enzymes may destroy the neurotransmitter. Acetylcholine, for example, is rapidly destroyed by the enzyme acetylcholinesterase (AChE), which is present in the synaptic cleft in close association with ACh receptors on the postsynaptic membrane (see Figure 45.14). When AChE is inhibited, ACh lingers in the synaptic cleft, causing spastic (contracted) muscle paralysis and usually resulting in death. Some of the most deadly nerve gases developed for chemical warfare work by inhibiting AChE. Some agricultural insecticides, such as malathion, also inhibit AChE and can poison farm workers if used without safety precautions.

Neurotransmitter can also simply diffuse away from the cleft, or be taken up via active transport by nearby cell membranes, most notably glial cell membranes. The antidepressant drug commonly prescribed under the brand name Prozac slows the reuptake of the neurotransmitter serotonin, thus enhancing serotonin's activity at the synapse.

The diversity of receptors makes drug specificity possible

Many drugs used to treat the nervous system act by modulating specific synaptic interactions. Drugs that mimic or potentiate the effect of a neurotransmitter are called **agonists**; those that block the actions of neurotransmitters are called **antagonists**. For example, morphine is an agonist at the endorphin receptor and therefore blocks pain. Propranolol, a widely used β -blocker, is an antagonist of certain adrenergic receptors and therefore decreases panic attacks and anxiety. A major emphasis in neurobiology is to identify neurotransmitter receptor subtypes and design drugs that selectively bind to them to have highly specific effects on nervous system activity.

RECAP 45.3

Chemical synapses involve the release of neurotransmitter molecules stored in vesicles in the presynaptic terminal. Action potentials reaching that terminal cause the fusion of vesicles with the presynaptic membrane, releasing neurotransmitter that can then bind to receptors on the postsynaptic membrane and influence its membrane potential. There is a great diversity of neurotransmitters and their receptors.

45.4

How Are Neurons and Glia Organized into Information-Processing Systems?

Nervous systems can process information because their neurons are organized into **neural networks**. These networks include three functional categories of neurons, which can be thought of as being involved with input, output, and integration:

- **Afferent neurons** carry sensory information into the nervous system. That information comes from specialized sensory cells that transduce (convert) various kinds of sensory stimuli (e.g., light, heat, pressure) into action potentials.
- **Efferent neurons** carry commands to physiological and behavioral effectors such as muscles and glands.
- **Interneurons** integrate and store information and communicate between afferent and efferent neurons.

Nervous systems range in complexity

Simple animals such as cnidarians (sea anemones, for example) process information with a limited number of simple neural networks that do little more than provide direct lines of communication from sensory cells to effectors; there is little or no integration or processing of signals (**Figure 45.17A**). The

(A) Sea anemone

A **nerve net** serves simple behaviors such as contraction and relaxation.

(B) Earthworm

In the earthworm, **ganglia** in each segment coordinate movement, and anterior ganglia control more complex behavior.

(C) Squid

In squid, more complex behaviors are served by collections of neurons in specialized ganglia that process and integrate information.

(D) Human

The human brain and spinal cord are the **central nervous system**...

...which communicates to the cells and organs of the body via the **peripheral nervous system**.

cnidarian's **nerve net** is most developed around the tentacles and the oral opening, where it facilitates detection of food or danger and causes tentacles to extend or retract.

Animals that are more complex and move about in search of food and mates must process and integrate larger amounts of information. Even earthworms fit this description, and their increased need for information processing is met by higher numbers of neurons organized into clusters of neuronal cell bodies called **ganglia** (singular *ganglion*). Ganglia serving different functions may be distributed around the body, as in earthworms and squid (Figure 45.17B,C). In animals that are

45.17 Nervous Systems Vary in Size and Complexity In animal species with increasingly complex sensory and behavioral abilities, information processing is increasingly centralized in ganglia (collections of neurons) or in a brain.

bilaterally symmetrical, ganglia frequently come in pairs, one on each side of the body. Also, as animals increase in complexity, some ganglia may become enlarged or fused together at the anterior end, forming a **brain**. Small nervous systems of invertebrates can be remarkably complex. Consider the nervous systems of spiders, which have programmed within them the thousands of precise movements necessary to construct an intricate web without prior experience or opportunities to learn the specific web architecture of their species.

In vertebrates, most cells of the nervous system are found in the **central nervous system (CNS)**. The CNS includes the brain and the spinal cord, which are the sites of most information processing, storage, and retrieval (Figure 45.17D). Information is transmitted from sensory cells to the CNS and from the CNS to effectors via neurons that extend or reside outside the brain and the spinal cord. These sensory and effector neurons and their supporting cells are the **peripheral nervous system (PNS)**.

The spinal cord conducts information in both directions between the brain and the peripheral neurons of the body's organs. Neural networks integrate information coming from the peripheral nervous system and issue motor commands. An example of an information-processing network in humans is the spinal knee-jerk reflex.

The knee-jerk reflex is controlled by a simple neural network

A cross section of the human spinal cord reveals a central area of gray matter in the shape of a butterfly, surrounded by an area of white matter (see Figure 45.18). In the nervous system, **gray matter** is rich in neural cell bodies, and **white matter** contains myelinated axons. The gray matter of the spinal cord contains the cell bodies of the spinal neurons; the white matter contains myelinated axons that conduct information up and down the spinal cord.

45.18 A Neural Network in the Spinal Cord

Generates the Knee-Jerk Reflex Sensory (afferent) information enters the spinal cord through the dorsal horns (red pathway), and motor (efferent) output leaves it via the ventral horns (blue pathways). Information travels to the brain in white matter tracts. Interneurons make connections within the spinal cord that result in a complex, coordinated behavior pattern.

Go to Animated Tutorial 45.5
Information Processing in the Spinal Cord
Life10e.com/at45.5

Spinal nerves extend from the spinal cord at regular intervals on each side. Each spinal nerve has two roots, one connecting with the dorsal horn of the gray matter, the other with the ventral horn. The afferent (sensory) axons in a spinal nerve enter the spinal cord through the dorsal root, and the efferent (motor) axons leave through the ventral root. The conversion of afferent to efferent information in the spinal cord without participation of the brain is called a **spinal reflex**. The neural network involved in one such spinal reflex—the “knee-jerk”—is diagrammed in **Figure 45.18**. The stimulus for this particular reflex is a tap on the knee with a small mallet. That tap stretches the tendon going over the knee, which attaches the muscle of the upper leg to bone in the lower leg. Stretching the tendon stretches muscle fibers in the upper leg, and stretch receptors in that muscle transduce the physical stimulus into action potentials. The action potentials are then conducted by a sensory neuron into the dorsal horn of the spinal cord. That sensory neuron goes all the way to the ventral horn and synapses onto a motor neuron, which fires action potentials. The axon of that motor neuron travels out through the ventral horn of the spinal cord and extends all the way to the same muscle that initially was stretched, causing that muscle to contract.

The function of this simple circuit is to sense an increased load on the muscle and to increase the strength of its contraction to compensate for that additional load. Because there is only one synapse between the afferent and efferent neurons in this simple network, it is called a monosynaptic reflex; most

spinal networks are more complex. For example, limb movement is controlled by antagonistic sets of muscles that work against each other. When one member of an antagonistic set of muscles contracts, it bends (flexes) the limb; it is therefore called a flexor. The antagonist muscle, the extensor, straightens (extends) the limb. For a limb to move, one muscle of the pair must relax while the other contracts. Thus sensory input that activates the motor neuron of one muscle also inhibits its antagonist. This coordination is achieved by an interneuron, which makes an inhibitory synapse onto the motor neuron of the antagonistic muscle (see Figure 45.18). Thus the reciprocal inhibition of antagonistic muscles involves an interneuron between the sensory cell and the motor neuron of the inhibited muscle, and therefore at least two synapses.

The withdrawal reflex is an example of a polysynaptic spinal reflex that involves many interneurons. When you step on a tack, you immediately pull back your foot: the tack stimulates pain receptors in the foot, and the sensory neurons transmit action potentials into the dorsal horn of the spinal cord on the same side of the body. In the dorsal horn, these neurons synapse with interneurons that send information through their axons to the brain, resulting in the conscious sensation of pain. Before the brain is aware of the pain, however, synapses of the sensory neurons with other interneurons stimulate and inhibit a variety of different motor neurons in the spinal cord. Interneurons on the same side of the spinal cord coordinate the activity of the muscles that withdraw the foot and leg. To

45.19 Brains Vary in Size and Complexity The brains of four vertebrate species—all of which may have a similar body mass—show immense differences. Note that the brainstem, which is involved in physiological regulation and stereotypic behavior, differs less among these species than does the cerebrum, which is responsible for complex behavior and learning.

pull away, however, the other leg has to extend and balance must be shifted. The coordination of these actions involves interneurons that make connections across the spinal cord to motor neurons on the opposite side. Thus a rather complex suite of movements is coordinated by a network in the spinal cord. By extension, you can appreciate how much more complex a neural network is required to enable you to execute complex movements in time with music and coordinated with another person—in other words, to dance.

The vertebrate brain is the seat of behavioral complexity

Vertebrates differ greatly in their behavioral complexity and in their physiological specializations, and their neural networks reflect this diversity. **Figure 45.19** shows the brains of four vertebrate species of similar body mass drawn to the same scale.

The human nervous system contains an estimated 10^{11} neurons. A given neuron in the brain can have 1,000 or more synapses. Thus the human brain can contain 10^{14} synapses (10^{11} neurons $\times 10^3$ synapses per neuron). Then there are the glia. A single astrocyte might participate in 100,000 synapses while at the same time monitoring signals in the extracellular fluid and the blood. And beyond these numbers, synapses are not constant but can be highly plastic. They can increase or decrease in number and size, and they can become more or less sensitive.

This astronomical number of neurons and synapses is divided into thousands of distinct but interacting networks that function in parallel. The possible number of informational networks in the brain is almost infinite, and therein lies the incredible ability of the human brain to process information, to learn, to do complex tasks, to remember, and to have emotions.

RECAP 45.4

Nervous systems are composed of neural networks that include afferent neurons, interneurons, and efferent neurons. Nervous systems range in complexity from simple nerve nets to the human brain. The spinal knee-jerk reflex is an example of a simple neural network, but networks that control more complex behavior become increasingly complicated.

- What are ganglia, and why are they concentrated in the anterior region of many invertebrates? [See p. 941 and Figure 45.17](#)
- Explain the components of a spinal reflex network. How can the same stimulus cause contraction in one muscle and relaxation in another? [See p. 942 and Figure 45.18](#)

What causes overinhibition in the nervous system, and how can it be reduced?

ANSWER

Some neurotransmitter–receptor combinations excite activity in the postsynaptic neuron, depolarizing it and making it likely to fire an action potential. Other neurotransmitter–receptor combinations inhibit the responses of the postsynaptic cell. Neurons integrate information by summing excitatory and inhibitory synaptic inputs. Overinhibition in the nervous system can arise when too much inhibitory neurotransmitter (such as GABA) is released, or if postsynaptic cells have too many receptors for inhibitory neurotransmitters. Drugs that decrease the synthesis and release of the inhibitory neurotransmitter can reduce the inhibition, as can drugs that block the receptors for such neurotransmitters. In the case of the Down syndrome model mice, drugs that blocked the GABA receptors that are also Cl^- channels reduced the level of inhibition in the mice nervous systems, apparently increasing the ability of the mice to learn and form memories.

45.1 What Cells Are Unique to the Nervous System?

- The cells of the nervous systems include many types of **neurons** and **glia**.
- All neurons are **excitable**, which means they can generate and conduct electric signals called **action potentials**. Glia support and modulate the activities of neurons but do not generate action potentials.
- A neuron generally receives information via its **dendrites**, of which there can be many, and transmits information via its single **axon**, which ends in **axon terminals**. **Review Figure 45.1**
- Where neurons and their target cells meet, information is transmitted across specialized junctions called **synapses**.
- Glia include **Schwann cells** and **oligodendrocytes**, both of which generate **myelin** sheets on axons. Glia also include **astrocytes**, which support neurons metabolically, modulate synaptic signaling, and contribute to the **blood–brain barrier**. **Review Figures 45.3, 45.4**

45.2 How Do Neurons Generate and Transmit Electric Signals?

- Neurons have an electric charge difference across their plasma membranes, the **membrane potential**. The membrane potential is created by ion transporters and channels. When a neuron is not firing action potentials, its membrane potential is referred to as the **resting potential**. **Review Figures 45.5, 45.6, ANIMATED TUTORIAL 45.1**
- The **sodium–potassium pump** concentrates K^+ on the inside of a neuron and Na^+ on the outside. Potassium leak channels allow K^+ to diffuse out of the neuron, leaving behind unbalanced negative charges. **Review Figures 45.6, 45.7**
- **Patch clamping** allows the study of single ion channels. **Review Figure 45.8**
- The resting potential is perturbed when ion channels open or close, changing the permeability of the plasma membrane to charged ions. Through this mechanism, the plasma membrane can become **depolarized** or **hyperpolarized** and therefore have a **graded membrane potential** response to input. **Review Figure 45.9**
- An action potential results from a rapid reversal in charge across a portion of the plasma membrane resulting from the sequential opening and closing of voltage-gated Na^+ and K^+ channels. These changes in voltage-gated channels occur when the plasma membrane depolarizes to a **threshold** level. **Review Figure 45.10, ANIMATED TUTORIAL 45.2**
- Action potentials are all-or-none, self-regenerating events. They are conducted down axons because local current flow depolarizes adjacent regions of membrane and brings them to threshold. **Review Figure 45.11**
- In myelinated axons, action potentials appear to jump between **nodes of Ranvier**, areas of axonal plasma membrane that are not covered by myelin. **Review Figure 45.12**

45.3 How Do Neurons Communicate with Other Cells?

- Neurons communicate with each other and with other cell types by transmitting information over **electrical synapses** or by the transmission of molecular signals called **neurotransmitters** over **chemical synapses**.
- The **neuromuscular junction** is a well-studied chemical synapse between a motor neuron and a skeletal muscle cell. Its neurotransmitter is **acetylcholine (ACh)**, which causes depolarization of the postsynaptic membrane when it binds to its receptor at the **motor end plate**. **Review Figure 45.13, ANIMATED TUTORIAL 45.3**
- When an action potential reaches an axon terminal, it causes the release of neurotransmitters, which diffuse across the **synaptic cleft** and bind to receptors on the postsynaptic membrane. **Review Figures 45.13, 45.14, ANIMATED TUTORIAL 45.4**
- Synapses between neurons can be either excitatory or inhibitory. A postsynaptic neuron integrates information by summing excitatory and inhibitory postsynaptic potentials in both spatially and temporally. **Review Figure 45.15**
- **Ionotropic receptors** are ion channels or directly influence ion channels. **Metabotropic receptors** influence the postsynaptic cell through various signal transduction pathways and can result in the opening or closing of ion channels. The actions of ionotropic synapses are generally faster than those of metabotropic synapses.
- There are many different neurotransmitters and even more types of receptors. The action of a neurotransmitter depends on the type of receptor to which it binds. **See ACTIVITY 45.1**
- Neurotransmitter molecules cannot be allowed to accumulate in a synapse but must be cleared in order to turn off responses in the postsynaptic cell. This may be done by enzymatic degradation, simple diffusion, or reuptake of the neurotransmitter.

45.4 How Are Neurons and Glia Organized into Information-Processing Systems?

- In vertebrates, the brain and spinal cord form the **central nervous system (CNS)**, which communicates with the rest of the body via the **peripheral nervous system (PNS)**. The CNS increases in complexity from invertebrates to vertebrates and from fish to mammals. **Review Figures 45.17, 45.19**
- **Neural networks** include **afferent neurons** and **efferent neurons**, generally connected through **interneurons**.
- A **spinal reflex** is an example of a simple neural network that integrates information and controls a response. **Review Figure 45.18, ANIMATED TUTORIAL 45.5**

CHAPTER REVIEW

REMEMBERING

1. The rising phase of an action potential is due to the
 - a. closing of K^+ channels.
 - b. opening of chemically gated Na^+ channels.
 - c. closing of voltage-gated Ca^{2+} channels.
 - d. opening of voltage-gated Na^+ channels.
 - e. spread of positive current along the plasma membrane.
2. Which statement about synaptic transmission is *not* true?
 - a. The synapses between neurons and skeletal muscle cells use ACh as their neurotransmitter.
 - b. A single vesicle of neurotransmitter can cause a muscle cell to contract.
 - c. The release of neurotransmitter at the neuromuscular junction causes the motor end plate to depolarize.
 - d. In vertebrates, the synapses between motor neurons and muscle fibers are always excitatory.
 - e. Inhibitory synapses cause the resting potential of the postsynaptic membrane to become more negative.
3. Which statement accurately describes an action potential?
 - a. Its magnitude increases along the axon.
 - b. Its magnitude decreases along the axon.
 - c. All action potentials in a single neuron are of the same magnitude.
 - d. During an action potential, the membrane potential of a neuron remains constant.
 - e. An action potential permanently shifts a neuron's membrane potential away from its resting value.
4. Graded membrane potentials
 - a. can be hyperpolarizing.
 - b. can be depolarizing.
 - c. integrate the many synaptic inputs to a cell.
 - d. are important means of summing sensory inputs.
 - e. All of the above
5. The binding of an inhibitory neurotransmitter to the postsynaptic receptors of a neuron at its resting potential results in
 - a. depolarization of the membrane.
 - b. generation of an action potential.
 - c. hyperpolarization of the membrane.
 - d. increased permeability of the membrane to sodium ions.
 - e. increased permeability of the membrane to calcium ions.

UNDERSTANDING & APPLYING

6. If you stimulate an axon in the middle, action potentials are conducted in both directions. Yet when an action potential is generated at the axon hillock, it goes only toward the axon terminals and does not backtrack. Explain why action potentials are bidirectional in the first example and unidirectional in the second.
7. How does a neuron integrate excitatory and inhibitory synapses?

ANALYZING & EVALUATING

8. Benzodiazepines are drugs that potentiate the effects of GABA on its receptor. What effects might you expect to observe in a person taking these drugs?
9. The language of the nervous system consists of one "word," the action potential. How can this single word convey a diversity of information? How can that information be quantified, and how can it be integrated?

CHAPTER OUTLINE

- 46.1** How Do Sensory Receptor Cells Convert Stimuli into Action Potentials?
- 46.2** How Do Sensory Systems Detect Chemical Stimuli?
- 46.3** How Do Sensory Systems Detect Mechanical Forces?
- 46.4** How Do Sensory Systems Detect Light?

A **RATTLESNAKE** can see to strike a running rodent in complete darkness. How can this be, when “seeing” means using the eyes to detect light waves, and “complete darkness” means no light? It is possible because these definitions are based on human capabilities. What we call “light” is actually only a small portion (red, orange, yellow, green, blue, indigo, and violet) of the spectrum of electromagnetic radiation. Other animals see wavelengths humans cannot. In Chapter 27 we saw that insects perceive patterns on flowers that reflect ultraviolet wavelengths invisible to humans. Similarly, rattlesnakes “see” infrared wavelengths that we cannot (although at high enough levels of intensity, humans feel infrared wavelengths as heat).

It is not the snake’s eyes that perceive infrared light. Rattlesnakes and their relatives have pit organs located between the nostril and the eye on each side of the skull that contain high densities of infrared-sensitive neurons. The two pits are positioned in such a way that sensory receptor cells in the pits receive directional information. The fields of “view” of the bilateral pits are overlapping and thus convey a three-dimensional perspective. Information from the pit organs goes to the same region of the brain as information from the eyes, so rattlesnakes actually do “see” the world in a range of electromagnetic radiation that is different from the human visual spectrum.

Our definition of silence is as arbitrary as our definition of darkness. “Sound” is actually pressure waves in the environment, and many animals are sensitive to pressure waves with frequencies, or pitches, we cannot

Sensing Infrared Radiation The “hole” to the right of this diamondback rattlesnake’s eye is one of its bilateral pit organs. Pit organs detect infrared radiation from the snake’s preferred prey—small rodents—with unerring precision, even in total darkness. The forked tongue also provides positional information, picking up molecular signals that are transmitted to the brain by a specialized organ in the roof of the snake’s mouth.

hear. Elephants communicate using sound waves that are below human hearing range; such long waves travel great distances, an advantage to large animals that roam over extensive areas. Bats emit incredibly loud, brief sound pulses that are above our range of hearing. A flying bat hears echoes of these pulses bouncing off objects in the environment. The pulses are so loud and the echoes so weak that it is rather like a construction worker trying to overhear a whispered conversation while using a pneumatic drill.

“Reality” is what our eyes see, our ears hear, our noses smell, and what we touch and taste. But human beings sense only a limited range of the information available. Animals with different ranges of sensitivity process different sources of information and may perceive “reality” quite differently.

How can bats emit loud pulses of sound and not be deaf to the faint echoes that return within milliseconds?

See answer on p. 963.

46.1 How Do Sensory Receptor Cells Convert Stimuli into Action Potentials?

Sensory receptor cells, usually simply called **sensors** or **receptors**, transduce (convert) physical and chemical stimuli such as light and sound waves, pressure (touch), and odorant and taste molecules into neural signals. These signals are then transmitted to the central nervous system (CNS) for processing and interpretation. The first step in this process of **sensory transduction** is a change in the membrane potential of the receptor cell in response to a specific type of stimulus.

Sensory transduction involves changes in membrane potentials

Sensory transduction typically begins with a **receptor protein** that opens or closes ion channels in response to a specific stimulus such as heat, light, chemicals, mechanical force (including sound waves), or electric fields. The resulting change in ion flow alters the receptor cell's membrane potential. A change in the membrane potential of a receptor cell in response to a stimulus is called a **receptor potential**. Receptor potentials are *graded membrane potentials* that spread over only short distances. In order to signal over long distances in the nervous system, receptor potentials must generate action potentials, which they can do in two ways:

- The receptor potential may trigger action potentials in the receptor cell itself.
- The receptor potential may cause the receptor cell to release neurotransmitters that can induce a postsynaptic neuron to generate action potentials.

A good model of how a receptor cell generates action potentials is the **stretch receptor** of a crayfish (**Figure 46.1**). Stretching the muscle to which the stretch receptor is attached causes receptor potentials. These receptor potentials spread to the base of the cell's axon, where they generate action potentials that travel down the axon to the CNS. The rate at which action potentials are fired depends on the magnitude of the receptor potential; that magnitude, in turn, depends on how much the muscle is stretched.

In a receptor cell that does not fire action potentials (such as the photoreceptors in the vertebrate eye), the spreading receptor potential reaches a presynaptic patch of plasma membrane and induces the release of a neurotransmitter. The intensity of the stimulus influences how much neurotransmitter is released. That neurotransmitter binds to receptor proteins on an associated sensory neuron, altering its membrane potential and causing it to increase or decrease its rate of firing action potentials. In a few cases, this second cell also does not generate action potentials, but simply changes the rate at which it releases neurotransmitter onto another neuron. Eventually, however, the stimulation of a sensory cell is always coded as a change in firing of action potentials in a sensory circuit.

Sensory receptor proteins act on ion channels

Sensory receptor proteins respond to stimuli by directly or indirectly opening or closing ion channels in the sensory cell

46.1 Stimulating a Sensory Cell Produces a Receptor Potential

Signal transduction in the stretch receptor of a crayfish can be investigated by measuring the membrane potential at different places on the stretch receptor neuron while stretching the muscle innervated by that sensory neuron.

(**Figure 46.2**), leading either to an action potential or to the release of neurotransmitter. Section 45.3 noted that synaptic receptor proteins are either ionotropic or metabotropic; the same distinction can be applied to sensory receptor proteins. Ionotropic sensory receptor proteins are either ion channels themselves or directly affect the opening of an ion channel. Examples are receptors that respond to physical force (mechanoreceptors) and those that respond to temperature (thermoreceptors). Electrosensors most likely do not have receptor proteins, but they are grouped with the ionotropic receptors; the plasma membrane of electrosensory cells is sensitive to the voltage across it and releases neurotransmitter in response to slight changes in membrane potential.

Metabotropic sensory receptor proteins influence ion channels indirectly, through G proteins and second messengers as described in Chapter 7. Examples are most chemoreceptors and photoreceptors.

Sensation depends on which neurons receive action potentials from sensory cells

All sensory systems process information in the form of action potentials. But the sensations we perceive—heat, pressure, light, smell, sound—differ because the messages from different kinds of sensory cells arrive at different places in the central nervous system. Action potentials arriving in the visual cortex

46.2 Sensory Cell Membrane Receptor Proteins Respond to Stimuli The receptor proteins in mechanoreceptors are ion channels. The activated receptor proteins of metabotropic chemoreceptors and photoreceptors initiate signal transduction cascades that eventually open or close ion channels.

of the brain, for example, are interpreted as light, whereas those that arrive in the olfactory bulb are perceived as smells.

A small patch of skin on your arm contains some sensory receptor cells that increase their firing rates when the skin is warmed and others that increase their activity when the skin is cooled. Other sensory cells in the same patch of skin respond to touch, irritants such as insect bites, and painful stimuli. These receptor cells transmit their messages through axons that enter the CNS at the spinal cord. The synapses made by those axons in the spinal cord and the subsequent pathways of transmission determine whether the stimulation of the skin on your arm is perceived as warmth, cold, touch, itch, or pain; even though the action potentials carried by all of these sensory axons look the same, the connectivity of each axon is specific for a given sensory modality. The *intensity* of a given sensation is coded by the frequency of the action potentials.

Some sensory cells transmit information about the body's internal conditions of which we may not be consciously aware. The brain continuously receives information about body temperature, the concentrations of carbon dioxide and oxygen in the blood, arterial pressure, muscle tension, and the position of the limbs. All of this information is important for homeostasis but does not necessarily result in conscious sensation.

Some sensory receptor cells are assembled with other types of cells into **sensory organs**, such as eyes, ears, and noses, that enhance the ability of sensory cells to collect, filter, and amplify stimuli. **Sensory systems** include the sensory cells, their associated organs, and the neural networks that process the information.

Many receptors adapt to repeated stimulation

Some sensory cells give gradually diminishing responses to maintained or repeated stimulation. This phenomenon, known as **adaptation**, enables an animal to ignore background or

unchanging conditions while remaining sensitive to changes and new information. (Note that this use of the term "adaptation" is different from its application in an evolutionary context.) When you get dressed, you feel each item of clothing touch your skin, but the sensation of clothes touching your skin is not constantly on your mind throughout the day. You are immediately aware of new sensations, however, such as your shoe coming untied or someone touching your back.

Some sensory cells adapt very little or very slowly; examples are some types of pain receptors and the mechanoreceptors that control balance. You do not want to ignore pain, which usually is signaling that something is wrong in your body, and to maintain equilibrium you must continuously know (albeit unconsciously) the tensions and forces on all of your joints and muscles.

RECAP 46.1

Sensory receptor cells have receptor proteins that respond to specific stimuli from the external or internal environment by opening or closing ion channels, which results in the generation of action potentials in sensory neurons.

- What is the difference between ionotropic and metabotropic sensory receptor proteins? [See p. 947 and Figure 46.2](#)
- How are we able to perceive action potentials—all of which are essentially the same—as different sensations?

[See pp. 947–948](#)

Now that we have a general view of how sensory systems code and process information, we will next discuss how sensory systems gather and filter stimuli, transduce specific stimuli into action potentials, and transmit action potentials to the central nervous system, which perceives them in many different forms.

46.2 How Do Sensory Systems Detect Chemical Stimuli?

A colony of corals responds to a small amount of meat extract in seawater by extending their bodies and tentacles in search of food; a solution of a single amino acid can stimulate this response. Conversely, a small amount of seawater in which corals were crushed will stimulate a defensive retraction of the coral polyps. Humans also react strongly to certain chemical stimuli. When we smell freshly baked bread we salivate and feel hungry, whereas when we smell rotting meat we feel nauseated.

All animals receive information about chemical stimuli through **chemoreceptors**, which are receptor proteins that bind to specific molecules—their **ligands**—and are responsible for smell and taste. Chemoreceptors are also responsible for monitoring some aspects of the internal environment, such as the level of carbon dioxide in the blood.

Olfaction is the sense of smell

The sense of smell, **olfaction**, depends on chemoreceptors. In vertebrates the olfactory sensors are neurons embedded in a layer of epithelial tissue in the uppermost region of the nasal cavity. Axons from these neurons extend into the **olfactory bulb** (the olfactory integration area of the brain), whereas their dendrites end in olfactory cilia on the surface of the nasal epithelium. A protective layer of mucus covers the epithelium. Molecules from the environment must diffuse through this mucus to reach the receptor proteins on the olfactory cilia. When you have a cold, the amount of mucus in your nose increases, and the epithelium swells. With this in mind, study **Figure 46.3**, and you will easily understand why respiratory infections can cause you to lose your sense of smell.

An **odorant** is a molecule in the environment that binds to and activates an olfactory receptor protein on the cilia of **olfactory receptor neurons (ORNs)**. Different olfactory receptor proteins bind specific subsets of odorant molecules. An odorant molecule binding to its receptor on an ORN activates a G protein. The G protein then activates an enzyme that causes an increase of a second messenger (cAMP in vertebrates) in the cytoplasm (see Figure 7.17). The second messenger binds to and opens cation channels in the ORN's plasma membrane, causing an influx of Na^+ into the ORN—which then depolarizes to threshold and fires action potentials. An interesting feature of ORNs is that they are continuously regenerated. Because they are embedded in nasal epithelium that, like other epithelial linings, is regularly shed, ORNs have to be constantly replaced.

The olfactory world has an enormous number of odors and a correspondingly large number of olfactory receptor proteins. In the 1990s Linda Buck and Richard Axel discovered a family of about 1,000 genes in mice (about 3 percent of the mouse genome) that code for olfactory receptor proteins. Each receptor protein that is expressed is found in a limited number of ORNs in the olfactory epithelium, and each ORN expresses just one receptor type. Using a combination of patch clamping (see Figure 45.8) and molecular techniques, the investigators were able to match specific gene products with the odorants they detect. For their discoveries of the molecular nature of the olfactory system, Buck and Axel received the Nobel Prize in 2004.

Olfactory sensitivity enables discrimination of many more odorants than there are olfactory receptors. An odorant molecule can be quite complex, and different regions of that molecule may bind to different receptor proteins. The next stage of processing olfactory information is in the olfactory bulb, where axons from ORNs expressing the same receptor protein cluster

together on olfactory bulb neurons, forming structures called glomeruli (see Figure 46.3). A complex odorant molecule can activate a unique combination of glomeruli in the olfactory bulb, so an olfactory system with hundreds of different receptor proteins can discriminate an astronomically large number of smells. The more odorant molecules that bind to ORNs, the greater the frequency of action potentials and thus the greater the intensity of the perceived smell.

Humans have a sensitive olfactory system, but in comparison with most mammals we depend far more on vision than on olfaction. The nasal epithelium of a typical dog is 15 to 20 times larger than a human's and has about 1 billion odorant receptors, compared with about 20 million in the average human. For some scents, the threshold sensitivity of the dog is 100 million times lower; a dog's nose reveals a huge amount of information not available to people.

Some chemoreceptors detect pheromones

A specialized type of chemical signal used for communication among conspecifics (individuals of the same species) is called a **pheromone**. Individual animals secrete pheromone molecules into the environment, triggering behavioral responses in other individuals of the species. Pheromones may communicate alarm signals, mark food trails, or define territories, among many other uses. Their function in mating and mate attraction especially illustrates the remarkable sensitivity of chemosensory systems, and the silkworm moth *Bombyx mori* is an extensively studied example.

To attract a mate, the female silkworm moth releases a pheromone called bombykol from a gland at the tip of her abdomen (Figure 46.4A). The male silkworm moth has about 10,000 receptors for this molecule on each of his feathery antennae

(Figure 46.4B). A single molecule of bombykol may be sufficient to generate action potentials in the antennal nerve, which transmits the signal to the male's CNS. The extreme sensitivity of the male bombykol receptors ensures that the sexual message sent by a female moth is likely to reach any male within a huge downwind area. When approximately 200 hairs per second are activated, a male orients upwind in search of the female. Because the rate of firing in the male's sensory nerves is proportional to the concentration of bombykol in the air, he can follow an airborne concentration gradient to "home in" on the signaling female.

The vomeronasal organ contains chemoreceptors

The **vomeronasal organ (VNO)** is a small, paired tubular structure embedded in the nasal epithelium of amphibians, reptiles, and many mammals (although not humans). In mammals the VNO is located on the septum dividing the two nostrils (see Figure 53.3).

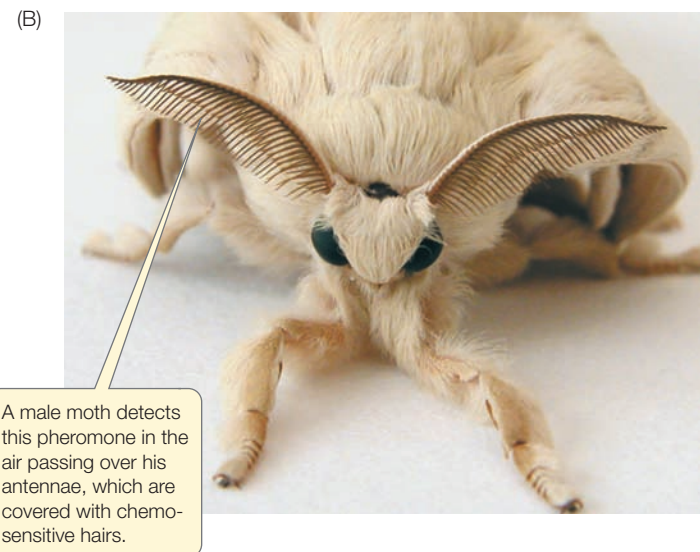

The vomeronasal organ has a pore that opens into the nasal cavity. When the animal sniffs, the VNO pulsates and draws a sample of nasal fluid over the chemoreceptors embedded in its walls. The information from these chemoreceptors goes to an accessory olfactory bulb in the brain, and from there to brain regions involved in sexual and other instinctive behaviors.

In snakes the VNO opens into the roof of the mouth cavity. Each time the snake's forked tongue darts in and out, the forks fit into the VNO openings and present the chemoreceptors located there with a sample of molecules from the surrounding air (see the chapter-opening photo). Thus the snake uses its tongue to smell its environment, not to taste it. Why doesn't the snake simply use the flow of air to and from its lungs, as we do, to smell the environment? In reptiles, air flows to and from

46.4 Pheromones Can Communicate over Great Distances

Mating in silkworm moths of the genus *Bombyx* is coordinated by a pheromone called bombykol.

the lungs slowly (and can even stop entirely for long periods of time), but the tongue can dart in and out rapidly. It is a quick source of olfactory information.

Studies on mice have led to the hypothesis that the mammalian VNO is a specialized olfactory organ that detects pheromones. Lawrence Katz and his colleagues at Duke University recorded the activity of neurons in the mouse accessory olfactory bulb, which receives input from chemosensors in the VNO. These accessory olfactory neurons were activated when a mouse attached to recording electrodes sniffed another mouse placed in the same cage. However, the neurons fired differentially, depending on the gender and strain of the “intruder” mouse. Other studies on mouse behavior have supported a role for the VNO in gender identification and sexual behaviors that are linked to pheromone perception (see Section 53.2).

Gustation is the sense of taste

In humans and other vertebrates, the sense of taste, **gustation**, depends on clusters of chemoreceptors called **taste buds**. The taste buds of terrestrial vertebrates are confined to the mouth cavity, but some fish have taste buds in the skin that enhance their ability to sense their environment. Some fish living in murky water are very sensitive to small amounts of amino acids in the water and can find food without the use of vision. The duck-billed platypus, a prototherian mammal (see Figure 33.26), has similar talents as a result of taste buds on the sensitive skin of its bill.

The human tongue has 5,000 to 10,000 taste buds embedded in the epithelium. Most of them are found on the sides of the papillae (Figure 46.5). (Look at your tongue in a mirror—the papillae make it look fuzzy.) The outer surface of a taste bud has a pore that exposes the tips of the sensory receptor cells. Microvilli (tiny hairlike projections) increase the surface area of these cells where their tips converge at the pore. These chemosensory cells generate action potentials and release neurotransmitter at their bases, where they form synapses with sensory neurons that convey the signals into the central nervous system.

The tongue does a lot of hard work, so its epithelium, along with cells of its taste buds, are shed and replaced at a rapid rate. Individual taste bud cells last about 10 days before they are replaced, but the sensory neurons associated with them live on, constantly forming new synapses as new taste buds form.

Humans perceive five taste classes: sweet, salty, sour, bitter, and umami. However, taste buds can distinguish among a variety of sweet-tasting molecules and a variety of bitter-tasting molecules, and small families of genes for receptor proteins responding to sweet and bitter tastes have been discovered. Umami is a savory, meaty taste that originates from receptors for amino acids, including monosodium glutamate (MSG), a commonly used flavor enhancer. In addition, spicy/hot tastes involve the activation of heat sensors, and minty tastes activate cold sensors. The full complexity of the chemosensitivity that enables us to enjoy the subtle flavors of food comes from the combined activation of gustatory and olfactory receptors,

46.5 Taste Buds Are Clusters of Sensory Cells A human tongue has as many as 10,000 taste buds, most of which are found on the papillae.

which is why you may lose your sense of taste when you have a cold.

Gustation begins with receptor proteins in the membranes of the microvilli of the taste bud sensory cells (see Figure 46.5). The nature of these proteins and the mechanisms by which they depolarize sensory receptor cells differ for the different tastes. Saltiness receptor proteins are ionotropic and allow Na^+ to diffuse into taste bud sensory cells through open Na^+ channels, depolarizing the sensory cell. Sourness receptors probably are ionotropic as well, and their depolarization is also due to a direct effect of H^+ ions on Na^+ channels. In contrast, sweet, bitter, and umami taste reception is metabotropic, involving families of G protein-coupled receptor proteins. The bitter taste may have evolved as a protective mechanism, since it enables animals to detect toxic plant compounds such as quinine, caffeine, and nicotine. Because many such toxic compounds occur in plants, where they have evolved in response to herbivorous predators, a variety of receptors is essential. Similarly, a large number of molecules in food could indicate nutritional value, so a variety of receptors is of value. The diversity of sweet receptors helps explain why it has been possible to invent many chemically distinct artificial sweeteners.

Regardless of the mechanism of taste transduction by the sensory cells of the taste buds, all these cells release neurotransmitter onto sensory neurons. These neurons then generate action potentials that are conducted to the CNS, where they are interpreted as specific taste sensations.

RECAP 46.2

All animals receive information about chemical stimuli through chemoreceptors, which have diverse structures and bind to a tremendous variety of stimulus molecules. Chemoreceptors are the basis of the sensations of olfaction and gustation and the reception of pheromones. They also monitor some aspects of an animal's internal environment.

- Why are we able to distinguish so many different smells? Why do some animals experience more or different odors than others? **See pp. 949–950 and Figure 46.3**
- What is distinctive about pheromones as opposed to odorant molecules? **See p. 950**
- Describe how different substances in food are transduced into action potentials in taste buds. **See p. 951 and Figure 46.5**

We have now seen how chemoreceptors give rise to the sensations of smell and taste, and how some animals use chemoreception to communicate with others of their species. Next we will describe the sensory cells that respond to mechanical forces, including the vibrations we perceive as sound.

46.3 How Do Sensory Systems Detect Mechanical Forces?

Mechanoreceptors respond to mechanical (physical) forces. Physical distortion of a mechanoreceptor's plasma membrane causes ion channels to open, altering the membrane potential of the cell to create a graded receptor potential, which in turn leads to either the release of neurotransmitter or the generation of action potentials. The rate of action potentials tells the CNS the strength of the stimulus to the mechanoreceptor. A considerable diversity of mechanosensory cells involved in many sensory systems has evolved. The functions of these cells range from interpreting skin sensations to sensing blood pressure to hearing and maintaining balance.

Many different cells respond to touch and pressure

Human skin (and that of other mammals) is packed with diverse mechanoreceptors that generate varied sensations (**Figure 46.6**). The most important tactile receptors, found in both hairy and nonhairy skin, are **Merkel's discs**, which adapt rather slowly and provide continuous information about anything touching the skin. **Meissner's corpuscles**, found primarily in nonhairy skin, are very sensitive but adapt rapidly; they provide information about *changes* in things touching the skin. The rapid adaptation of Meissner's corpuscles is why you roll a small object between your fingers (rather than holding it still) to discern its shape and texture: as you roll it, the object continually stimulates Meissner's corpuscles.

Deeper in the skin, **Ruffini endings** adapt slowly and are good at providing information about vibrating stimuli of low frequencies, while **Pacinian corpuscles**, which adapt rapidly, provide information about vibrating stimuli of higher frequencies. Even deeper in the skin, the dendrites of sensory neurons

46.6 The Skin Feels Many Sensations Even a very small patch of skin contains a variety of sensory cells, making the skin a multi-modal receptor that can sense temperature, pressure, texture, pain, touch, and itch.

wrap around hair follicles. When the surface hairs are displaced, those neurons are stimulated.

The density of tactile mechanoreceptor cells varies across the body's surface. By touching the skin with two toothpicks simultaneously, you can determine how far apart two stimuli have to be before a person can tell whether the sensations are produced by one toothpick or by two. On a person's back, for example, stimuli have to be relatively far apart before they are perceived as two discrete stimuli. But when this same "two-point spatial discrimination test" is applied to the lips or fingertips, a person can identify two stimuli as separate even when they are quite close together, meaning that receptor density is much greater in these regions.

Mechanoreceptors are also found in muscles, tendons, and ligaments

An animal receives information from mechanoreceptors about the position of its limbs and the stresses on its muscles and joints. These mechanoreceptors supply information continuously to the CNS, and this information is essential for postural control and the coordination of movements.

The mechanoreceptors in skeletal muscle are the **muscle spindles**. These stretch receptors are modified muscle cells embedded in connective tissue inside muscles and innervated by sensory neurons (**Figure 46.7A**). When a muscle is stretched, the muscle spindles are stretched as well, signaling the spindle neurons transmit action potentials to the central nervous system. Figure 46.1 showed how crayfish stretch receptors transduce physical force into action potentials; the actions of muscle spindles are similar. The CNS uses the information from

46.7 Stretch Receptors Stretch receptors provide information about the stresses on muscles and joints in an animal's limbs. (A) Signals from muscle spindles to the CNS initiate muscle contraction. (B) Golgi tendon organs in tendons and ligaments inhibit a contraction that becomes too forceful, triggering a reduction in muscle tension and protecting the muscle from tearing.

muscle spindles to adjust the strength of the muscle contraction so that it matches the load put on the muscle; thus a person can hold a mug steady while it is being filled.

Another type of mechanoreceptor, the **Golgi tendon organ**, is found in tendons and ligaments and provides information about the force generated by a contracting muscle (**Figure 46.7B**). When a contraction becomes too forceful, action potentials from the Golgi tendon organ inhibit the spinal cord motor neurons innervating that muscle, causing the muscle to relax and protecting it from tearing. (You may recall a cell organelle called the Golgi apparatus. What these two very different structures have in common is their discovery in the late nineteenth century by the Italian anatomist Camillo Golgi.)

Hair cells are mechanoreceptors of the auditory and vestibular systems

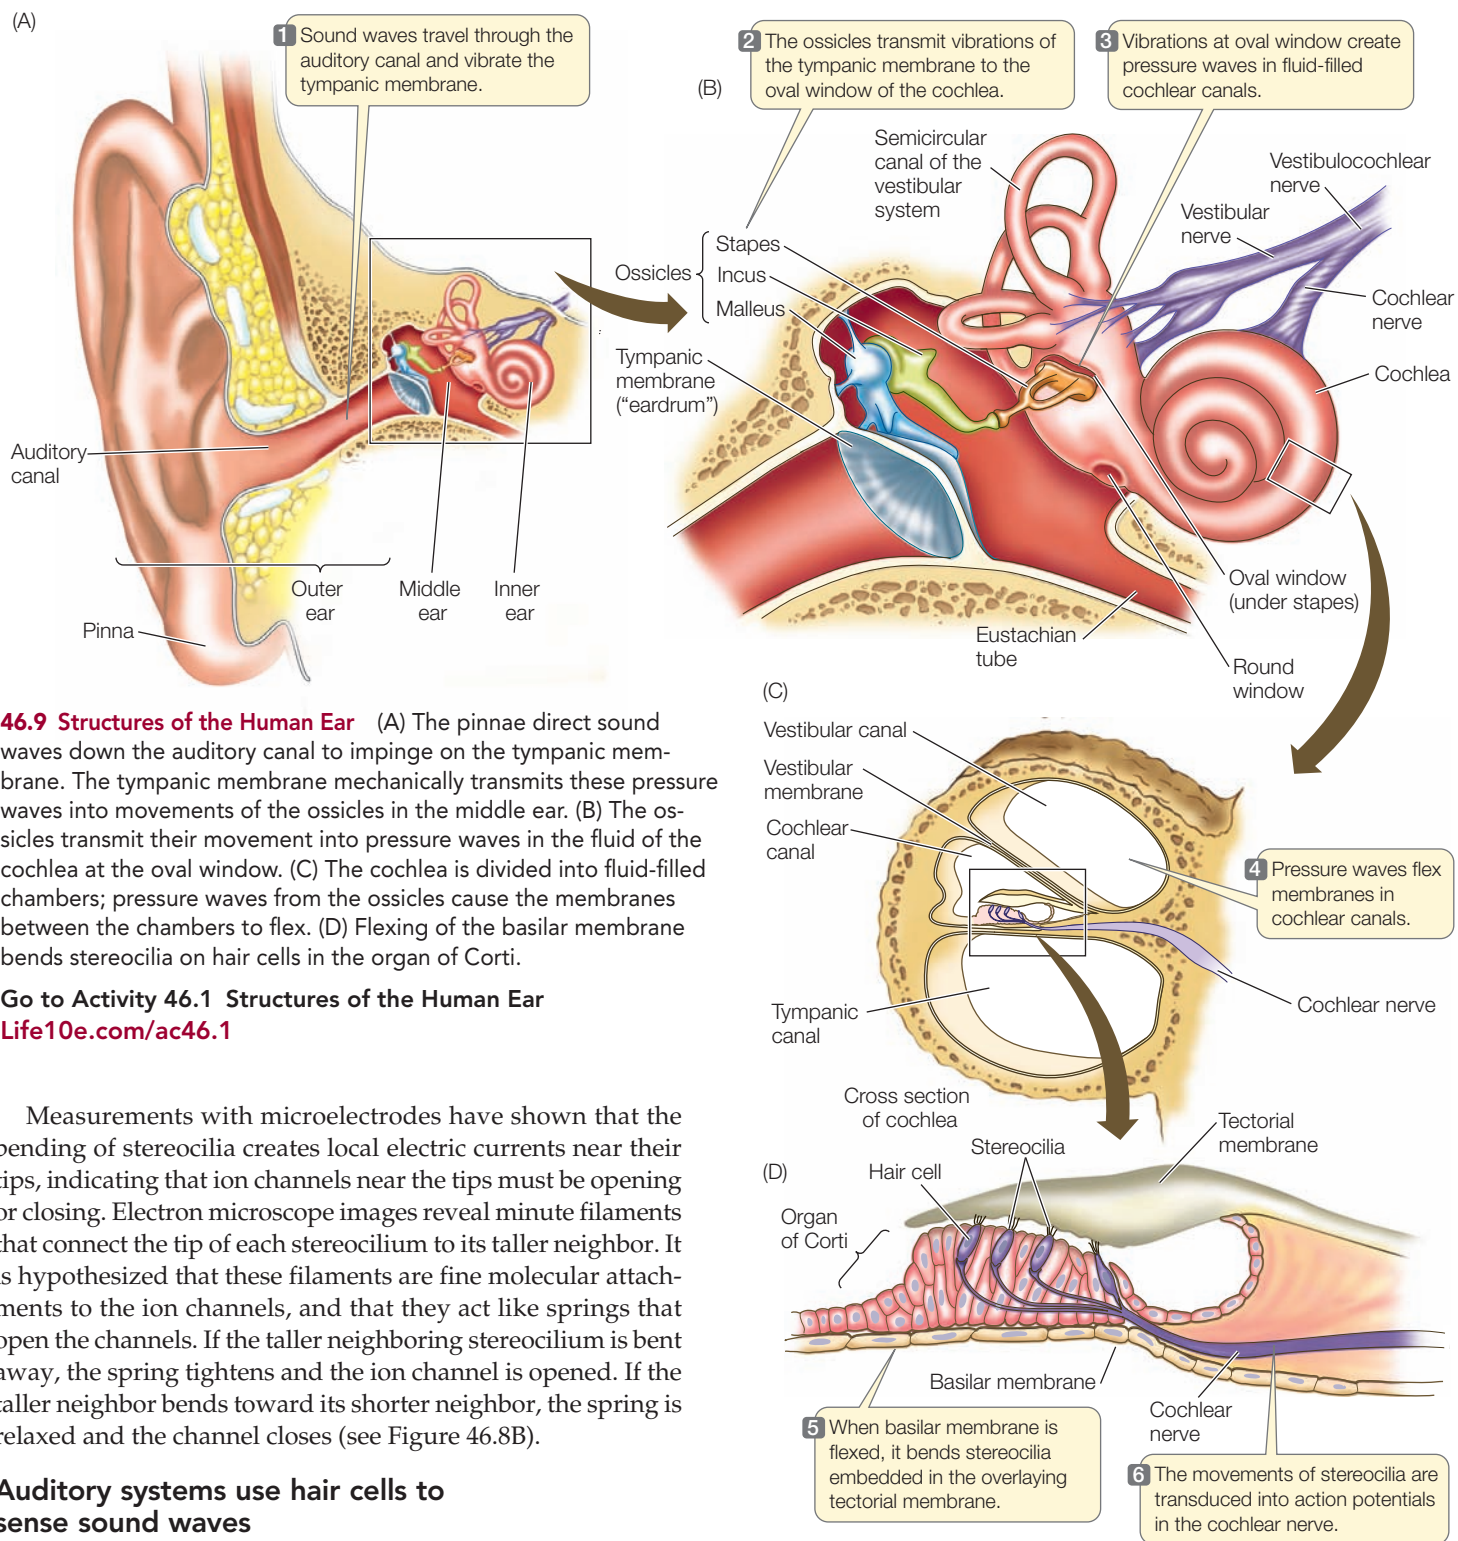

Hair cells are the mechanoreceptors for the vertebrate auditory system (sound-perceiving) and vestibular (equilibrium-maintaining) systems. Both of these systems are housed in the complex structures of the vertebrate ear. **Stereocilia**—fingerlike

extensions of the cell membrane stiffened by cross-linked actin filaments—project from the surface of each hair cell like a set of organ pipes (**Figure 46.8A**). Stereocilia bend in response to waves of pressure; bending of the stereocilia in one direction depolarizes the hair cell, and bending in the other direction hyperpolarizes it (**Figure 46.8B**).

46.8 Hair Cells Have Mechanosensors on Their Stereocilia

(A) Hair cells have stereocilia that are connected with each other by small filaments. (B) When a cilium is bent in one direction, the filament opens a mechanosensory ion channel at the tip of the neighboring cilium. The depolarized hair cell releases neurotransmitter onto a sensory neuron.

46.9 Structures of the Human Ear (A) The pinnae direct sound waves down the auditory canal to impinge on the tympanic membrane. The tympanic membrane mechanically transmits these pressure waves into movements of the ossicles in the middle ear. (B) The ossicles transmit their movement into pressure waves in the fluid of the cochlea at the oval window. (C) The cochlea is divided into fluid-filled chambers; pressure waves from the ossicles cause the membranes between the chambers to flex. (D) Flexing of the basilar membrane bends stereocilia on hair cells in the organ of Corti.

Go to Activity 46.1 Structures of the Human Ear
[Life10e.com/ac46.1](https://life10e.com/ac46.1)

Measurements with microelectrodes have shown that the bending of stereocilia creates local electric currents near their tips, indicating that ion channels near the tips must be opening or closing. Electron microscope images reveal minute filaments that connect the tip of each stereocilium to its taller neighbor. It is hypothesized that these filaments are fine molecular attachments to the ion channels, and that they act like springs that open the channels. If the taller neighboring stereocilium is bent away, the spring tightens and the ion channel is opened. If the taller neighbor bends toward its shorter neighbor, the spring is relaxed and the channel closes (see Figure 46.8B).

Auditory systems use hair cells to sense sound waves

The stimuli that animals perceive as sounds are pressure waves. Auditory systems use mechanoreceptors to convert pressure waves into receptor potentials. Auditory systems include special structures that gather sound waves, direct them to the sensory organ, and amplify their effect on the mechanoreceptors. A good example of an auditory system is the human ear, which can be divided into three major areas: the outer, middle, and inner ear (**Figure 46.9A**).

OUTER EAR The outer ear consists of the pinnae (singular, pinna) and the auditory canal. The pinnae collect sound waves and direct them into the auditory canals; watch a dog change

the orientation of its ears to focus on a particular sound to get the idea of the role pinnae play in hearing. Covering the end of the auditory canal is the **tympanic membrane** (commonly called the eardrum), which vibrates in response to pressure waves traveling down the canal, thus converting the pressure waves to physical forces in the middle ear.

MIDDLE EAR On the other side of the tympanic membrane is the middle ear, an air-filled cavity connected to the throat at the back of the mouth through the **eustachian tube** (also called the pharyngotympanic tube). Because the eustachian

tube is also filled with air, pressure equilibrates between the middle ear and the environment. When you have a cold, the tube can become blocked by mucus or tissue swelling and you have difficulty equilibrating the pressure in the middle ear with the outside air pressure (as you have to do when changing altitude in an airplane).

The middle ear contains the **ossicles**, three delicate bones individually named the malleus (“hammer”), incus (“anvil”), and stapes (“stirrup”) (**Figure 46.9B**). The ossicles transmit the vibrations of the tympanic membrane to another flexible membrane, the **oval window**. The ossicles act as a lever (like a hammer pulling out a nail), translating a large movement of the tympanic membrane into a smaller movement of the oval window, but a movement of greater force. Because the oval window is much smaller than the tympanic membrane, the pressure the stapes transmits to the oval window is more than 20 times greater than the pressure exerted by a sound wave on the tympanic membrane.

Behind the oval window lies the fluid-filled inner ear. Movements of the oval window impart pressure changes to that enclosed fluid. These pressure waves are transduced into action potentials.

INNER EAR The inner ear is a bony structure consisting of two sets of canals. One is the organ of balance, the **vestibular system**, and the other is the organ of hearing, the **cochlea**. The cochlea (“snail” or “spiral shell”) is a long, tapered, coiled structure. A cross section of the cochlea reveals that it is composed of three parallel canals separated by two membranes, the vestibular membrane and the basilar membrane (**Figure 46.9C**). Sitting on the basilar membrane is the **organ of Corti**, which transduces pressure waves into action potentials. The organ of Corti contains hair cells with stereocilia (see Figure 46.8). The tips of the hair cells are embedded in a gelatinous overhanging shelf called the tectorial membrane (**Figure 46.9D**).

Stereocilia are not motile, but because their tips are attached to the more rigid tectorial membrane, stereocilia bend when the basilar membrane flexes. The response of the hair cell is a graded membrane potential. The hair cells do not fire action potentials, but the changes in their membrane potential alter the rate at which the hair cells release neurotransmitter onto the sensory neurons whose axons make up the auditory nerve and transmit action potentials to the brain.

The vestibular and tympanic canals are separate until they reach the distal end of the cochlea (the end farthest from the oval window), where they join; thus they form one continuous canal that turns back on itself (see Figure 46.10). Just as the oval window is a flexible membrane at the beginning of the vestibular canal, the **round window** is a flexible membrane at the end of the tympanic canal. When the oval window vibrates, the waves of fluid pressure create traveling waves, or flexions, in the basilar membrane.

Flexion of the basilar membrane is perceived as sound

What causes the basilar membrane to flex, and how does this mechanism distinguish sounds of different frequencies? Air

46.10 Sensing Pressure Waves in the Inner Ear Pressure waves of different frequencies flex the basilar membrane at different locations. Information about sound frequency is specified by which hair cells are activated. For simplicity, this representation illustrates the cochlea as uncoiled, and leaves out the middle ear.

Go to Animated Tutorial 46.1
Sound Transduction in the Human Ear
[Life10e.com/at46.1](https://www.life10e.com/at46.1)

is highly compressible but fluids are not; therefore a pressure wave can travel through air without displacing much air, whereas a pressure wave in fluid displaces that fluid. When the stapes pushes on the oval window, the fluid in the vestibular canal is displaced. If the movement of the oval window occurs slowly, the cochlear fluid pressure wave travels down the vestibular canal, around the bend, and back through the tympanic canal (**Figure 46.10**). At the end of the tympanic canal, the displacement pressure is dissipated by the outward bulging of the round window.

The basilar membrane is not uniform—it is thicker and stiffer at its base and wider and thinner at its apical end.

(A) In a semicircular canal

(B) In the utricle and saccule

46.11 Organs of Equilibrium The vestibular system consists of bony chambers and fluid-filled canals. (A) Each semicircular duct has a cupula containing stereocilia. When fluid moves against the cupula, the stereocilia bend. (B) In the saccule and utricle, stereocilia are bent by gravitational forces on the otoliths.

Pressure waves in the cochlear fluid have different frequencies and set up different patterns of traveling waves. High-frequency waves cause maximal flexion at the basal end of the basilar membrane, whereas low-frequency pressure waves result in maximal flexion at the apical end (see Figure 46.10). Thus different pitches of sound flex the basilar membrane at different locations and activate different sets of hair cells. Action potentials stimulated by the mechanoreceptors at different positions along the organ of Corti travel along the cochlear nerve and are transmitted to different regions of the brain's auditory cortex by the vestibulocochlear nerve.

Various types of damage can result in hearing loss

There are two general types of acquired hearing loss, or deafness. Conduction deafness is caused by the loss of function of the tympanic membrane and/or the ossicles of the middle ear. Repeated infections of the middle ear can cause scarring of the tympanic membrane and stiffening of the connections between the ossicles. The consequence is less efficient conduction of sound waves from the tympanic membrane to the oval window. With increasing age, the ossicles inevitably stiffen, resulting in a gradual loss of the ability to hear high-frequency sounds.

Nerve deafness is caused by damage to the inner ear or the auditory pathways. A common cause of nerve deafness is damage to the hair cells of the delicate organ of Corti by exposure to loud sounds such as jet engines, pneumatic drills, or highly amplified music. Consistent exposure to sounds above 85 decibels can damage hearing; this damage is cumulative and irreversible. Even using earphones can put you at risk for hearing loss because they generate high-pressure sound waves close to the tympanic membrane. Personal stereo earphones can reach 120 decibels, and people commonly use them at 100 decibels (equivalent to being at a rock concert).

The vestibular system uses hair cells to detect forces of gravity and momentum

Hair cells in the vestibular system of the inner ear detect the position and movement of the head—information that is essential for maintaining equilibrium (balance). Information from the vestibular system is also crucial for the control of eye movements. When you look at something, you can move your head while staying focused on the object because of your vestibulo-ocular reflex.

In the mammalian inner ear, the vestibular system consists of three bony **semicircular canals** and a bony chamber called the **vestibule**. Within each canal is a membranous semicircular duct, and within the vestibule are the membranous saccule and the utricle. The ducts and the saccule and utricle are filled with fluid. In the semicircular ducts, the fluid shifts when the head changes position (**Figure 46.11A**). Since the three semicircular

canals have different orientations, the fluid in their ducts responds differentially to the direction of movement. Projecting into the base of each duct is a **cupula**, a gelatinous swelling enclosing a cluster of hair cell stereocilia. When the shifting fluid pushes on the cupula, it bends the stereocilia and causes a graded potential in their hair cell plasma membranes.

The stereocilia in the saccule and utricle are bent in a different way. These stereocilia are embedded gelatinous membranes that contain otoliths (“ear stones”) that are crystals of calcium carbonate. When the head changes position or when it accelerates or decelerates, gravitational forces are exerted on the otoliths and the stereocilia bend (**Figure 46.11B**).

As in the cochlea, the hair cells of the vestibular system do not fire action potentials, but they release neurotransmitter at synapses with sensory neurons, which in turn fire action potentials.

Mechanoreceptors
Life10e.com/at46.2

RECAP 46.3

Sensations that derive from mechanoreceptors include touch, tickle, pressure, joint position, muscle load, hearing, and equilibrium.

- Describe some of the different mechanoreceptors in the skin and their properties. **See p. 952 and Figure 46.6**
- How do hair cells transduce force into action potentials? **See pp. 953–954 and Figure 46.8**
- How do different frequencies of sound result in action potentials being fired in different acoustic neurons? **See pp. 954–955 and Figures 46.9 and 46.10**

We turn next to another example of metabotropic sensory reception, one in which light is the stimulus. We will see how light energy is converted into action potentials that in higher vertebrates are perceived as vision, perhaps the most elaborate of the senses.

46.4 How Do Sensory Systems Detect Light?

Sensitivity to light—**photosensitivity**—confers on the simplest animals the ability to orient to the sun and sky, and it gives more complex animals rapid and extremely detailed information about objects in their environment. Photosensitivity is ubiquitous in the animal kingdom, and the molecular basis for that sensitivity is a family of visual that has been evolutionarily conserved.

In this section we will learn how a visual pigment molecule responds when stimulated by light energy and how that response is transduced into neural signals. We will also examine the structures of eyes, the organs that gather light energy and focus it onto **photoreceptor cells**, the metabotropic sensory receptors that transform light energy into action potentials, and the routes those impulses travel to the brain.

Rhodopsin is a vertebrate visual pigment

Photosensitivity depends on the ability of visual pigments to absorb photons of light and to undergo a change in conformation. One such pigment is **rhodopsin**, a well-studied vertebrate visual pigment. A rhodopsin molecule consists of the protein **opsin** (which by itself is not photosensitive) and **11-*cis*-retinal**, a nonprotein, light-absorbing functional group cradled in the center of the opsin protein and covalently bound to it (**Figure 46.12**). The entire rhodopsin molecule sits within the plasma membrane of a photoreceptor cell, such as the rod cells of humans (see p. 960).

When 11-*cis*-retinal absorbs a photon of light energy, it changes into a different isomer of retinal, called **all-*trans*-retinal**. This change puts a strain on the bonds between retinal and opsin, changing the conformation of opsin and thus signaling the detection of light. In vertebrate eyes, the retinal and the opsin eventually separate from each other (a process called **bleaching**), which causes the molecule to lose its photosensitivity. A series of enzymatic reactions returns the all-*trans*-retinal to the 11-*cis* isomer, which then recombines with opsin so that it once again becomes the photosensitive pigment rhodopsin.

46.12 Light Changes the Conformation of Rhodopsin The light-absorbing molecule 11-*cis*-retinal bonds with the protein opsin to form the vertebrate visual pigment rhodopsin.

46.13 Ommatidia: The Functional Units of Insect Eyes

(A) The micrograph shows the compound eye of a fruit fly. (B) The rhodopsin-containing retinula cells are the photoreceptors in ommatidia.

How does the conformational change of rhodopsin transduce light into a cellular response? After retinal is converted from the 11-*cis* to the all-*trans* form, its interactions with opsin pass through several unstable intermediate stages. One of these stages triggers a cascade of reactions involving a G protein signaling mechanism that results in the alteration of membrane potential that is the photoreceptor cell's response to light.

Photosensitivity

Life10e.com/at46.3

Invertebrates have a variety of visual systems

Photoreceptors and visual pigments are incorporated into a variety of visual systems, from simple to complex. Flatworms obtain directional information about light from photoreceptor cells that are organized into **eye cups**. The eye cups are paired, bilateral structures, each partly shielded from light by a layer of pigmented cells lining the cup. The photoreceptors on the two sides of the animal are unequally stimulated unless the animal is facing directly toward or away from a light source. The flatworm generally uses directional information from the eye cups to move away from light.

Arthropods have **compound eyes** that provide them with information about patterns or images in the environment. These eyes are called compound because each eye consists of many optical units called **ommatidia** (singular *ommatidium*), each with its own narrow-angle lens (Figure 46.13). In contrast, a vertebrate eye consists of just one optical unit with a wide-angle lens. The number of ommatidia in a compound eye varies from only a few in some ants to 800 in fruit flies and to 30,000 in some dragonflies.

Each ommatidium has a lens that directs light onto photoreceptor cells. Flies, for example, have eight elongated photoreceptors in each ommatidium. The inner borders of the photoreceptors are covered with microvilli that contain rhodopsin and trap light. Axons from the photoreceptors send the light information to the nervous system. Since each ommatidium of a compound eye is directed at a slightly different part of the visual world, only a low-resolution (pixillated) image can be communicated from the compound eye to the CNS.

Image-forming eyes evolved independently in vertebrates and cephalopods

Both vertebrates and cephalopod mollusks have eyes with exceptional abilities to form detailed images of the visual world. Like cameras, both of these eye types focus inverted images on an internal surface that is sensitive to light. Considering that they evolved completely independently of each other, their degree of similarity is remarkable (Figure 46.14).

The vertebrate eye (see Figure 46.14A) is a spherical, fluid-filled structure bounded by a tough connective tissue layer called the **sclera**. At the front of the eye, the sclera forms the transparent **cornea**, through which light passes to enter the eye. Just inside the cornea is the pigmented **iris**, which gives the eye its color. The iris controls the amount of light that reaches the photoreceptor cells at the back of the eye, just as the diaphragm of a camera controls the amount of light reaching the film. The central opening of the iris is the **pupil**. The iris is under neural control. In bright light, the iris constricts and the pupil is very small. As light levels fall, the iris relaxes and the pupil enlarges.

Behind the iris is the crystalline protein **lens**, which makes fine adjustments in the focus of images falling on the photosensitive layer—the **retina**—at the back of the eye. The cornea and the fluids within the eye bend light rays passing through them so that they are focused on the retina. The lens makes fine adjustments to the focus and allows the eye to accommodate—that is, to focus on objects at various locations in the near visual field. To focus a camera on objects close at hand, you adjust the distance between the lens and the internal surface sensitive to light. Fishes, amphibians, and non-avian reptiles accommodate in a similar manner, moving the lenses of their eyes closer to or farther from their retinas. Mammals and birds use a different method; they alter the shape of the lens.

The mammalian lens is contained in a connective tissue sheath that tends to keep it in a spherical shape, but it is attached to suspensory ligaments that pull it into a flatter shape. Circular ciliary muscles counteract the pull of the suspensory ligaments, permitting the lens to round up. When the ciliary muscles are at rest, the flatter lens has the correct optical properties to focus distant images on the retina. Contracting the

46.14 Convergent Evolution of Eyes The lenses of vertebrate (A) and cephalopod (B) eyes focus images on layers of photoreceptor cells.

ciliary muscles rounds up the lens, changing its light-bending properties to bring close images into focus (**Figure 46.15**).

Lenses become less elastic with age, so we lose the ability to focus on objects close at hand without the help of corrective lenses. Most people over the age of 45 need the assistance of reading glasses or bifocal lenses.

Go to Activity 46.2 Structure of the Human Eye
Life10e.com/ac46.2

The vertebrate retina receives and processes visual information

During embryonic development, neural tissue grows out from the brain to form the retina. In addition to a layer of photoreceptor cells, the retina includes four additional types of cells that process visual information from the photoreceptors (see Figure 46.20). Light must pass through all the layers of retinal cells before being captured by photosensors. In humans and other day-active animals, the light that is not captured is absorbed by a black-pigmented epithelial tissue layer behind the retina. In contrast, nocturnal animals such as deer and raccoons have an iridescent reflective layer behind their retinas, which maximizes the capture of photons by reflecting them back onto the photoreceptors. This is why a deer in the headlights appears to have bright white eyes. Because humans do not have

a white reflective layer in the retina, photographs taken indoors often have a “red-eye effect,” caused by the flash of light from the camera being reflected by the abundant blood vessels in the retina.

The pigmented epithelium also plays a role in the renewal of the photoreceptors. The photoreceptor cells are always shedding discs from their distal ends as new ones are being generated by the inner segments of those cells. The pigmented epithelial cells phagocytose the shed discs. Each outer segment is totally renewed about every two weeks.

46.15 Staying in Focus Mammals and birds focus their eyes by changing the shape of the lens depending on the eye's distance from the object of focus.

46.16 Rods and Cones This scanning electron micrograph of photoreceptors in the retina of a mud puppy (an amphibian) shows cylindrical rods and tapered cones.

Rod and cone cells are the photoreceptors of the vertebrate retina

The photoreceptors of the vertebrate retina are two types of modified neurons called **rod cells** and **cone cells** based on their shapes (Figure 46.16). Rod cells are highly light-sensitive and perceive shades of gray in dim light. Cone cells function at high light levels and are responsible for high-acuity color vision. The human retina has about 5 million cones and 100 million rods, but the density of each varies across the retina.

ROD CELLS Rod cells do not produce action potentials, but they release neurotransmitter from their bases, where they form synapses with the next neurons in the visual pathway. Each rod cell has an outer segment, an inner segment, and a synaptic terminal (Figure 46.17). The highly specialized outer segment contains a stack of discs made up of plasma membrane densely packed with the visual pigment rhodopsin (see p. 957). The function of these discs is to capture photons of light. The inner segment contains the cell nucleus, mitochondria, and other organelles. The synaptic terminal is where the rod cell communicates with other neurons.

To see how a rod cell responds to light, we can penetrate a single rod cell with an electrode and record its membrane potential in the dark and in the light, as shown in Figure 46.17. From what we have learned about other types of sensory receptors, we might expect that stimulation of the rod cell by light would make its membrane potential less negative, but the opposite is true—it becomes more negative.

When a rod cell is kept in the dark, it has a relatively depolarized resting potential compared with other neurons. In fact, the plasma membrane of the rod cell is almost as permeable to Na^+ as to K^+ . In the dark, Na^+ continually enters the outer segment of the cell—the dark current. When light is flashed on the dark-adapted

INVESTIGATINGLIFE

46.17 A Rod Cell Responds to Light The plasma membrane of a rod cell hyperpolarizes—becomes more negative—in response to a flash of light. Rod cells do not fire action potentials, but in response to the absorption of light energy, the neuron experiences a change in membrane potential.^a

HYPOTHESIS When a rod cell absorbs photons (light energy), its membrane potential changes in proportion to the strength of the light stimulus.

- Method**
1. Record membrane potentials from the inner segment of a rod cell.
 2. Stimulate the rod cells with light flashes of varying intensity and record the results.

Results

CONCLUSION The membrane potential of rod cells is depolarized in the dark and hyperpolarizes (becomes more negative) in response to light.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

^aBaylor, D. A. et al. 1979. *Journal of Physiology* 288: 589–634.

rod cell, its membrane potential becomes more negative—it hyperpolarizes (see Figure 46.17). The rate of neurotransmitter release changes as membrane potential changes. As the rod cell hyperpolarizes, its release of neurotransmitter decreases.

Membrane Currents and Light Intensity in Rod Cells

Original Paper

Baylor, D. A., T. D. Lamb, and K.-W. Yau. 1979. The membrane current of single rod outer segments. *Journal of Physiology* 288: 589–611.

Analyze the Data

In a slightly different set of experiments than that described in Figure 46.17, researchers measured the effect of light on the current across the rod cell membrane. The figure at right shows a series of recordings of the membrane currents (i.e., inward currents of positive ions) generated when rod cells were illuminated by light flashes of varying intensities. The initial values for the membrane currents represent the condition of a rod cell in total darkness. The light flash was given at time 0, and the intensity of the flashes is indicated on the right side of the response curves.

QUESTION 1

Why is there no difference between the *maximum* currents induced by flashes of light at 7.8 and 16 photons per μm^2 ?

QUESTION 2

Why does a rod maintain its maximum current for longer in response to a flash of light at 16 photons per μm^2 than it does to one at 7.8 photons per μm^2 ?

QUESTION 3

If you measured membrane potential instead of an outward current, how would the resulting recordings differ from the one shown here?

Go to **BioPortal** for all **WORKING WITH DATA** exercises

How does the absorption of light by rhodopsin hyperpolarize the rod cell? When rhodopsin is excited by light, it initiates a cascade of events. The dark-adapted rod cell has open Na^+ channels, allowing a depolarizing dark current (Figure 46.18). Light photons excite rhodopsin, which activates a G protein called transducin. Activated transducin in turn activates a phosphodiesterase (PDE). Activated PDE converts cyclic GMP

(cGMP) to GMP, which causes the Na^+ channels to close. Na^+ is pumped out and the cell hyperpolarizes.

This cascade may seem like a roundabout way of doing business, but its advantage is its enormous amplification ability. Each molecule of light-excited rhodopsin can activate several hundred transducin molecules, thus activating a large number of PDE molecules. The catalytic capacity of PDE is great—one PDE molecule can hydrolyze several hundred molecules of cGMP per second. The bottom line is that a single photon of light can result in the closure of a huge number of Na^+ channels.

CONE CELLS Cone cells are responsible for the high-acuity color vision of day-active vertebrates such as humans. It is therefore logical that the highest density of cone cells is in the area of the retina that receives light

46.18 Light Absorption Closes Sodium Channels

The absorption of light by rhodopsin initiates a signaling cascade that hyperpolarizes the rod cell. (A) In the dark, Na^+ channels in the plasma membrane of the rod cell's outer segment are held open by cGMP, allowing positive charges to enter the cell (upper right of panel). When the rod cell is stimulated by light, it activates transducin (lower portion of panel). (B) Transducin activates a molecule of phosphodiesterase (PDE). (C) Activated PDE catalyzes the breakdown of cGMP to GMP. The depletion of cGMP results in closure of the Na^+ channels and hyperpolarization of the cell.

from the center of the visual field, a region called the **fovea**. The human fovea has about 160,000 cones per square millimeter. But humans are not the champions of high-acuity vision; a hawk's fovea has almost twice that number of cones, making the hawk's vision much sharper than ours. Birds also have *two* foveae in each eye; one receives light from straight ahead, the other from a more lateral field of vision. The forward-looking foveae make binocular vision possible, while the lateral-looking foveae provide high-acuity vision. Birds use both sets of foveae by frequently turning their heads slightly; they cannot move their eyes in the sockets as humans can.

Cones have low sensitivity to light and contribute little to night vision. Night vision depends mostly on rod cells, which is why vision in dim light is mostly in shades of gray and acuity is low. You may have trouble seeing a small object at night when you are looking straight at it—that is, when its image is falling on your fovea. If you look a little to the side, so that the image falls on a rod-rich area of your retina, you see the object better. Astronomers looking for faint objects in the sky learned this trick a long time ago. The retinas of nocturnal animals, such as flying squirrels, contain a high percentage of rods. By contrast, some animals that are active only during the day (such as chipmunks) have mostly cones in their retinas.

The human retina has three kinds of cone cells, each containing slightly different opsin molecules that differ in the wavelengths of light they absorb best. Although the same 11-*cis*-retinal group is the light-absorber in all three kinds of cones (see Figure 46.12), its molecular interactions with opsin determine the spectral sensitivity of the cone cell as a whole (**Figure 46.19**). Because different wavelengths of light are differentially absorbed by the different cone cell visual pigments, the brain interprets the relative inputs from the different classes as a full

46.19 Absorption Spectra of Cone Cells The three kinds of cone cells contain slightly different visual pigments that absorb different wavelengths of light.

range of color. Color blindness in humans results from the absence or dysfunction of one or more of the three classes of cone cells. Some mammals have only one or two classes of cone cells, whereas birds have four.

Information flows through layers of neurons in the retina

The human retina is organized into layers of neurons that receive visual information and process it before sending it to the brain (**Figure 46.20**). Closest to the lens (and thus to light

Go to Media Clip 46.1
Into the Eye
Life10e.com/mc46.1

46.20 The Human Retina Five layers of neurons receive and process visual information. The rods and cones are photoreceptors. The other four layers are the ganglion cells, the bipolar cells, the horizontal cells, and the amacrine cells, all of which are involved in transmitting light signals received by the photoreceptors to the brain.

Go to Activity 46.3 Structure of the Human Retina
Life10e.com/ac46.3

input) is a layer of **ganglion cells**; a central layer contains three neuronal types, **bipolar cells**, **horizontal cells**, and **amacrine cells**; and at the “rear” of the retina lie the photoreceptors (rods and cones). The layers of cells between the photoreceptors and the ganglion cells process information about the visual field.

GANGLION AND BIPOLAR CELLS From our discussion of rod cells, we know that the photoreceptor cells at the back of the retina hyperpolarize in response to light and do not generate action potentials. The ganglion cells lie at the front of the retina, and they do fire action potentials. The axons of ganglion cells form the **optic nerve** that travels to the brain.

The ganglion cells are connected to the photoreceptors by bipolar cells. Changes in the membrane potential of rods and cones in response to light alter the rates at which the rods and cones release neurotransmitter at their synapses with the bipolar cells. In response to this neurotransmitter, the membrane potentials of the bipolar cells change, altering the rate at which they release neurotransmitter onto ganglion cells. The rate of neurotransmitter release from the bipolar cells determines the rate at which ganglion cells fire action potentials. Thus the direct flow of information in the retina is from photoreceptor to bipolar cell to ganglion cell. The ganglion cells send the information to the brain via the optic nerve.

Each human eye contains about 1.2 million ganglion cells but more than 100 million rods and cones. Therefore there must be convergence of information as it passes from the photoreceptors to the ganglion cells. A given bipolar cell can receive input from multiple rods or multiple cones, but not from both. The relationship between photoreceptors, bipolar cells, and ganglion cells depends on their location on the retina. In the fovea, a ganglion cell may receive input from as few as five photoreceptors, but in the periphery of the retina, a ganglion cell may receive input from thousands of photoreceptors. Visual acuity is a reflection of these quantitative relationships.

The patch of photoreceptors that communicates with a ganglion cell forms a circular receptive field. When light falls on a receptive field, its ganglion cell can be either excited or inhibited. As mentioned above, each ganglion cell sends an axon to the brain in the optic nerve. Thus the information coming from the retina to the brain is about the pattern of patches of light and dark falling on the retina.

HORIZONTAL AND AMACRINE CELLS The other two cell layers, the horizontal cells and the amacrine cells, consist of interneurons that communicate laterally across the retina. Horizontal cells form synapses with neighboring photoreceptors and bipolar cells. Thus light falling on one photoreceptor can influence the sensitivity of its neighbors to light. This lateral flow

of information enables the retina to sharpen the perception of contrast between light and dark patterns. Amacrine cells form local interconnections between bipolar cells and ganglion cells. Some amacrine cells are highly sensitive to changing illumination or to motion. Others assist in adjusting the sensitivity of the eyes according to the overall level of light falling on the retina. When background light levels change, amacrine cell connections to the ganglion cells help the ganglion cells remain sensitive to temporal changes in stimulation. Thus even with large changes in background illumination, the eyes are sensitive to smaller, more rapid changes in the pattern of light falling on the retina.

RECAP 46.4

A family of photosensitive visual pigments are responsible for light sensitivity in all animals. Receptor cells, including rod and cone cells in humans, transduce the photosensitivity of visual pigments to light and use it to form images of the environment.

- Explain how a photon of light affects the membrane potential in a rod cell. [See pp. 960–961 and Figures 46.12, 46.17, and 46.18](#)
- What is the mechanism of color vision? [See pp. 961–962 and Figure 46.19](#)
- Describe the flow of signals that takes place in the eye in response to light. [See pp. 962–963 and Figure 46.20](#)

Knowing the path of information from sensory receptor cells to the central nervous system still does not tell us how that information is processed by the brain. What does the eye tell the brain, for example, in response to a pattern of light falling on the retina? In Chapter 47 we will describe how the mammalian brain reassembles sensory information into our perception of the world.

How can bats emit loud pulses of sound and not be deaf to the faint echoes that return within milliseconds?

ANSWER

Bat “echolocation” allows these mammals to navigate around objects and to find prey in total darkness. Bats emit sound waves at frequencies well above the range of human hearing; these sound waves bounce off objects, including potential prey. The bat perceives the echoes that bounce back almost immediately and uses these echoes to locate prey and other objects. The loud pulses of sound still being emitted don’t “drown out” the weak echoes because small muscles in a bat’s ears contract to dampen its hearing sensitivity while the sounds are being emitted, but relax in time for the bat to hear the echo—a truly remarkable ability, considering that the sound pulses are emitted at rates of 20 to 80 per second.

46.1 How Do Sensory Receptor Cells Convert Stimuli into Action Potentials?

- Sensory receptor cells, also known as **sensors** or **receptors**, transduce information about an animal's external and internal environment into action potentials that the brain perceives as different forms of sensory information.
- **Receptor potentials** can spread to regions of the cell's plasma membrane that generate action potentials. Some sensors do not fire action potentials but release neurotransmitter onto sensory neurons that do fire action potentials. **Review Figure 46.1**
- Sensors have **receptor proteins** that cause ion channels to open or close, affecting the receptor cell's membrane potential. Metabotropic receptors act through signal transduction pathways to generate receptor potentials. Mechanoreceptors are ionotropic sensory receptors that open ion channels physically through forces such as pressure or stretch. **Review Figure 46.2**
- The interpretation of action potentials as particular sensations depends on which neurons in the central nervous system receive them.
- **Adaptation** enables the nervous system to ignore irrelevant or continuous stimuli while remaining responsive to relevant or new stimuli.

46.2 How Do Sensory Systems Detect Chemical Stimuli?

- **Chemoreceptors** are responsible for **olfaction**, **gustation**, and the sensing of **pheromones**.
- Mammalian **olfactory receptor neurons (ORNs)** project directly to the **olfactory bulb** of the brain. ORNs for the same **odorant** project to the same area of the olfactory bulb.
- Each ORN expresses one receptor protein that can bind a specific type of molecule or ion. Binding causes a second messenger to open ion channels, which creates an action potential. **Review Figure 46.3**
- In vertebrates, **taste buds** in the mouth cavity are responsible for gustation. The five basic tastes are sweet, salty, sour, bitter, and umami. **Review Figure 46.5**

46.3 How Do Sensory Systems Detect Mechanical Forces?

- The skin contains a variety of ionotropic **mechanoreceptors** that respond to touch and pressure. The density of mechanoreceptors in any skin area determines the sensitivity of that area. **Review Figure 46.6**
- Stretch receptors in **muscle spindles** and in the **Golgi tendon organ** inform the CNS of the positions of and loads on parts of the body. **Review Figure 46.7**
- **Hair cells** are mechanoreceptors of the auditory and vestibular systems. Physical bending of their **stereocilia** alters their receptor proteins and therefore their membrane potentials. **Review Figure 46.8**

- In mammalian auditory systems, ear pinnae collect and direct sound waves to the **tympanic membrane**, which vibrates in response to sound waves. The movements of the tympanic membrane are amplified through a chain of **ossicles** that conduct the vibrations to the **oval window**. Movements of the oval window create pressure waves in the fluid-filled **cochlea**. **Review Figure 46.9, ACTIVITY 46.1**
- The basilar membrane running down the center of the cochlea is distorted by pressure waves at specific locations that depend on the frequency of the wave. These distortions cause hair cells in the **organ of Corti** to bend and to release neurotransmitter, generating action potentials in the cochlear nerve that are transmitted to the auditory cortex of the brain. **Review Figure 46.10, ANIMATED TUTORIAL 46.1**
- Hair cells are also the mechanoreceptors of the organs of equilibrium in the mammalian vestibular system, which include the **semicircular ducts** and the **saccul**e and **utricle**. **Review Figure 46.11, ANIMATED TUTORIAL 46.2**

46.4 How Do Sensory Systems Detect Light?

- **Photosensitivity** depends on the absorption of photons of light by visual pigment molecules that consist of a protein called **opsin** and a light-absorbing group. Absorption of light is the first step in a cascade of intracellular events leading to a change in the membrane potential of the **photoreceptor cell**. **Review Figure 46.12, ANIMATED TUTORIAL 46.3**
- Visual systems range from the simple **eye cups** of flatworms, which sense the direction of a light source, to the **compound eyes** of arthropods, which detect shapes and patterns, to the image-forming eyes of vertebrates and cephalopods. **Review Figures 46.13, 46.14**
- Vertebrate and cephalopod eyes focus detailed images of the visual field onto dense arrays of photoreceptors that transduce the visual image into neural signals. **Review Figures 46.14, 46.15, ACTIVITY 46.2**
- Vertebrates have two types of photoreceptors, **rod cells** and **cone cells**. Rod cells are more sensitive to light and are responsible for dim light vision. Cone cells are less sensitive to light but are responsible for high-acuity and color vision.
- Photoreceptors do not fire action potentials. When not stimulated by light they release neurotransmitter continuously. Light hyperpolarizes rod cells, and their release of neurotransmitter decreases. **Review Figures 46.17, 46.18**
- **Rhodopsin** is the visual pigment of rod cells. The visual pigments of cone cells have three different opsin components, which gives them different spectral sensitivities. **Review Figure 46.19**
- The vertebrate **retina** consists of layers of neurons lining the back of the eye. The light-absorbing photoreceptor cells are at the rear of the retina. The axons of the **ganglion cells** are bundled together in the **optic nerve**. Between the photoreceptors and the ganglion cells are neurons that process information from the photoreceptors. **Review Figure 46.20, ACTIVITY 46.3**

CHAPTER REVIEW

REMEMBERING

- Which statement about sensory systems is *not* true?
 - Sensory transduction involves the conversion (direct or indirect) of a physical or chemical stimulus into changes in membrane potentials.
 - In general, a stimulus causes a change in the flow of ions across the plasma membrane of a sensory receptor cell.
 - The term “adaptation” refers to the process by which a sensory system becomes insensitive to a continuing source of stimulation.
 - The more intense a stimulus, the greater the magnitude of each action potential fired by a sensory neuron.
 - Sensory adaptation plays a role in the ability of organisms to discriminate between important and unimportant information.
- Which statement about olfaction is *not* true?
 - In general, mammals depend more on vision than on olfaction as their dominant sensory modality.
 - Olfactory stimuli are recognized by the interaction between odorant molecules and receptor proteins on olfactory hairs.
 - The more odorant molecules that bind to receptors, the more action potentials are generated.
 - The greater the number of action potentials generated by an olfactory receptor, the greater the intensity of the perceived smell.
 - The perception of different smells results from the activation of different combinations of olfactory receptors.
- The membrane most directly responsible for the ability to discriminate different pitches of sound is the
 - round window.
 - oval window.
 - tympanic membrane.
 - tectorial membrane.
 - basilar membrane.
- Which statement is *not* true?
 - The transmembrane potential of a rod cell becomes more negative when the rod cell is exposed to light.
 - A photoreceptor releases the most neurotransmitter when in total darkness.
 - Whereas in vision the intensity of a stimulus is encoded by the degree of hyperpolarization of photoreceptors, in hearing the intensity of a stimulus is encoded by changes in firing rates of sensory neurons.
 - Stiffening of the ossicles in the middle ear can lead to deafness.
 - The interaction among hammer (malleus), anvil (incus), and stirrup (stapes) conducts sound waves across the fluid-filled middle ear.
- Which of the following statements about information flow in the vertebrate visual system is true?
 - Action potentials in bipolar cells cause the release of neurotransmitter onto ganglion cells.
 - Amacrine cells integrate the activity of neighboring rod and cone cells.
 - When photons of light enter the eye, the first cells they encounter in the retina are ganglion cells.
 - The highest density of rod cells in the human retina is centrally located in the fovea, resulting in high-acuity dim-light vision.
 - Pigmented epithelial cells at the back of the retina provide information about the level of ambient light for contrast adjustments.

UNDERSTANDING & APPLYING

- What are the similarities and differences in the functioning of olfactory receptors and taste receptors? How do these sensory cells enable the central nervous system to discriminate between an apple and an orange?
- If you were blindfolded and sitting in a wheeled chair, how would you know if you were being pushed forward or backward?
- To human ears, sounds are louder underwater than in air. Why is this so?

ANALYZING & EVALUATING

- Fish have fluid-filled channels called lateral line canals running down the sides of their bodies. These canals contain hair cells, as illustrated below. Describe what you think the functions of these lateral-line hair cells are.

10. An owl can capture a mouse scurrying across a forest floor in total darkness. What sensory information do you think the owl uses, and how does it get directional information from that sensory information?

COMPARE the Google maps of London and New York City at the same scale. In which city do you think it is easier to drive a taxi? In the city with sequentially numbered avenues and streets laid out at right angles to each other, or the city with a maze of arbitrarily named streets going in every direction?

Eleanor Maguire at University College London was so impressed with the navigational abilities of London taxi drivers that she decided to see if there was anything “special” about their brains. Using the brain imaging technique known as MRI (magnetic resonance imaging), Maguire and her colleagues examined the brains of taxi drivers with varying numbers of years of experience and compared them with each other and with the brains of control subjects who were not taxi drivers. The studies revealed significant changes in the anatomy of the hippocampus among taxi drivers.

The hippocampus is an area of the brain involved in learning and memory. The posterior hippocampus in particular is implicated in the memory of spatial relationships among objects in the environment. Maguire found that the posterior hippocampi of taxi drivers was larger than that of the control subjects and that, among the cab drivers themselves, there was a positive correlation between the size of the posterior hippocampus and years of driving experience.

In M. A. Wilson’s lab at the Massachusetts Institute of Technology, researchers recorded the activity of hippocampal neurons of rats as they navigated a maze. They located specific neurons, referred to as “place cells,” that fire only when the rat is at a particular

A Mind-Expanding Maze The extraordinary ability of taxicab drivers in London to navigate its maze of streets and byways prompted a study that revealed London cabbies to have larger than normal posterior hippocampi—a brain region implicated in the memory of spatial relationships in the environment.

location in the maze. In a sense these researchers can see what the rat is thinking, because when the animal is not moving through the maze, the neurons will occasionally fire in the same pattern as when it is running the maze—or they will fire in the reverse sequence, representing where the rat has just been. But these replays of firing patterns are much faster; the rat *thinks* about its experience in the maze about 25 times faster than the actual experience. In a maze that had a choice point (go right or go left), the firing pattern seen when the animal was held at the start position predicted which direction it would turn. Similar firing patterns occur when the rats are sleeping. Are they dreaming about the maze? Are they transferring memory of today’s experience in the maze into long-term memory?

Does the firing pattern of hippocampal place cells during sleep represent a memory of recent experience being transferred into long-term memory?

See answer on p. 983.

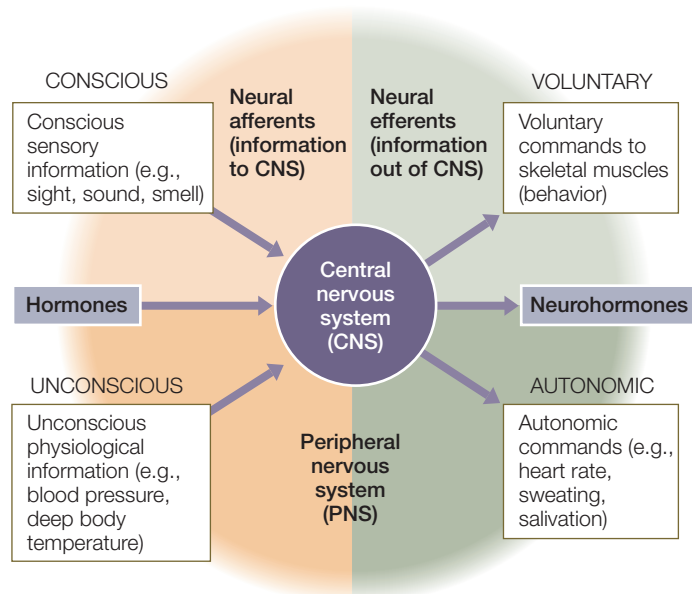

47.1 How Is the Mammalian Nervous System Organized?

The organization of the mammalian nervous system can be described anatomically and functionally. In anatomical terms, all vertebrate nervous systems consist of three parts: a brain, a spinal cord, and a set of peripheral nerves that reach all parts of the body. As discussed in Section 45.4, the brain and spinal cord are the **central nervous system**, or **CNS**, and the nerves that connect the CNS to all the tissues and sensors of the body are the **peripheral nervous system**, or **PNS**. An additional division of the nervous system exists in the gut; we will discuss this **enteric nervous system** in Chapter 51.

Recall from Section 45.1 that a neuron is an electrically excitable cell that communicates via an axon. When used in the context of a nervous system, the term **nerve** refers to a bundle of axons that carries information about many things simultaneously. Some axons in a nerve may be carrying information to the CNS while other axons in the same nerve are carrying information from the CNS to the body's organs. A discussion of the functional organization of the nervous system refers to these paths of information flow. In this chapter we will divide the anatomy of the mammalian brain, spinal cord, and peripheral nervous system into smaller, discrete functional units.

Functional organization is based on flow and type of information

Figure 47.1 illustrates the major avenues of information flow through the human nervous system. The white boxes represent the four divisions of the peripheral nervous system; two of these bring information from the periphery to the CNS, and two transmit information from the CNS to the periphery.

47.1 Organization of the Nervous System The peripheral nervous system carries information to (afferent) and from (efferent) the central nervous system (center circle in the diagram). The CNS also receives hormonal inputs and produces hormonal outputs.

- The **afferent** portion of the PNS carries information from sensory receptor cells to the CNS. We are *conscious* of much of this information (e.g., light, sound, skin temperature, limb position), but we are usually *unconscious* of the information involved in physiological regulation (e.g., blood pressure, deep body temperature, blood oxygen levels).
- The **efferent** portion of the PNS carries information from the CNS to the muscles and glands of the body. Efferent pathways are divided into a *voluntary* division that executes our conscious movements; and an *involuntary*, or *autonomic*, division that controls physiological functions.

In addition to the neural information it receives from the PNS, the central nervous system receives chemical information from hormones circulating in the blood. In turn, neurohormones released by neurons enter the circulation and affect neurons and other cells distant from the site of release (see Section 41.1).

The anatomical organization of the CNS emerges during development

Early in the development of a vertebrate embryo, a tube of neural tissue forms (see Section 44.4). At its anterior end, this neural tube forms three swellings that become the **hindbrain**, **midbrain**, and **forebrain**. The rest of the neural tube becomes the spinal cord. Peripheral nerves sprout from the midbrain and hindbrain (the cranial nerves) and from the spinal cord (the spinal nerves). From these early stages we see the linear axis of information flow in the nervous system. Although the developing brain will fold and become a complex structure, the information flow in the adult nervous system will follow paths that emerge from the simple, linear neural tube.

Each of these three regions of the embryonic brain develops into several structures in the adult brain (**Figure 47.2**). From the embryonic midbrain come structures that integrate information from the different senses and coordinate motor responses. From the hindbrain come the **medulla**, the **pons**, and the **cerebellum**. The medulla is continuous with the spinal cord, the pons is in front of the medulla, and the cerebellum is a dorsal outgrowth of the pons. The medulla and pons contain distinct groups of neurons involved in controlling physiological functions such as breathing, circulation, and basic motor patterns such as swallowing and vomiting. All information traveling between the spinal cord and higher brain areas must pass through the pons, the medulla, and the midbrain, which are collectively known as the **brainstem**.

The cerebellum is involved in coordinating muscle activity and maintaining balance. It is like the director of a movie; the cerebellum receives a "script" of the commands going to the muscles from higher brain areas, and it receives information about the actual performance coming up the spinal cord from the "actors"—the joints and muscles. The cerebellum compares the "script" with the performance and refines motor commands accordingly. Damage to the cerebellum results in loss of fine motor control and coordination.

The embryonic forebrain develops a central region called the **diencephalon** and a surrounding structure called the **telencephalon**. The diencephalon is the core of the forebrain and consists of an upper structure, the thalamus, and a lower

Adult brain (midsagittal section, right cerebral hemisphere)

47.2 Development of the Central Nervous System In vertebrate embryos, the anterior end of the hollow neural tube differentiates into forebrain, midbrain, and hindbrain. Each of these regions develops into several structures of the adult brain. The remainder of the neural tube becomes the spinal cord.

structure, the hypothalamus. The thalamus is the final relay station for sensory information going to the telencephalon. The hypothalamus receives a lot of physiological information of which we are not conscious, and it uses that information to regulate many physiological functions and biological drives.

The telencephalon—also called the **cerebrum**—consists of the left and right **cerebral hemispheres**. The outer layer of the telencephalon is the **cerebral cortex**, a thin layer rich in cell bodies. If we compare vertebrate groups from fish through amphibians, reptiles, and mammals, the telencephalon increases in size, complexity, and importance—an evolutionary trend called telencephalization (see Figure 45.19). In humans, the telencephalon is by far the largest part of the brain and plays major roles in sensory perception, learning, memory, and conscious behavior.

The spinal cord transmits and processes information

The spinal cord conveys information to and from the brain. However, the spinal cord is more than an information pipe. As we saw in Section 45.4, the spinal cord carries out integrative functions as well. The knee-jerk reflex (see Figure 45.18) is an example of a circuit between the PNS and the spinal cord that controls a simple behavioral function. That simple circuit, however, can be built on to control more complex behaviors such as the withdrawal reflex, which involves readjusting tension in many muscles on both sides of the body to coordinate movement and maintain balance. Complex motor programs also exist in the spinal cords of many vertebrates. A shark can swim perfectly well after its spinal cord is separated from its brain, and there is the proverbial chicken running around with its head cut off. Central pattern generation in the spinal cord has been demonstrated in mammals by the fact that an experimental animal (usually a cat) with a spinal cord transection that has isolated its hind limbs from its brain can still coordinate its hind limb movements to walk on a treadmill.

The brainstem carries out many autonomic functions

Swallowing, salivating, breathing, eye movements, blood pressure regulation, and gut activity are only a few of the many autonomic functions that are localized in the medulla, the pons, and the midbrain. To carry out these functions, the brainstem has its own components of the PNS, the 12 paired **cranial nerves**. You encountered the olfactory nerve, the optic nerve, and the auditory nerve (cranial nerves I, II, and VIII) in Chapter 46. Another one, cranial nerve X, is called the vagus (“wandering”) nerve because it travels into the body cavity and communicates with many of the organs, including the heart and the gut. We will encounter the vagus nerve in subsequent chapters.

Within the highly complex networks of axons and dendrites in the brainstem, there are many discrete groups of neurons that share a common characteristic such as the neurotransmitter they produce and release. Such an anatomically distinct group of neurons is called a **nucleus** (not to be confused with the nucleus of a single cell). Many of these brainstem nuclei

send their axons to various regions of the brain to modulate their activity; for example, brainstem nuclei are involved in keeping the higher brain areas awake or allowing them to sleep. All of the sensory information coming up the neural axis from the spinal cord passes through the brainstem on its way to the forebrain, and many of these ascending neuronal tracts give off collateral branches to the awake-promoting nuclei in the brainstem. Because the neuronal circuitry in this part of the brain is so complicated and because activity in these ascending sensory pathways can promote wakefulness, the core of the brainstem has been termed the **reticular activating system** (reticular means net-like). Damage to the brain or spinal cord below the reticular activating system can result in paralysis but leave sleep–wake cycle behavior normal. Damage above the level of the reticular activating system can result in coma.

The core of the forebrain controls physiological drives, instincts, and emotions

As mentioned above, the diencephalon consists of the thalamus and the hypothalamus. The thalamus communicates sensory information to the cerebral cortex; the hypothalamus receives information about physiological conditions in the body and regulates many homeostatic functions. Section 40.5 described how the hypothalamus is involved in regulating body temperature, and Section 41.3 discussed the intimate association between the hypothalamus and the pituitary gland in the control of many homeostatic functions.

Surrounding the diencephalon of all vertebrates are phylogenetically older structures of the telencephalon. These structures comprise the **limbic system** (Figure 47.3), which is responsible for instincts, long-term memory formation, physiological drives such as hunger and thirst, and emotions such as fear. Within the limbic system are areas that, when stimulated with small electric currents, can cause intense sensations of pleasure, pain, or rage. A rat given the opportunity to stimulate its own pleasure centers by pressing a switch will ignore food and water, pushing the switch until it is exhausted.

Pleasure and pain centers in the limbic system are believed to play roles in learning and in physiological drives. One component of the limbic system—the **amygdala**—is involved in fear and fear memory. If a certain portion of the amygdala is damaged or chemically blocked, an animal cannot learn to be afraid of a stimulus or a situation that would normally induce a strong fear reaction. The amygdala is involved in post-traumatic stress disorder (PTSD). Another part of the limbic system, the **hippocampus**, is necessary in humans for the transfer of certain types of short-term memory to long-term memory, as we will discuss in Section 47.3.

Regions of the telencephalon interact to control behavior and produce consciousness

The cerebrum is the dominant structure in the mammalian brain. In humans it is so large that it covers all other parts of the brain except the cerebellum (Figure 47.4A). The cerebral cortex covering the cerebrum is only about 4 millimeters thick, but it covers a surface area larger than a square meter because

47.3 The Limbic System The evolutionarily primitive parts of the telencephalon are referred to as the limbic system. The hippocampus is involved in forming long-term memory. The amygdala triggers fear emotions and fear memories.

it is folded into ridges (**gyri**; singular *gyrus*) and valleys (**sulci**; singular *sulcus*). These foldings, or **convolutions**, enable the large surface of the cortex to fit within the skull.

As we explore the functions of the cerebral cortex and other parts of the brain, we will occasionally mention an individual whose brain was damaged by an accident or other unfortunate event. Until recently the study of such individuals has been the main source of functional information about the human brain, but new imaging technologies such as positron emission tomography (PET) and magnetic resonance imaging (MRI) are providing a wealth of new information and opportunities to study the human brain.

A curious feature of the human nervous system is that the left side of the body is served (in both sensory and motor aspects) mostly by the right side of the brain, and the right side of the body is served mostly by the left side of the brain. Thus sensory input from the right hand goes to the left cerebral hemisphere, and sensory input from the left hand goes to the right cerebral hemisphere. The exception is the head, where the left side is controlled by the left cerebral hemisphere and the right side by the right cerebral hemisphere. The two hemispheres are not symmetrical with respect to all functions. Language abilities, for example, reside predominantly in the left hemisphere.

Different regions of the cerebral cortex have specific functions (Figure 47.4B). Some of those functions are easily defined, such as receiving and processing sensory information or generating motor commands, but most of the cortex is involved in

higher-order information processing that is less easy to define. These latter areas are given the general name of **association cortex**, so named because they integrate, or *associate*, information from different sensory modalities and from memory.

To understand the cerebral cortex, it helps to have an anatomical road map. Viewed from the left side, the left cerebral hemisphere looks like a boxing glove for the right hand with the fingers pointing forward, the thumb pointing out, and the wrist at the rear. The “thumb” area is the **temporal lobe**, the fingers the **frontal lobe**, the back of the hand the **parietal lobe**, and the wrist the **occipital lobe** (see Figure 47.4A). The right cerebral hemisphere shows a mirror image of this arrangement. We will look at each lobe separately.

THE TEMPORAL LOBE The upper region of the temporal lobe receives and processes auditory information. The association areas of this lobe are involved in recognizing, identifying, and naming objects. Damage to the temporal lobe results in disorders called agnosias, in which the individual is aware of an object but cannot identify it.

Damage to a certain area of the temporal lobe results in the inability to recognize faces. Even old acquaintances cannot be identified by facial features, although they may be identified by other attributes such as voice, body features, and posture. Using monkeys, it has been possible to record the activity of neurons in this region that respond selectively to faces in general. These neurons do not respond to other stimuli in the visual field, and their responsiveness decreases if some of the facial features are missing or appear in inappropriate locations (Figure 47.5). Damage to other association areas of the temporal lobe causes deficits in understanding spoken language, although speaking, reading, and writing abilities may be intact.

THE FRONTAL LOBE The frontal and parietal lobes are separated by a deep valley called the central sulcus. A strip of the frontal lobe cortex just in front of the central sulcus is called the

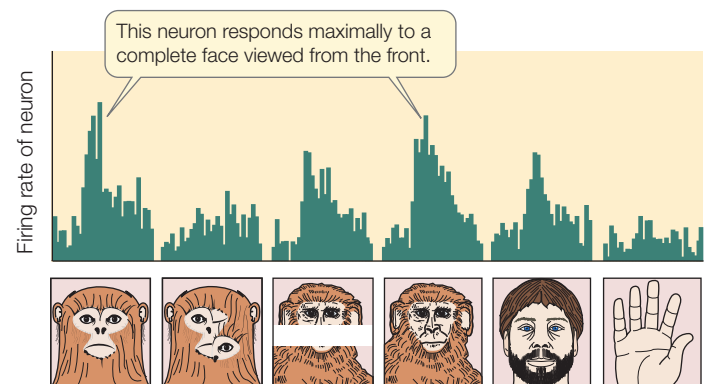

47.4 The Human Cerebrum (A) Each cerebral hemisphere is divided into frontal, temporal, parietal, and occipital lobes. (B) Different functions are localized in particular areas of the four cerebral lobes.

Go to Activity 47.1 The Human Cerebrum
Life10e.com/ac47.1

primary motor cortex (see Figure 47.4B). The neurons in this region control muscles in specific parts of the body; the parts of the body have been mapped onto the primary motor cortex, largely during neurosurgical procedures. As part of these procedures, electrodes were used to stimulate small areas of cortex. In the area just anterior to the central sulcus, stimulation causes specific muscles to contract. Parts of the body with fine motor control, such as the face and hands, have disproportionate representation (Figure 47.6A). Stimulation of neurons in the primary motor cortex causes twitches of muscles, not coordinated movements.

The association functions of the frontal lobe are diverse and are best described as having to do with feeling and planning. They contribute significantly to personality. People with

47.5 “Face Neurons” in One Region of the Temporal Lobe

The electrode traces represent the firing rate of a neuron in the temporal lobe of a monkey in response to the pictures shown below them. Highest firing is stimulated by the appearance of a complete face.

47.6 The Body Is Represented in Primary Motor and Primary Somatosensory Cortexes

Neurons in the primary motor cortex (A) control muscles in specific parts of the body, while neurons in the primary somatosensory cortex (B) receive information from specific parts of the body. The locations of these neurons within each cortex correspond to “maps” on which regions of the body are represented in proportion to the amount of innervation they receive.

frontal lobe damage have drastic alterations of personality and difficulty planning future events. A dramatic case of frontal lobe damage is the story of Phineas Gage, who in 1848 was an industrious and responsible young railroad construction foreman. Then a blasting accident shot a meter-long, 3-centimeter-wide iron tamping rod through his brain. The rod entered Gage's head below his left eye, passed through his frontal lobe, and exited the top of his head (**Figure 47.7**).

Remarkably, Gage survived, but he was a completely different person. He was quarrelsome, impatient, obstinate, and used profane language, which he had never done before. He lost his railroad job and spent his days as a drifter, earning money by telling his story and exhibiting his scars (and the tamping iron). He died of a seizure in 1860, at the age of 38. If you are in Boston, you can pay him a visit—his skull, death mask, and the tamping iron are on display in the Warren Anatomical Museum of Harvard Medical School.

THE PARIETAL LOBE The strip of parietal lobe cortex just behind the central sulcus is the **primary somatosensory cortex** (see Figure 47.4B). This area receives touch and pressure information relayed from the body through the thalamus.

The entire body surface can be mapped onto the primary somatosensory cortex (**Figure 47.6B**). Areas of the body that have a high density of tactile mechanoreceptors and are capable of making fine discriminations in touch (such as the lips and fingers) have disproportionately large representation. If a very small area of the primary somatosensory cortex is stimulated

47.7 A Mind-Altering Experience Phineas Gage miraculously survived a nineteenth-century railroad construction accident in which an explosion blew an iron rod through his brain. His personality, however, was permanently altered from a responsible foreman to a quarrelsome drifter. The path of the iron rod through Gage's brain is superimposed on this reconstruction of his skull.

electrically, the subject reports feeling specific sensations, such as touch, in a localized part of the body.

A major association function of the parietal lobe is attending to complex stimuli. Damage to the right parietal lobe causes a condition called contralateral neglect syndrome, in which the individual tends to ignore stimuli from the left side of the body or the left visual field. Such individuals have difficulty performing complex tasks, such as dressing the left side of the body; an afflicted man may not be able to shave the left side of his face. When asked to copy simple drawings, a person who exhibits this syndrome can do well with the right side of the drawing but not the left.

The parietal cortex is not symmetrical with respect to its role in attention. Damage to the left parietal cortex does not cause the same degree of neglect of the right side of the body. We will see similar asymmetries in cortical function later in the chapter when we discuss language.

THE OCCIPITAL LOBE The occipital lobe receives and processes visual information. The association areas of the occipital cortex are essential for making sense of the visual world and translating visual experience into language. Some deficits resulting from damage to these areas are specific. In one case, a woman with limited damage was unable to see motion. Her vision was intact, but she could see a waterfall only as a still image, and an approaching car only as a series of a stationary object at different distances.

The size of the human brain is off the curve

Humans are sometimes called “big-brain primates,” and that is an accurate characterization. Across vertebrate species there is a correlation between body size and brain size (Figure 47.8). Higher primates such as chimpanzees, baboons, and gorillas all fall above this regression line, but humans stand out because they are so far above the regression line. Gorillas are much larger than humans, but they have smaller brains. Elephants and whales have large brains, but they fall closer to the regression line. Dolphins and humans stand out as having

47.8 Evolution of the Human Brain Brain size scales to body size across a wide range of vertebrates. The higher primates have larger brains than predicted by the correlation, and humans stand outside this relationship with much bigger brains. The increase in brain size in humans is mostly due to an increase in the cerebral cortex. The human brain is also highly convoluted, and more of it is devoted to associative functions.

much larger brains than would be predicted by their body sizes.

The correlation of brain size to body size does not tell the whole story of human brain evolution, however. In Figure 45.19, which compares the brains of four vertebrates, we see that the forebrain is larger than other brain regions, and in mammals this is seen as an elaboration of the cerebral cortex. If we look just at mammals, another feature is the degree of convolution of the cortex. Since the cortex is a layered, two-dimensional array of neurons, the area of cortex is increased by convolutions, which are greatest in humans. And finally, the percent of the cortex that is association cortex (i.e., the brain regions devoted to the integration of information) is by far the greatest in humans. It is these evolutionary changes, primarily in the cortex, that provide the resources for the intellectual capacity of humans—a topic to which we will return at the end of the chapter.

RECAP 47.1

The central nervous system communicates with the rest of the body through the peripheral nervous system. We are conscious of some sensory information coming into the CNS, but we are not conscious of other afferent information used in physiological regulation. Different regions of the brain have specific functions. Evolution of the human brain has resulted in a greatly increased cerebral cortex devoted to integration of information.

- Explain how the major functional divisions of the nervous system relate to their origins in the embryonic neural tube. **See pp. 968–969 and Figure 47.2**
- Describe the spatial relations and functions of the major divisions of the telencephalon. **See pp. 970–971 and Figure 47.4**
- What features distinguish the human brain from the brains of other mammals? **See p. 973 and Figure 47.8**

Having briefly described the structure and function of different regions of the nervous system, we will now explore some examples of how information is processed by the neural circuitry in some specific brain regions.

47.2

How Is Information Processed by Neural Networks?

Specific functions are localized in specific parts of the nervous system and depend on the neural circuits, or networks, in those structures. A major focus of modern neuroscience is understanding how the various functions of the nervous

47.9 The Autonomic Nervous System The autonomic nervous system is divided into the sympathetic and parasympathetic divisions. The two divisions work in opposition to each other in their effects on most organs; one results in an increase and the other a decrease in activity.

system, ranging from simple reflexes to complex learning and memory, are accomplished by the interactions of neurons in circuits. Two extensively studied examples of how neural networks process information are the autonomic nervous system (an output pathway) and the visual system (an input pathway).

Pathways of the autonomic nervous system control involuntary physiological functions

The **autonomic nervous system**, or **ANS**, comprises the output pathways of the CNS that control involuntary functions, such as heart rate, blood flow, sweating, and digestive activities. Its

control of diverse organs and tissues is crucial to homeostasis. The ANS has two divisions, **sympathetic** and **parasympathetic**, that work in opposition to each other in their effects on most organs: one division causes an increase in an activity and the other a decrease (**Figure 47.9**). The sympathetic and parasympathetic divisions are easily distinguished by their anatomy, neurotransmitters, and actions.

The best-known functions of the ANS are those of the sympathetic division that produce the fight-or-flight response: increasing heart rate, blood pressure, and cardiac output and preparing the body for emergencies (see Figure 41.3). In contrast, the parasympathetic division slows the heart and lowers blood pressure; its actions have been characterized as “rest and digest.” It is tempting to think of the sympathetic division as speeding things up and the parasympathetic division as slowing things down, but it is not that simple; for example, the

sympathetic division slows down the digestive system whereas the parasympathetic division accelerates it.

Whether sympathetic or parasympathetic, every autonomic efferent pathway begins with a cholinergic neuron (that is, a neuron that uses acetylcholine as its neurotransmitter) that has its cell body in the brainstem or spinal cord. These cells are called preganglionic neurons because the second neuron in the pathway with which they synapse resides in a collection of neurons outside the CNS called a **ganglion** (plural *ganglia*). The second neuron is called a postganglionic neuron because its axon extends out from the ganglion. The axon of the postganglionic neuron synapses with cells in the target organs (see Figure 47.9).

The postganglionic neurons of the sympathetic division are called noradrenergic because they use norepinephrine (also known as noradrenaline) as their neurotransmitter. In contrast, the postganglionic neurons of the parasympathetic division are cholinergic. In organs that receive both sympathetic and parasympathetic input, the target cells respond in an opposite manner to norepinephrine and to acetylcholine. This happens, for example, in a region of the heart called the pacemaker, which generates the heartbeat. Stimulating the sympathetic nerve to the heart or dripping norepinephrine onto pacemaker cells increases their firing rate and causes the heart to beat faster. In contrast, stimulating the parasympathetic nerve to the heart or dripping acetylcholine onto pacemaker cells decreases their firing rate and causes the heart to beat more slowly.

The sympathetic and parasympathetic divisions of the ANS can also be distinguished by anatomy. The preganglionic neurons of the parasympathetic division come from the cranial nerves of the brainstem and the sacral (lowest) region of the spinal cord; those of the sympathetic division come from the thoracic and lumbar regions of the spinal cord (see Figure 47.9). Most of the ganglia of the sympathetic division are lined up in two chains, one on either side of the spinal cord. The parasympathetic ganglia are close to the target organs.

The autonomic nervous system is an important link between the CNS and many physiological functions. Its control of diverse organs and tissues is crucial to homeostasis. Despite the complexity of the ANS, work by neurobiologists and physiologists over many decades has made it possible to understand its functions in terms of neuronal properties and circuits.

The visual system is an example of information integration by the cerebral cortex

The visual system is one of the most-studied input pathways to the central nervous system. In Section 46.4 we described how light falling on the retina produces signals that are transmitted through the cellular circuits of the retina, resulting in action potentials in the optic nerve. But how does the central nervous system use this information to reconstruct the visual world in the brain? The experiments that have investigated this question are some of the most famous experiments in neurobiology.

RETINAL RECEPTIVE FIELDS Section 46.4 described how a retinal ganglion cell collects information from a number of photoreceptors—an example of “convergence of information.” Each

ganglion cell is communicating to the brain something more than simply the presence or absence or intensity of light falling on a portion of the retina. What information does the retinal ganglion cell extract from the photoreceptors?

This question was addressed in classic experiments by Stephen Kuffler, then at Johns Hopkins University. He used electrodes to record the activity of single ganglion cells of cat eyes while stimulating their retinas with spots of light (**Figure 47.10**). These experiments were the starting point for understanding how the brain assembles information from single cells to create visual images—in other words, of how the brain sees.

Kuffler’s experiments revealed that each ganglion cell has a well-defined **receptive field** composed of a group of photoreceptor cells that receive light from a small area of the entire visual field. Stimulating these photoreceptors with light activates the ganglion cell, which sends action potentials to the thalamus and on to the visual cortex (the area of the occipital lobe where visual information is processed; see Figure 47.4). Information from many photoreceptors is therefore communicated to the brain as a single message. Individual photoreceptors may contribute to the receptive fields of multiple ganglion cells, so that receptive fields overlap.

The receptive fields of most ganglion cells are circular, but whether a spot of light falling on a receptive field excites or inhibits its ganglion cell depends both on the nature of the receptive field and on where the spot of light falls on it. Receptive fields have a center and a concentric surround, and can be either “on-center” or “off-center.” Light falling on the center of an on-center receptive field excites the ganglion cell, and light falling on the center of an off-center receptive field inhibits the ganglion cell. Light falling on the surround has the opposite effect: the surround for an on-center receptive field inhibits the ganglion cell, and the surround for an off-center field is excitatory. Thus the activity of the ganglion cell reflects how much of the light stimulus is on the center and how much is on the surround of its receptive field (see Figure 47.10).

Center effects are always stronger than surround effects. Thus a small dot of light directly on the center of a receptive field has the maximal effect, and a larger light stimulus illuminating the center and parts of the surround has a smaller effect. A uniform patch of light falling equally on the center and surround has very little effect on the firing rate of the ganglion cell for that receptive field.

Visual Receptive Fields
Life10e.com/at47.1

How are cells in the retina connected to each other to create receptive fields? Remember from Section 46.4 that photoreceptors synapse onto bipolar cells and bipolar cells onto ganglion cells. This pattern of connectivity describes the relationship between the photoreceptors in the center of a receptive field. The photoreceptors in the surround area modify communication between the center photoreceptors and their bipolar cells through the lateral connections of horizontal cells and amacrine cells. Thus the receptive field of a ganglion cell results

INVESTIGATINGLIFE

47.10 What Does the Eye Tell the Brain? Stephen Kuffler's experiments recorded the activity of single ganglion cells in the eyes of cats. These groundbreaking experiments revealed the existence of a circular receptive field for each of the retina's ganglion cells.

Signals from photoreceptor cells in a receptive field are either excitatory or inhibitory to the ganglion cell, which sends action potentials via the optic nerve to the brain.^a

HYPOTHESIS Retinal ganglion cells are excited or inhibited by light and dark stimuli falling on local areas of the retina.

Method

1. Place electrodes next to an individual retinal ganglion cell.
2. Stimulate the retina with different combinations of light and dark stimuli and record the responses of the ganglion cell.
3. Continue recording and move the stimuli around the retina to find the area of sensitivity—the receptive field—for a specific ganglion cell.

**Results**

Stimulus patterns on retina

Action potentials in on-center ganglion cell

Action potentials in off-center ganglion cell

Complete darkness

Small spot falling on center of receptive field

Large spot covering receptive field

Ring of light excluding center of receptive field

An on-center ganglion cell is maximally stimulated by light falling on its receptive field's center and is inhibited by a ring of light falling on its receptive field's surround.

An off-center ganglion cell is maximally stimulated by light falling on its receptive field's surround and is inhibited by light falling on its center.

CONCLUSION Ganglion cells use a center-surround dichotomy to encode patterns of contrast between light and dark.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

^aKuffler, S. W. 1953. *Journal of Neurophysiology* 16: 37–68.

from a pattern of synapses between photoreceptors, horizontal cells, amacrine cells, and bipolar cells. A general lesson to learn from this seemingly confusing chain of events is that inhibition can be as important as excitation in neural circuits.

In summary, the neural circuitry of the retina results in the generation of signals in the axons of the optic nerve to the brain that communicate simple information about the contrasting patterns of light and dark falling on different parts of the retina. But once the action potentials in the optic nerve reach their destinations, how does the brain integrate them to construct visual images of the outside world?

RECEPTIVE FIELDS OF CELLS IN THE VISUAL CORTIX The axons of the optic nerves terminate in a region of the thalamus that is a relay station receiving information from both the right and left eyes. From the thalamus, the information encoded in the activity of axons in the optic nerves is relayed to the visual cortex in the occipital lobes at the back of the brain. In the 1960s David Hubel and Torsten Wiesel of Harvard University studied the activity of neurons in the visual cortex by shining spots and bars of light on retinas while recording the activities of single cells in the cortex. They found that neurons in the visual cortex, like retinal ganglion cells, have receptive fields.

Neurons in the visual cortex respond selectively to bars of light of different orientations falling on the retina and in some

cases to movement of those bars of light in different directions. The concept that emerges from these experiments is that the brain assembles a mental image of the visual world by analyzing edges in patterns of light falling on the retina. Each retina sends a million axons to the brain, but there are *hundreds of millions* of neurons in the visual cortex. The action potentials from one retinal ganglion cell are received by hundreds of cortical neurons, each responsive to a different combination of orientation, position, color, and movement of contrasting lines in the patterns of light and dark falling on the retina.

Three-dimensional vision results from cortical cells receiving input from both eyes

How do we perceive objects in three dimensions? The short answer is that a person's front-facing two eyes see overlapping, yet slightly different, visual fields—that is, humans have **binocular vision**. A person who is blind in one eye has difficulty discriminating distances. Animals whose eyes are on the sides of the head rather than facing front have minimal overlap in their fields of vision and, as a result, poor depth vision; however, they can see predators creeping up from all sides.

The story of how the brain integrates information from two eyes begins with the paths of the optic nerves. The two optic nerves run along the underside of the brain, join just under the hypothalamus, and then separate again (**Figure 47.11A**). The place where they join is called the **optic chiasm**. Axons from the half of each retina closest to the nose cross in the optic chiasm and go to the opposite side of the brain. The axons from the

47.11 Anatomy of Binocular Vision (A) Each eye transmits information to both sides of the brain; however, the right side of the brain processes all information from the left visual field (red), and the

left side of the brain processes all information from the right visual field (green). (B) The visual cortex sorts visual field information according to whether it comes from the right or left eye.

outer half of each retina do not cross over at the optic chiasm; axons from the outer left retina go to the left side of the brain, and vice versa for axons from the outer right retina.

The functional consequence of the optic chiasm is that all of the visual information from the left side of your field of vision when you are looking straight ahead goes to the right side of your brain, and all of the visual information from the right side of your field of vision goes to the left side of your brain. These relationships are shown in red and green in Figure 47.11A.

Cells in the visual cortex are organized in stripes and columns. Stripes refer to the organization across the surface of the cortex, and columns to the organization through the depth of the cortex (**Figure 47.11B**). Stripes and columns alternate according to the source of their input: left eye, right eye, left eye, right eye, and so on. Cells closest to the border between two stripes or columns receive input from both eyes and thus are called binocular cells. Binocular cells interpret distance by measuring the *disparity* between the points at which the same stimulus falls on the two retinas.

What is disparity? Hold your finger out in front of you and look at it closing one eye and then the other. Your finger appears to jump back and forth because its image falls on a different position on each retina. Repeat the exercise with a distant object. It doesn't jump back and forth as much because there is less disparity in the positions of the image on the two retinas. Certain binocular cells respond optimally to a stimulus falling on both retinas with a particular disparity. Which set of binocular cells is stimulated depends on how far away the stimulus is.

When we look at something, we can detect its shape, color, depth, and movement. Where does all this information come together? Is there a single cell that fires only when a red sports car drives by? The answer to that is "no." Specific visual experience comes from simultaneous activity in a large collection of cells. In addition, most visual experiences are enhanced by information from the other senses and from memory, which helps explain why about 75 percent of the cerebral cortex is association cortex.

RECAP 47.2

Information in the nervous system is processed by cellular interactions in neural networks. The opposing actions of the sympathetic and parasympathetic divisions of the ANS can be understood in terms of neural pathways consisting of just two neurons. Vision involves a more complex interaction of neurons, organized into receptive fields, to process patterns of light and dark falling on the retina.

- Describe the anatomical and functional differences between the sympathetic and parasympathetic divisions. **See pp. 974–975 and Figure 47.9**
- Explain the cellular basis for the receptive fields of retinal ganglion cells. **See p. 975 and Figure 47.10**
- How do cells in the visual cortex interpret information about how far away an object is? **See pp. 977–978 and Figure 47.11**

By studying the neural circuitry of the visual system and the autonomic nervous system, you have gained some understanding

of how information reaches the central nervous system and how the CNS controls various functions of the body. But what about the higher functions of the mammalian CNS—the complex functions between input and output, such as language, learning, memory, and dreams?

47.3 Can Higher Functions Be Understood in Cellular Terms?

The higher brain functions discussed in the remaining pages of this chapter are undeniably complex. Nevertheless, neuroscientists, using a wide range of techniques, are making considerable progress in understanding some of the cellular and molecular mechanisms involved in those processes. The following discussion will address several aspects of brain and behavior that present challenges to neuroscientists: sleep and dreaming, learning and memory, language use, and consciousness.

Sleep and dreaming are reflected in electrical patterns in the cerebral cortex

A dominant feature of behavior is the daily cycle of sleep and waking. All birds and mammals, probably all other vertebrates, and also many invertebrates, sleep. We humans spend one-third of our lives sleeping, yet we do not know why or how. We do know, however, that we need to sleep. Loss of sleep impairs alertness and performance. Many people in our society—certainly most college students—are chronically sleep-deprived. Accidents and serious mistakes that endanger lives can be attributed to impaired alertness caused by lack of sleep. Insomnia (difficulty in falling or staying asleep) is one of the most common medical complaints.

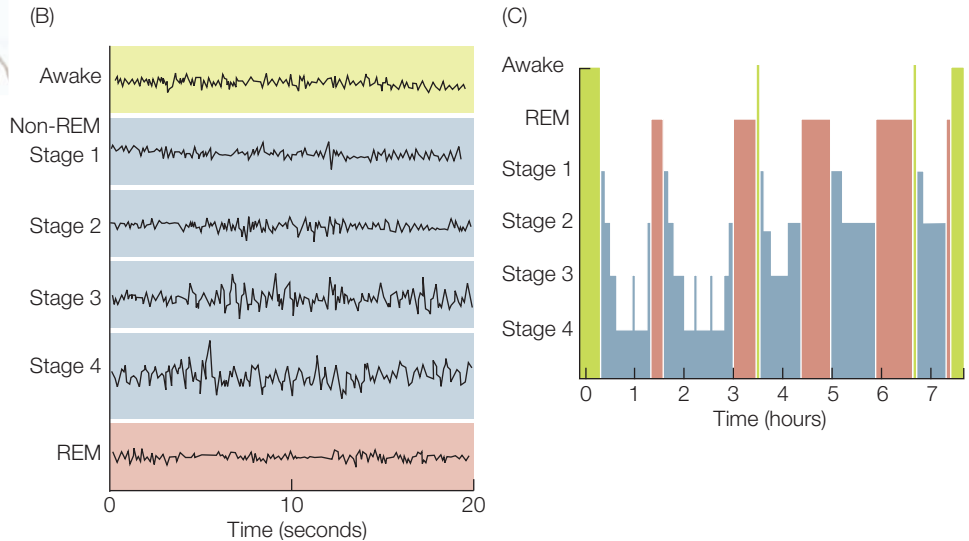

THE ELECTROENCEPHALOGRAM A common tool of sleep researchers is the **electroencephalogram**, or **EEG**. Rather than recording the activity of single neurons, the EEG characterizes activity in huge numbers of neurons. EEG electrodes are much larger than the very fine electrodes used to detect single cell activity. Placed at different locations on the head and scalp (**Figure 47.12A**), EEG electrodes record changes in the electric potential differences between electrodes over time. These differences reflect the electrical activity of the neurons in the brain regions under the electrodes, primarily regions of the cerebral cortex. Usually the electrical activity of one or more skeletal muscles is also recorded; this record is called an electromyogram (EMG). Movements of the eyes are recorded as an electrooculogram (EOG).

EEG, EMG, and EOG patterns reveal the transition from being awake to being asleep. They also reveal that there are different states of sleep. In mammals other than humans, two major sleep states are easily distinguished: **slow-wave sleep** and **rapid eye movement (REM) sleep**. Slow-wave sleep gets its name from the high-amplitude, slow-frequency waves in the EEG. REM sleep gets its name from jerky movements of the eyeballs that occur during this state. In humans, sleep states are characterized as non-REM sleep and REM sleep. Human

(A)

47.12 Stages of Sleep (A) Electrical activity in the cerebral cortex is detected by electrodes that are placed on the head and record changes in voltage between the electrodes through time. (B) The resulting record is an electroencephalogram, or EEG. (C) Humans cycle through different stages of sleep throughout the night.

non-REM sleep is divided into four stages, of which the two deepest stages are considered true slow-wave sleep.

When you fall asleep, the first state entered is stage 1 non-REM sleep, which then progresses through stages 2, 3, and 4 (**Figure 47.12B**). Stages 3 and 4 are deep, restorative, slow-wave sleep. This first full cycle of non-REM sleep is followed by an episode of REM sleep. Throughout the night you experience four or five cycles of non-REM and REM sleep (**Figure 47.12C**). About 80 percent of your sleep is non-REM sleep. The most vivid dreams and nightmares occur during the 20 percent of sleep that is REM sleep.

CELLULAR CHANGES DURING SLEEP When we are awake, several nuclei in the brainstem reticular formation are continuously active. Axons from neurons in these nuclei extend to the thalamus and throughout the cerebral cortex, where they release depolarizing neurotransmitters (acetylcholine, norepinephrine, and serotonin). These broadly distributed neurotransmitters keep the resting potential of the neurons of the thalamus and cortex close to threshold and sensitive to synaptic inputs, thereby maintaining the responsiveness of the brain that characterizes being awake.
